It follows that, to a first approximation, one can regard the mirror V of U as the moduli space of pairs $[(L, \nabla)]$ where L is a fiber of f and ∇ is a $U(1)$ local system. We define local holomorphic coordinates on V as follows (a complexified version of the integral affine coordinates y_γ of Construction 4-3). For $L_0 = f^{-1}(b_0)$ a smooth fiber, $\gamma \in$

$H_1(L_0, \mathbb{Z})$, and $(L = f^{-1}(b), \nabla)$ a nearby fiber together with a $U(1)$ local system, let Γ be a cylinder over a short path from b_0 to b with initial fiber Γ_{b_0} in class γ and final fiber Γ_b. We define

$$z^\gamma([(L, \nabla)]) = \exp\left(-2\pi y_\gamma(b)\right) \cdot \operatorname{hol}_\nabla(\Gamma_b) = \exp\left(-2\pi \int_\Gamma \omega\right) \cdot \operatorname{hol}_\nabla(\Gamma_b).$$

Suppose now that U is a log Calabi–Yau variety, and (X, D) is a log Calabi–Yau compactification such that ω extends to a 2-form on X. The homology groups $H_2(X, L = f^{-1}(b))$ form a local system over B^o; let $T\colon H_2(X, L_0) \to H_2(X, L)$ be the local trivialization given by parallel transport. Then, for $\beta \in H_2(X, L_0)$, we define

$$z^\beta([(L, \nabla)]) = \exp\left(-2\pi \int_{T(\beta)} \omega\right) \cdot \operatorname{hol}_\nabla(\partial T(\beta)).$$

Then $z^\beta = c z^{\partial\beta}$ where $c = \exp(-2\pi \int_\beta \omega) \in \mathbb{R}_{>0}$.

We can attempt to define global holomorphic functions ϑ_q on V for each $q = (F, k) \in U^{\mathrm{trop}}(\mathbb{Z}) \setminus \{0\}$ as follows Cho and Oh [2006], Auroux [2009]. Let (X, D) be a log Calabi–Yau compactification of U such that F is a component of the boundary D and ω extends to X. Let L be a smooth fiber of f. For $\beta \in H_2(X, L, \mathbb{Z})$, let N_β be the (virtual) count of holomorphic discs $h\colon (\mathbb{D}, \partial\mathbb{D}) \to (X, L)$ such that h meets F with contact order k and is disjoint from the remaining boundary divisors, and $h(\partial\mathbb{D})$ passes through a general point $p \in L$. We assume that N_β is well defined (independent of the choice of $p \in L$). We define

$$\vartheta_{(F,k)}([(L, \nabla)]) = \sum_{\beta \in H_2(X, L, \mathbb{Z})} N_\beta z^\beta([(L, \nabla)]).$$

(Note that the sum may not converge in general.)

Example 4-5. Let $U = T = N \otimes \mathbb{C}^\times \simeq (\mathbb{C}^\times)^n$. Let $(\bar{X}, \bar{D})$ be a toric compactification and $F \subset \bar{D}$ a boundary divisor corresponding to a primitive vector $v \in N$. Let $g\colon \mathbb{C}^\times \to T$ be the associated 1-parameter subgroup of T. Then g extends to a morphism $\bar{g}\colon \mathbb{C} \to \bar{X}$ such that $\bar{g}$ meets F transversely at a single point and is disjoint from the other boundary divisors. Let h be the restriction of $\bar{g}$ to the closed unit disc $\mathbb{D} \subset \mathbb{C}$. Let $K \subset T \subset \bar{X}$ be the compact torus. Then $h\colon (\mathbb{D}, \partial\mathbb{D}) \to (\bar{X}, K)$ is a holomorphic disc ending on the fiber K of the moment map and passing through the point $e \in K$. It is the unique such disc and counts with multiplicity 1. The same applies to any choice of fiber and marked point (because they are permuted simply transitively by T). Similarly, there is a unique disc meeting F with contact order k given by the multiple cover $\tilde{h}(z) = h(z^k)$. See Cho and Oh [2006, Theorems 5.3 and 6.1].

The functions ϑ_q as defined above are discontinuous in general, because the counts of holomorphic discs N_β ending on an SYZ fiber $L = f^{-1}(b)$ vary discontinuously with b. This is due to the existence of SYZ fibers which bound holomorphic discs in U. Such fibers lie over (thickened) real codimension 1 walls in the base B. In more detail, suppose $\{L_t\}_{t\in[0,1]}$ are the SYZ fibers over a path crossing a wall in the base. If L_{t_0} bounds a holomorphic disc in U, then there may exist a family of holomorphic discs h_t in X ending on L_t for $t < t_0$, such that the limit of h_t as $t \to t_0$ is a *stable disc* given by the union of two discs ending on L_{t_0}, one of which is contained in U, and such that this stable disc does *not* deform to a holomorphic disc in X ending on L_t for $t > t_0$.

Example 4-6. (Auroux [2009], Example 3.1.2.) Let $(\bar{X}, \bar{D}) = (\mathbb{C}^2_{z_1,z_2}, (z_1z_2 = 0))$ with Kähler form $\frac{1}{2\pi}\frac{i}{2}(dz_1\wedge d\bar{z}_1 + dz_2\wedge d\bar{z}_2)$. Let $\pi : X \to \bar{X}$ be the blow up of $p = (1,0) \in \bar{X}$ with exceptional curve E, and $D \subset X$ the strict transform of $\bar{D}$. As in Example 4-4, we have a Kähler form ω on X and a map $\bar{f} : X \to \bar{B}$ which restricts to a Lagrangian torus fibration $f : U \to B$ over the interior B of $\bar{B}$. Moreover, over the complement of a small neighborhood N of $\bar{f}(E)$ the map $\bar{f}$ agrees with the moment map $\mu : \bar{X} \to \mathbb{R}^2_{\geq 0}$, $(z_1, z_2) \mapsto \frac{1}{2}(|z_1|^2, |z_2|^2)$. The map $\bar{f} : X \to \bar{B} \simeq \mathbb{R}^2_{\geq 0}$ is defined by $\frac{1}{2}|\pi^* z_1|^2$ and μ_{S^1}, the moment map for the S^1 action on (X, ω), normalized so that $\mu_{S^1} = 0$ on the strict transform of the z_1-axis. (Then on the singular fiber $\mu_{S^1} = \int_E \omega = \epsilon > 0$.)

There is a real codimension 1 wall H in the base B defined by $|\pi^* z_1| = 1$. Note that $(\pi^* z_1 = 1) \subset U$ is the union of two copies of $\mathbb{A}^1$ meeting in a node: $E \setminus E \cap D$ and the strict transform of $(z_1 = 1)$. (The node is the singular point of the pinched torus fiber of f.) These curves are S^1-equivariant and map to the wall in the base with fibers the S^1-orbits (which collapse to the singular point at the pinched torus fiber). Thus each smooth fiber over the wall bounds a holomorphic disc in U contained in one of the two curves.

Now let $D_1 = (\pi^* z_1 = 0) \subset X$ and consider the associated function ϑ_{D_1} defined by counting holomorphic discs in X meeting D transversely at a point of D_1, ending on an SYZ fiber L, and passing through a marked point $p \in L$. We assume L lies over the region $R = B \setminus N$ where the fibration f agrees with the moment map μ. Note that $f^{-1}R \subset U \setminus E \simeq \bar{U}$. Let $\pi(p) = (\nu_1, \nu_2) \in \bar{U} = (\mathbb{C}^\times)^2_{z_1,z_2}$, so $L = (|\pi^* z_1| = |\nu_1|, |\pi^* z_2| = |\nu_2|)$. If $|\nu_1| < 1$ then there is a unique disc given by the strict transform of the disc $\mathbb{D} \to \bar{X} = \mathbb{C}^2$, $z \mapsto (\nu_1 z, \nu_2)$. If $|\nu_1| > 1$ there are two discs, one described as before and the second given by the strict transform of the disc $z \mapsto (\nu_1 z, \nu_2(\frac{\nu_1 z - 1}{\bar{\nu}_1 - z})/(\frac{\nu_1 - 1}{\bar{\nu}_1 - 1}))$. See Cho and Oh [2006, Theorem 5.3]. Writing $\beta_1, \beta_1' \in H_2(X, L)$ for the classes of the two discs, observe that $\beta_1' = \beta_1 + \alpha \in H_2(X, L)$ where α is the parallel transport of the class of the disc associated to the portion of the wall meeting R. (More precisely, if $\{L_t\}_{t\in[0,1]}$ are the fibers over a path γ in $R \subset B$ crossing the wall at time t_0 from $|\pi^* z_1| > 1$ to $|\pi^* z_1| < 1$, then the limit of the holomorphic disc in class β_1' ending on L_t as $t \to t_0$ from below is the union of the holomorphic discs ending on L_{t_0} in classes β_1 and α.) We thus have

$$\vartheta_{D_1} = \begin{cases} z^{\beta_1} & \text{if } |\pi^* z_1| < 1 \\ z^{\beta_1} + z^{\beta_1'} = z^{\beta_1} \cdot (1 + z^{\alpha}) & \text{if } |\pi^* z_1| > 1. \end{cases}$$

On the other hand, let D_2 be the strict transform of $(z_2 = 0)$. Then, with notation as above, there is a unique disc meeting D transversely at a point of D_2, ending on L, and passing through $p \in L$, given by the inverse image of the disc $z \mapsto (\nu_1, \nu_2 z)$ in $\bar{X} = \mathbb{C}^2$. (For $\nu_1 = 1$, this is the stable disc given by the union of the strict transform of disc in $\bar{X}$ (which is the disc associated to the wall) and the exceptional curve E.) Thus, writing $\beta_2 \in H_2(X, L)$ for the class of this disc, we have $\vartheta_{D_2} = z^{\beta_2}$.

We have defined (using the local holomorphic coordinates z^{γ}, $\gamma \in H_1(L, \mathbb{Z})$) a complex structure on the total space of the dual fibration $V^o \to B^o$ of the smooth locus of the SYZ fibration $f : U \to B$. However it is expected that this does *not* extend to a complex structure on a fibration $V \to B$. Roughly speaking, if $V \to B$ is a topological extension of the fibration $V^o \to B^o$, and $W \subset V$ is a neighborhood of a point $p \in V \setminus V^o$, there are too few holomorphic functions defined on $W \cap V^o$ for the complex structure to extend. For instance, some of the z^{γ} are not well defined due to the monodromy action on $H_1(L, \mathbb{Z})$. The naive definition of the mirror V^o must be corrected to account for discs ending on SYZ fibers. These glueing corrections are such that the ϑ_q define global holomorphic functions on V^o, and can be used to define an extension $V^o \subset V$.

For instance, in Example 4-6, the corrected mirror V^o is an analytic open subset of $\hat{V}^o = (\mathbb{C}^{\times})^2_{w_1,w_2} \cup (\mathbb{C}^{\times})^2_{w_1',w_2'}$, where the two torus charts correspond to the two connected components $|\pi^* z_1| < 1$ and $|\pi^* z_1| > 1$ of the complement of the wall H in the base B, the glueing is given by

$$(w_1, w_2) \mapsto (w_1(1 + c w_2)^{-1}, w_2),$$

and $w_1 = w_1' = z^{\beta_1}$ and $w_2 = w_2' = z^{\beta_2}$ on the naive mirror (and we have trivialized the local system $H_2(X, L)$ over the the region $R \subset B$ as above). The parameter c is given by $c = z^{-E}$, $z^E := \exp(-2\pi \int_E \omega)$, so that $c w_2 = z^{-E} z^{\beta_2} = z^{\alpha}$ (since $\beta_2 = \alpha + [E]$ in $H_2(X, L)$). Then ϑ_{D_1} and ϑ_{D_2} are the global functions on V^o which restrict to w_1 and w_2 in the first chart. In fact, defining $\hat{V} = \operatorname{Spec} H^0(\mathcal{O}_{\hat{V}^o})$, we have an isomorphism

$$\hat{V} \longrightarrow (uv = 1 + cw) \subset \mathbb{A}^2_{u,v} \times \mathbb{C}^{\times}_w$$

given by $u \mapsto w_1$, $v \mapsto w_1'^{-1}$, $w \mapsto w_2$, and $\hat{V}^o = \hat{V} \setminus \{q\}$ where $q \mapsto (0, 0, -1/c)$ (cf. Section 3.2). The mirror $V \subset \hat{V}$ equals $V^o \cup \{q\}$, an analytic open subset of the affine variety $\hat{V}$.

Remark 4-7. The point $q \in V$ should correspond under HMS to the pinched torus fiber of the SYZ fibration $f : U \to B$ regarded as an immersed Lagrangian S^2 (with the trivial $U(1)$ local system). See Seidel [2013, Lecture 11].

In general, the wall crossing transformations should take the following form, cf. Abouzaid, Auroux, and Katzarkov [2016], p. 207. Let $\{L_t\}_{t\in[0,1]}$ be the fibers of $f : U \to B$ over a path crossing a wall in the base B. Assume for simplicity that all the holomorphic discs in U bounded by the L_t have relative homology class some fixed $\alpha \in H_2(U, L)$. The boundaries of these discs sweep out a cycle $c \in H_{n-1}(L)$. Then the wall crossing transformation in the local coordinates z^γ, $\gamma \in H_1(L)$, is given by

$$z^\gamma \mapsto z^\gamma \cdot f(z^\alpha)^{c\cdot\gamma}$$

where $f(z^\alpha) = 1 + z^\alpha + \cdots \in \mathbb{Q}[[z^\alpha]]$ is a power series encoding virtual counts of multiple covers of the discs.

4.3 Symplectic cohomology. Suppose that U is a positive log Calabi–Yau variety with maximal boundary. Suppose V is HMS mirror to U, so that we have an equivalence $\mathcal{F}(U) \simeq D(V)$ between the wrapped Fukaya category of U and the derived category of coherent sheaves on V. Symplectic cohomology SH^* is a version of Hamiltonian Floer cohomology for noncompact symplectic manifolds Seidel [2008]. There is a *closed-open string map* $SH^*(U) \to HH^*(\mathcal{F}(U))$ which is conjectured to be an isomorphism, cf. Seidel [2002], §4. (Recently, Ganatra–Pardon–Shende and Chantraine–Dimitroglou-Rizell–Ghiggini–Golovko have announced results which, combined with Ganatra [2012], would establish this result.) Recall that

$$HH^n(D(V)) \simeq \oplus_{p+q=n} H^p(\wedge^q T_V)$$

(the Hochschild–Kostant–Rosenberg isomorphism), in particular,

$$HH^0(D(V)) \simeq H^0(\mathcal{O}_V)$$

Thus the above conjecture and HMS would yield an isomorphism of $\mathbb{C}$-algebras $SH^0(U) \simeq H^0(\mathcal{O}_V)$. In particular, assuming the mirror V is affine, it can be constructed as $V = \operatorname{Spec} SH^0(U)$.

Conjecturally, $SH^0(U)$ has a natural basis parametrized by $U^{\mathrm{trop}}(\mathbb{Z})$. (This was proved by Pascaleff in dimension 2 Pascaleff [2013]; there is ongoing work of Ganatra–Pomerleano on the general case.) We expect that this basis corresponds to the global functions ϑ_q, $q \in U^{\mathrm{trop}}(\mathbb{Z})$ under the above isomorphism $SH^0(U) \simeq H^0(\mathcal{O}_V)$ (where we define $\vartheta_0 = 1$). In particular, we expect that the ϑ_q, $q \in U^{\mathrm{trop}}(\mathbb{Z})$ form a basis of $H^0(\mathcal{O}_V)$.

4.4 The Fock–Goncharov mirror of a cluster variety. Fock and Goncharov [2006] defined a candidate for the mirror V of a cluster variety U by a simple combinatorial recipe which we reproduce in our notation here. We will give a partial justification for the Fock–Goncharov construction in Section 5.

Recall that $U = X \setminus D$ is described (up to codimension two) as a union of copies T_α, $\alpha \in A$ of the algebraic torus $T = N \otimes \mathbb{C}^\times \simeq (\mathbb{C}^\times)^n$ with transition maps given by compositions of mutations

$$\mu = \mu_{(m,v)} : T_\alpha \dashrightarrow T_\beta, \quad \mu^*(z^{m'}) = z^{m'} \cdot (1 + cz^m)^{-\langle m', v\rangle}$$

for some $c \in \mathbb{C}^\times$. In addition we have a non-degenerate log 2-form σ on U such that $\sigma|_{T_\alpha} = \bar{\sigma} \in \wedge^2 M_{\mathbb{C}}$ for each α. We assume that the sign of m above has been chosen according to the convention of §5.3.

The Fock–Goncharov mirror $(V, \sigma^\vee)$ is described as follows. Let $T^\vee = N^* \otimes \mathbb{C}^\times$ be the dual algebraic torus to $T = N \otimes \mathbb{C}^\times$. We write $N^\vee = H_1(T^\vee, \mathbb{Z}) = N^* = M$ and $M^\vee = (N^\vee)^* = N$. Then (up to codimension two) V is a union of copies $T_\alpha^\vee$, $\alpha \in A$ of $T^\vee$, with transition maps given by

$$\mu^\vee = \mu_{(v,-m)} : T_\alpha^\vee \dashrightarrow T_\beta^\vee \quad \mu^{\vee *}(z^{v'}) = z^{v'} \cdot (1 + c^\vee z^v)^{\langle v', m\rangle}$$

for some $c^\vee \in \mathbb{C}^\times$. Let

$$\phi : N_{\mathbb{C}} \to M_{\mathbb{C}}, \quad \phi(v) = \bar{\sigma}(v, \cdot)$$

be the isomorphism determined by the non-degenerate form $\bar{\sigma}$ on $N_{\mathbb{C}}$ and $\bar{\sigma}^\vee$ the form on $N_{\mathbb{C}}^\vee = M_{\mathbb{C}}$ given by

$$\bar{\sigma}^\vee(m_1, m_2) = \bar{\sigma}(\phi^{-1}(m_1), \phi^{-1}(m_2)).$$

Then the log 2-form $\sigma^\vee$ on V is given by $\sigma^\vee|_{T_\alpha^\vee} = \bar{\sigma}^\vee \in \wedge^2 M_{\mathbb{C}}^\vee$.

Equivalently, given the data $N, \bar{\sigma} \in \wedge^2 M_{\mathbb{C}}, m_i \in M, v_i \in N, \lambda_i \in \mathbb{C}^\times, i = 1, \ldots, r$ of Section 3.3 determining the cluster variety $U = X \setminus D$ in terms of a toric model $\pi : (X, D) \to (\bar{X}, \bar{D})$, the Fock–Goncharov mirror is associated to the data $N^\vee = M$, $\bar{\sigma}^\vee$, $v_i \in M^\vee$, $-m_i \in N^\vee$, and some $\lambda_i^\vee \in \mathbb{C}^\times$, $i = 1, \ldots, r$.

Remark 4-8. Recall that, for mirror Calabi–Yau varieties U and V, symplectic deformations of U correspond to complex deformations of V, and vice versa. In particular, if we regard U as a symplectic manifold (forgetting the complex structure) and V as a complex manifold (forgetting the Kähler form), then the parameters $\lambda_i^\vee$ for V are determined by the class of the symplectic form on U (and the parameters λ_i for U are irrelevant).

Remark 4-9. The Fock–Goncharov mirror construction is an involution. The isomorphism between U and the mirror of the mirror of U is given in the torus charts by the map $T \to T$, $t \mapsto t^{-1}$.

Remark 4-10. We expect that the mirror of a log Calabi–Yau variety U with maximal boundary is of the same type if and only if U is positive. If U is a positive cluster variety, we expect that the Fock–Goncharov mirror is the mirror in the sense of SYZ and HMS. For a general cluster variety U, we expect that the true mirror is an analytic open subset of the Fock–Goncharov mirror. Cf. the discussion of completion of the mirror via symplectic inflation in the positive case in Auroux [2009, Sec. 2.2].

Example 4-11. Let $\bar{X}$ be the smooth projective toric surface given by the complete fan in $\mathbb{R}^2$ with rays generated by $(1,0)$, $(0,1)$, $(-1,2)$, $(-1,1)$, $(-1,0)$, $(-1,-1)$, $(0,-1)$, $(1,-1)$, $(2,-1)$. The toric boundary $\bar{D} \subset \bar{X}$ is a cycle of smooth rational curves with self-intersection numbers $-2,-2,-1,-2,-2,-1,-2,-2,-1$. Let $\pi : X \to \bar{X}$ be the blow up of three points in the smooth locus of $\bar{D}$, one point on each of the (-1)-curves, and D the strict transform of $\bar{D}$. Then $U = X \setminus D$ is a cluster variety. The divisor $D = \sum D_i$ is a cycle of nine (-2)-curves; in particular the intersection matrix $(D_i \cdot D_j)$ is negative semi-definite, and U is *not* positive. It is expected (cf. Auroux, Katzarkov, and Orlov [2006], Auroux [2009], §5) that the mirror of U is the log Calabi–Yau surface $V = Y \setminus E$ where $Y = \mathbb{P}^2$ and $E \subset Y$ is a smooth elliptic curve. In particular, there does not exist an open inclusion of an algebraic torus $(\mathbb{C}^\times)^2$ in V, so V is not a cluster variety.

Remark 4-12. In dimension 2, we may assume (multiplying σ by a non-zero scalar) that $\mathbb{Z} \cdot \bar{\sigma} = \wedge^2 M$. Let $\psi : N \to M$ be the isomorphism given by $\psi(v) = -\bar{\sigma}(v, \cdot)$. Then $\psi(v_i) = -m_i$ and $\psi^*(v_i) = -\psi(v_i) = m_i$. So if we take $\lambda_i^\vee = \lambda_i$ then the isomorphism $\psi \otimes \mathbb{C}^\times : T \to T^\vee$ extends to an isomorphism $U \to V$. That is, in dimension two the Fock–Goncharov mirror V of U is deformation equivalent to U.

Note that 2-torus fibrations are self-dual by Poincaré duality, so SYZ mirrors are diffeomorphic in dimension 2. For U a log Calabi–Yau surface with maximal boundary, the Fock–Goncharov mirror construction is valid if and only if U is positive (cf. Gross, Hacking, and Keel [2015b], Keating [2015]), and in that case the mirror V is deformation equivalent to U.

5 Scattering diagrams

Given a cluster variety U together with a choice of toric model, we explain how to build a *scattering diagram* in $U^{\mathrm{trop}}(\mathbb{R})$. Heuristically, this is the tropicalization of the collection of walls in the base of the SYZ fibration together with the attached generating functions encoding counts of holomorphic discs in U ending on SYZ fibers described in Section 4.1. We use the scattering diagram to construct a canonical topological basis ϑ_q, $q \in U^{\mathrm{trop}}(\mathbb{Z})$ of the algebra of global functions on a formal completion of the Fock–Goncharov mirror family. We expect that when U is positive this basis is algebraic and defines a canonical basis of global functions on the Fock–Goncharov mirror. We prove this under certain hypotheses on U related to positivity.

5.1 Definitions and algorithmic construction of scattering diagrams. Let $A = \mathbb{C}[t_1, \dots, t_r]$ and $\mathfrak{m} = (t_1, \dots, t_r) \subset A$. We write $\hat{M}$ for the $\mathfrak{m}$-adic completion $\varprojlim M/\mathfrak{m}^l M$ of an A-module M.

Let $N \simeq \mathbb{Z}^n$ be a free abelian group of rank n, and write $M = N^*$. Let $\bar{\sigma} \in \wedge^2 M_{\mathbb{C}}$ be a non-degenerate skew form.

Definition 5-1. A *wall* is a pair $(\mathfrak{d}, f)$ consisting of a codimension 1 rational polyhedral cone $\mathfrak{d} \subset N_{\mathbb{R}}$ together with an attached function $f \in \widehat{A[N]}$ satisfying the following properties. Let $m \in M$ be a primitive vector (determined up to sign) such that $\mathfrak{d} \subset m^{\perp}$. Then there exists a primitive vector $v \in N$ such that

1. $\bar{\sigma}(v, \cdot) = \nu \cdot m$ for some $\nu \in \mathbb{C}^{\times}$,
2. $f \in \widehat{A[z^v]} \subset \widehat{A[N]}$, and
3. $f \equiv 1 \bmod \mathfrak{m} z^v \widehat{A[z^v]}$.

(Note in particular $v \in m^{\perp}$ because $\bar{\sigma}$ is skew-symmetric.)

The cone $\mathfrak{d}$ is called the *support* of the wall. The vector $-v$ is called the *direction* of the wall. We say a wall $(\mathfrak{d}, f)$ is *incoming* if $v \in \mathfrak{d}$, otherwise, we say it is *outgoing*. (The terminology comes from the dimension 2 case, where the support of an outgoing wall is necessarily the ray $\mathbb{R}_{\geq 0} \cdot (-v)$ in the direction of the wall.)

Crossing a wall $(\mathfrak{d}, f)$ defines an associated automorphism θ of $\widehat{A[N]}$ over $\hat{A}$ such that $\theta \equiv \mathrm{id} \bmod \mathfrak{m}$. Let $m \in M$ be as in Definition 5-1. Then the automorphism associated to crossing the wall from $(m > 0)$ to $(m < 0)$ is given by

$$\theta \colon \widehat{A[N]} \to \widehat{A[N]}, \quad z^u \mapsto z^u \cdot f^{\langle u, m \rangle}.$$

A *scattering diagram* $\mathfrak{D}$ is a collection of walls such that for all $l \in \mathbb{N}$, there are finitely many walls $(\mathfrak{d}, f)$ such that $f \not\equiv 1 \bmod \mathfrak{m}^l$ (so that the associated automorphism is non-trivial modulo $\mathfrak{m}^l$).

The *support* $\operatorname{Supp} \mathfrak{D}$ of $\mathfrak{D}$ is the union of the supports of the walls. A *joint* of $\mathfrak{D}$ is an intersection of walls of codimension 2 in $N_{\mathbb{R}}$. The *singular locus* $\operatorname{Sing} \mathfrak{D}$ is the union of the joints of $\mathfrak{D}$ and the relative boundaries of the walls of $\mathfrak{D}$. A *chamber* of $\mathfrak{D}$ is the closure of an open connected component of $N_{\mathbb{R}} \setminus \operatorname{Supp} \mathfrak{D}$.

If $\gamma \colon [0, 1] \to N_{\mathbb{R}} \setminus \operatorname{Sing} \mathfrak{D}$ is a smooth path such that $\gamma(0), \gamma(1) \notin \operatorname{Supp}(\mathfrak{D})$ and γ is transverse to each wall it crosses, it defines an automorphism $\theta_{\mathfrak{D},\gamma}$ given by composing wall crossing automorphisms. In more detail, let $\mathfrak{D}_l \subset \mathfrak{D}$ be the finite subset of the scattering diagram consisting of walls $(\mathfrak{d}, f)$ such that $f \not\equiv 1 \bmod \mathfrak{m}^l$. Let $0 < t_1 < \dots < t_k < 1$ be the times at which γ crosses a wall of $\mathfrak{D}_l$, and θ_i the composition of the automorphisms associated to the walls crossed at time t_i (note that if two walls lie in the same hyperplane then the associated automorphisms commute, so θ_i is well defined). Let $\theta^l_{\mathfrak{D},\gamma}$ be the automorphism $\theta_k \circ \cdots \circ \theta_1$ of $(A/\mathfrak{m}^l)[N]$. Then $\theta_{\mathfrak{D},\gamma} = \varprojlim \theta^l_{\mathfrak{D},\gamma}$.

We say two scattering diagrams $\mathfrak{D}$, $\mathfrak{D}'$ are *equivalent* if $\theta_{\mathfrak{D},\gamma} = \theta_{\mathfrak{D}',\gamma}$ for all paths γ such that $\theta_{\mathfrak{D},\gamma}$ and $\theta_{\mathfrak{D}',\gamma}$ are defined.

A version of the following result was proved in dimension two in Kontsevich and Soibelman [2006], §10. The general case follows from Gross and Siebert [2011].

Theorem 5-2. *(Gross, Hacking, Keel, and Kontsevich [2018], Theorem 1.12) Let $\mathfrak{D}_{\text{in}}$ be a scattering diagram such that the support of each wall is a hyperplane. Then there is a scattering diagram $\mathfrak{D} = \operatorname{Scatter}(\mathfrak{D}_{\text{in}})$ containing $\mathfrak{D}_{\text{in}}$ such that*

1. *$\mathfrak{D} \setminus \mathfrak{D}_{\text{in}}$ consists of outgoing walls, and*
2. *$\theta_{\mathfrak{D},\gamma} = \mathrm{id}$ for all loops γ such that $\theta_{\mathfrak{D},\gamma}$ is defined.*

Moreover, $\mathfrak{D}$ is uniquely determined up to equivalence by these properties.

The theorem is proved modulo $\mathfrak{m}^l$ for each $l \in \mathbb{N}$ by induction on l. The inductive step is an explicit algorithmic construction. A self-contained proof in dimension two is given in Gross, Pandharipande, and Siebert [2010], Theorem 1.4. The basic construction in the general case is the same, cf. Gross, Hacking, Keel, and Kontsevich [2018], Appendix C.

5.2 Initial scattering diagram for cluster variety. Let (U, σ) be a cluster variety. Recall the combinatorial data from Section 3.3 describing U in terms of a toric model $\pi\colon (X, D) \to (\bar{X}, \bar{D})$: Let $T = \bar{X} \setminus \bar{D} \simeq (\mathbb{C}^\times)^n$ be the big torus, $N = H_1(T, \mathbb{Z}) \simeq \mathbb{Z}^n$, and $M = N^*$. We have $\bar{\sigma} = \sigma|_T \in H^0(\Omega^2_{\bar{X}}(\log \bar{D})) = \wedge^2 M_{\mathbb{C}}$ a non-degenerate skew matrix. We have primitive vectors $m_i \in M$, $v_i \in N$, $i = 1, \ldots, r$ such that $\bar{\sigma}(v_i, \cdot) = \nu_i m_i$, some $\nu_i \in \mathbb{C}^\times$. The rays $\mathbb{R}_{\geq 0} \cdot v_i$ are contained in the fan of $\bar{X}$ so correspond to components $\bar{D}_i \subset \bar{D}$. Then π is given by the blow up of the smooth centers

$$Z_i = \bar{D}_i \cap \overline{(z^{m_i} = \lambda_i)} \subset \bar{X}$$

for some $\lambda_i \in \mathbb{C}^\times$.

For the cluster variety U, we define

$$\mathfrak{D}_{\text{in}} = \{(m_i^\perp, 1 + t_i z^{v_i}) \mid i = 1, \ldots, r\}.$$

The enumerative interpretation is as follows. The strict transform of the divisor $\overline{(z^{m_i} = \lambda_i)} \subset \bar{X}$ in U is swept out by holomorphic discs ending on SYZ fibers L with boundary class $v_i \in H_1(L, \mathbb{Z}) = N$. These are the holomorphic discs corresponding to the ith initial wall. The two dimensional case is explained in Example 4-6. In dimension $n > 2$, U is locally isomorphic to a product $U' \times (\mathbb{C}^\times)^{n-2}$ (see Remark 3-5).

Example 5-3. Let $r = 2$ and $v_1, v_2 = (1,0), (0,1) \in N = \mathbb{Z}^2$. Then $\mathfrak{D} = \mathrm{Scatter}(\mathfrak{D}_{\mathrm{in}})$ consists of the two incoming walls $(\mathbb{R}\cdot(1,0), 1+t_1 z^{(1,0)})$ and $(\mathbb{R}\cdot(0,1), 1+t_2 z^{(0,1)})$ and one outgoing wall $(\mathbb{R}_{\geq 0}(-1,-1), 1+t_1t_2z^{(1,1)})$.

Here is the enumerative interpretation of the outgoing wall. The cluster variety U has toric model $\pi\colon (X,D) \to (\bar{X},\bar{D})$ where $\bar{X} = \mathbb{P}^2$ with toric boundary $\bar{D} = \bar{D}_1+\bar{D}_2+\bar{D}_3$, and π is given by blowing up two points p_1, p_2 in the smooth locus of $\bar{D}$, with $p_1 \in \bar{D}_1$ and $p_2 \in \bar{D}_2$. Let C be the strict transform of the line through p_1 and p_2. Then C meets D in a single point p. Holomorphic discs associated to the outgoing wall are approximated by holomorphic discs contained in $C \setminus \{p\}$. (One can also give an explicit description using Cho and Oh [2006] as in Example 4-6.)

Note that in general the walls of the scattering diagram may be dense in some regions of $N_{\mathbb{R}}$, and the attached functions are not polynomial. See e.g. Gross, Pandharipande, and Siebert [2010], Example 1.6 and Remark 5-5 below.

For $U = X \setminus D$ a log Calabi–Yau surface with maximal boundary, Gross, Pandharipande, and Siebert [ibid.] proves an enumerative interpretation of the scattering diagram in terms of virtual counts of maps $f\colon \mathbb{P}^1 \to X$ meeting the boundary D in a single point. A similar interpretation in terms of log Gromov-Witten invariants is expected in general Gross and Siebert [2016], §2.4.

The following lemma (which will be needed in Section 5.4 below) is left as an exercise.

Lemma 5-4. *Let U be a cluster variety with associated combinatorial data $v_i \in N$, $m_i \in M$, $i = 1,\dots,r$. Then*

$$\mathrm{Pic}(U) = \mathrm{im}(H^2(X,\mathbb{Z}) \to H^2(U,\mathbb{Z})) = \mathrm{coker}((v_1,\dots,v_r)^T : M \to \mathbb{Z}^r)$$

and $\pi_1(U) = H_1(U,\mathbb{Z}) = \mathrm{coker}((v_1,\dots,v_r)\colon \mathbb{Z}^r \to N)$.

5.3 Reduction to irreducible case and sign convention.

For (U,σ) a cluster variety such that $H_1(U,\mathbb{Q}) = 0$, there is an étale cover $\tilde{U} \to U$ which decomposes as a product of cluster varieties (U_i,σ_i), $U_i = X_i \setminus D_i$, such that $H^0(\Omega^2_{X_i}(\log D_i)) = \mathbb{C}\cdot\sigma_i$ for each i (cf. the Bogomolov decomposition theorem in the compact setting).

We now assume that $H^0(\Omega^2_X(\log D)) = \mathbb{C}\cdot\sigma$. It follows from Section 3.1 that the subspace $H^0(\Omega^2_X(\log D)) \subset H^0(\Omega^2_{\bar{X}}(\log \bar{D})) = \wedge^2 M_{\mathbb{C}}$ is defined over $\mathbb{Q}$. So we may assume, multiplying by a nonzero scalar, that $\sigma \in \wedge^2 M$. Then $\bar{\sigma}(v_i,\cdot) = \nu_i m_i$ for some $\nu_i \in \mathbb{Q}$. Note that the blow up description of $U = X \setminus D$ depends on m_i through the center $Z_i = D_i \cap \overline{(z^{m_i} = \lambda_i)}$. So we may assume (replacing m_i by $-m_i$ and λ_i by λ_i^{-1} if necessary) that $\nu_i > 0$.

In this case, it follows from the proof of Theorem 5-2 that for all walls $(\mathfrak{d}, f)$ in $\mathfrak{D} = \mathrm{Scatter}(\mathfrak{D}_{\mathrm{in}})$ we have $\mathfrak{d} \subset m^{\perp}$ for some nonzero $m \in M$ such that $m = \sum a_i m_i$ with

$a_i \geq 0$ for each i. In particular, if the m_i are linearly independent then $\mathfrak{D}$ has two chambers given by

$$\mathcal{C}^+ = \{v \in N_{\mathbb{R}} \mid \langle m_i, v\rangle \leq 0 \text{ for all } i = 1, \dots, r\}$$

and $\mathcal{C}^- := -\mathcal{C}^+$.

5.4 Reduction to the case of linearly independent m_i: Universal deformation and universal torsor. We now explain how to reduce to the case that the $m_i \in M$ are linearly independent. Assume for simplicity that M is generated by the m_i. Equivalently, by Lemma 5-4, the Fock–Goncharov mirror V of U is simply connected.

The surjection $(m_1, \dots, m_r)\colon \mathbb{Z}^r \to M$ determines a surjective homomorphism $\varphi\colon (\mathbb{C}^\times)^r \to T^\vee$ and, dually, an injective homomorphism $T \hookrightarrow (\mathbb{C}^\times)^r$

We have the universal deformation $p\colon \mathcal{U} \to S := (\mathbb{C}^\times)^r/T$ of $U = p^{-1}([(\lambda_i)])$ given by varying the parameters λ_i.

Our assumption implies that $\operatorname{Pic} V = \operatorname{coker}(m_1, \dots, m_r)^T$ is torsion-free by Lemma 5-4. Let $L_1, \dots, L_s$ be a basis of $\operatorname{Pic} V$. The *universal torsor* $q\colon \tilde{V} \to V$ is the fiber product of the $\mathbb{C}^\times$-bundles $L_i^\times$ over V. It is a principal bundle with group $\operatorname{Hom}(\operatorname{Pic} V, \mathbb{C}^\times) = \ker(\varphi)$.

The 2-form σ on U lifts canonically to a *relative* 2-form $\sigma_{\mathcal{U}}$ on $\mathcal{U}/S$ (non-degenerate on each fiber). Equivalently, $\sigma_{\mathcal{U}}$ defines a Poisson bracket on $\mathcal{U}$ with symplectic leaves the fibers of p. The 2-form $\sigma^\vee$ on V pulls back to a degenerate 2-form on $\tilde{V}$.

Write $N_{\mathcal{U}} = \mathbb{Z}^r$ with standard basis $e_1, \dots, e_r$ and $M_{\mathcal{U}} = N_{\mathcal{U}}^*$ with dual basis $f_1, \dots, f_r$. We have the inclusion $(m_1, \dots, m_r)^T\colon N \subset N_{\mathcal{U}}$. The variety $(\mathcal{U}, \sigma_{\mathcal{U}})$ is a (generalized) cluster variety with toric model given by the combinatorial data $N_{\mathcal{U}}$, $\bar{\sigma}_{\mathcal{U}} = \bar{\sigma} \in \wedge^2 M_{\mathbb{C}}$, $v_i \in N_{\mathcal{U}}$, $f_i \in M_{\mathcal{U}}$, $i = 1, \dots, r$. The variety $(\tilde{V}, q^*\sigma^\vee)$ is the (generalized) Fock–Goncharov mirror cluster variety. Cf. Gross, Hacking, and Keel [2015a], §4.

Roughly speaking, in the terminology of Fock and Goncharov, $\mathcal{U}$ is the $\mathcal{X}$-variety for the given combinatorial data and $\tilde{V}$ is the $\mathcal{A}$-variety for the Langlands dual data. The Fomin–Zelevinsky (upper) cluster algebra is the ring of global functions $H^0(\tilde{V}, \mathcal{O}_{\tilde{V}})$.

One can construct the scattering diagram associated to $\mathcal{U}$ in $(N_{\mathcal{U}})_{\mathbb{R}} \supset N_{\mathbb{R}}$ as before using the relative 2-form $\bar{\sigma}_{\mathcal{U}} = \bar{\sigma} \in \wedge^2 M_{\mathbb{C}}$. (Condition (1) in Definition 5-1 can be rewritten $\bar{\sigma}^\vee(-m, \cdot) = \nu^\vee v$, where $\nu^\vee = \nu^{-1}$, that is, the corresponding condition for the Fock–Goncharov mirror V. In this form it generalizes to the above setting.)

Note that $H^0(\tilde{V}, \mathcal{O}_{\tilde{V}}) = \oplus_{L \in \operatorname{Pic} V} H^0(V, L)$ is the Cox ring of V. The torus $\operatorname{Hom}(\operatorname{Pic} V, \mathbb{C}^\times)$ acts with weight $L \in \operatorname{Pic} V$ on the summand $H^0(V, L)$. Our construction of a canonical basis of $H^0(\tilde{V}, \mathcal{O}_{\tilde{V}})$ is equivariant for the torus action. In particular we obtain a canonical basis of $H^0(V, \mathcal{O}_V)$ (and also $H^0(V, L)$ for each $L \in \operatorname{Pic} V$). Thus we may replace (U, σ) and $(V, \sigma^\vee)$ by $(\mathfrak{U}, \sigma_{\mathfrak{U}})$ and $(\tilde{V}, q^*\sigma^\vee)$ and assume that the m_i are linearly independent.

5.5 Mutation invariance of the support of the scattering diagram and cluster complex. The support of the scattering diagram $\mathfrak{D}$ is invariant under mutation Gross, Hacking, Keel, and Kontsevich [2018, Sec. 1.3]. That is, if $\pi\colon (X, D) \to (\bar{X}, \bar{D})$ and $\pi'\colon (X, D) \to (\bar{X}', \bar{D}')$ are two toric models for (X, D) related by a mutation $\mu\colon T \dashrightarrow T'$ as in (3-7), and $\mathfrak{D}$, $\mathfrak{D}'$ are the scattering diagrams associated to π, π' then $\mu^{\text{trop}}(\operatorname{Supp} \mathfrak{D}) = \operatorname{Supp} \mathfrak{D}'$. Heuristically, this is so because $\operatorname{Supp} \mathfrak{D}$ is the union of the tropicalizations of all holomorphic discs in U ending on SYZ fibers, viewed in $N_{\mathbb{R}}$ using the $\mathbb{Z}$PL identification $U^{\text{trop}}(\mathbb{R}) \simeq N_{\mathbb{R}}$ corresponding to the open inclusion $T = \bar{X} \setminus \bar{D} \subset U = X \setminus D$ of log Calabi–Yau varieties.

Let $\mu = \mu_{(m,v)}$ as in (3-7). Let (m_i, v_i), $i = 1, \dots, r$, be the combinatorial data for the toric model π, with $(m, v) = (m_1, v_1)$. Recall the explicit formula in Example 3-10 for μ^{trop}. In particular, μ^{trop} is linear on the halfspaces $\mathcal{H}_+ = (m \geq 0)$ and $\mathcal{H}_- = (m \leq 0)$. Let T_+, T_- be the linear automorphisms of $N_{\mathbb{R}}$ which agree with μ^{trop} on $\mathcal{H}_+$ and $\mathcal{H}_-$. Then $T_+ = \text{id}$ and T_- is the symplectic transvection

$$T_-(w) = w - \langle m, w \rangle v = w - \nu^{-1} \cdot \bar{\sigma}(v, w) v.$$

Then the combinatorial data (m_i', v_i'), $i = 1, \dots, r$ for π' is given by

$$(m_i', v_i') = \begin{cases} (-m_1, -v_1) & \text{if } i = 1 \\ ((T_+^*)^{-1}(m_i), T_+(v_i)) & \text{if } v_i \in \mathcal{H}_+ \text{ and } i > 1 \\ ((T_-^*)^{-1}(m_i), T_-(v_i)) & \text{if } v_i \in \mathcal{H}_- \text{ and } i > 1. \end{cases}$$

(The sign reversal $v_1' = -v_1$ follows from the description of the elementary transformation in Section 3.2. The signs of the m_i' are determined by the sign convention of Section 5.3.)

Using the explicit formula in Example 3-10 for μ^{trop}, we see that the chambers $\mu^{\text{trop}}(\mathcal{C}^+)$ and $\mathcal{C}^{+'}$ in $\mathfrak{D}'$ meet along the codimension 1 face defined by $m = 0$.

Applying elementary transformations repeatedly, we obtain a simplicial fan $\Delta^+ \subset U^{\text{trop}}(\mathbb{R}) \simeq N_{\mathbb{R}}$ with maximal cones the positive chambers $\mathcal{C}_\alpha^+$ associated to each torus chart T_α, such that two maximal cones meet along a codimension 1 face if and only if the torus charts are related by a mutation. This is the Fock–Goncharov *cluster complex* (the dual graph is the Fomin–Zelevinsky *exchange graph*). The maximal cones of Δ^+ are chambers of the scattering diagram $\mathfrak{D}$. Thus the scattering diagram is discrete in the interior of the support of Δ^+ in $N_{\mathbb{R}}$.

Remark 5-5. Note that here we are using our assumption that the m_i are linearly independent (see Section 5.4). Without this assumption, the scattering diagram can be everywhere dense in $N_{\mathbb{R}}$. For example, this is the case for $U = X \setminus D$ where $X \subset \mathbb{P}^3$ is a smooth cubic surface and D is a triangle of lines on X (equivalently, (X, D) is obtained from $\bar{X} = \mathbb{P}^2$ together with its toric boundary $\bar{D}$ by blowing up six general points in the smooth locus of $\bar{D}$, two on each line). To see this, first observe that we can construct another toric model of U of the same combinatorial type as follows. Let $\bar{D}_1, \bar{D}_2, \bar{D}_3$ be the components of $\bar{D}$. Let $\bar{X}^1$ be the blowup of the point $p = \bar{D}_1 \cap \bar{D}_2 \in \bar{X}$. Then $\bar{X}^1$ is a ruled surface with sections the exceptional divisor E and the strict transform of $\bar{D}_3$. Let p_1, p_2 be the two centers of $\pi : X \to \bar{X}$ on $\bar{D}_3$ and let $\bar{X}^1 \dashrightarrow \bar{X}^2$ be the composite of the elementary transformations with centers p_1 and p_2. Finally, blow down the strict transform of $\bar{D}_3$ to obtain $\bar{X}' \simeq \mathbb{P}^2$ with toric boundary $\bar{D}'$ given by the strict transforms of $\bar{D}_1$, $\bar{D}_2$, and E. Then by construction we have another toric model $\pi' \colon (X', D') \to (\bar{X}', \bar{D}')$ of U given by blowing up two points on each boundary divisor. The rational map $T = \bar{X} \setminus \bar{D} \dashrightarrow T' = \bar{X}' \setminus \bar{D}'$ is a composite of two mutations. Let $v_1, v_2 \in N$ correspond to the boundary divisors $\bar{D}_1, \bar{D}_2$ of $\bar{X}$ under the identification $U^{\mathrm{trop}}(\mathbb{Z}) = N$ given by $T \subset U$, then the boundary divisor E of $\bar{X}'$ correponds to $v_1 + v_2 \in N$ under this identification. Recall that the scattering diagram associated to a toric model has an incoming wall associated to each blow up. The support of the wall contains the ray corresponding to the boundary divisor containing the center of the blow up. Moreover, the support of the scattering diagram is invariant under mutation. In particular, it follows that the rays generated by v_1, $v_1 + v_2$, and v_2 lie in $\mathrm{Supp}(\mathfrak{D})$. Repeating the above construction one can prove by induction that every rational ray lies in $\mathrm{Supp}(\mathfrak{D})$.

In terms of the construction of the versal deformation $\mathfrak{U}$ of U in Section 5.4, the scattering diagram $\mathfrak{D}$ for U is the slice of the scattering diagram $\mathfrak{D}_{\mathfrak{U}}$ for $\mathfrak{U}$ by the subspace $(m_1, \ldots, m_r) \colon N_{\mathbb{R}} \hookrightarrow \mathbb{R}^r$. This slice can miss the discrete part of $\mathfrak{D}_{\mathfrak{U}}$ so that there are no chambers in $\mathfrak{D}$.

The functions attached to walls of the scattering diagram change in a simple way under mutation. Each wall of the cluster complex corresponds to a portion of an incoming wall for some seed (and there are no outgoing walls with support contained in an incoming wall Gross, Hacking, Keel, and Kontsevich [2018], Remark 1.29). So one can describe the functions attached to walls of the cluster complex explicitly. One finds that they are polynomials (in fact of the form $1+cz^v$ for $c \in A = \mathbb{C}[t_1, \ldots, t_r]$ a monomial and $v \in N$). So one can define an algebraic family $\mathcal{V}/\mathbb{A}^r_{t_1,\ldots,t_r}$ as follows: $\mathcal{V}$ is a union of copies of $T^\vee \times \mathbb{A}^r$ indexed by chambers $\mathcal{C}^+ \in \Delta^+$, with transition maps $T^\vee \times \mathbb{A}^r \dashrightarrow T^\vee \times \mathbb{A}^r$ given by $\theta_{\mathfrak{D},\gamma}$ for γ a path in $\mathrm{Supp}\,\Delta^+$ from the first chamber to the second. One finds that the restriction of $\mathcal{V}/\mathbb{A}^r$ to $(\mathbb{C}^\times)^r$ is the family of Fock–Goncharov mirrors to U. Moreover, because the automorphisms are trivial modulo $\mathfrak{m} = (t_1, \ldots, t_r)$, the special fiber $\mathcal{V}_0$ equals the torus $T^\vee$.

5.6 Broken lines. We now describe the construction of global functions $\vartheta_q, q \in U^{\text{trop}}(\mathbb{Z})$ on the mirror family $\mathcal{V}/\mathbb{A}^r$ using a tropical analogue of the heuristic construction described in Section 4.2.

Definition 5-6. Let $v \in U^{\text{trop}}(\mathbb{Z}) = N$ be a nonzero vector and $p \in N_{\mathbb{R}}$ a general point. A *broken line* for v with endpoint p is a continuous piecewise-linear path $\gamma : (-\infty, 0] \to N_{\mathbb{R}}$ together with, for each domain of linearity $L \subset (-\infty, 0]$, a monomial $c_L \cdot z^{v_L}$, $c_L \in A = \mathbb{C}[t_1, \dots, t_r]$, $v_L \in N$, such that

1. There is an initial unbounded domain of linearity with attached monomial $1 \cdot z^v$.
2. For all L and $t \in L$, $\gamma'(t) = -v_L$.
3. If γ is not linear at $t \in (-\infty, 0]$ then γ crosses a wall at time t. Let L and L' be the domains of linearity before and after crossing the wall and θ the wall crossing automorphism. Then $c_{L'} z^{v_{L'}}$ is a monomial term in $\theta(c_L z^{v_L}) \in \widehat{A[N]}$.
4. $\gamma(0) = p$.

We write $M(\gamma)$ for the final monomial attached to a broken line γ.

Recall that the Fock–Goncharov mirror V of U is a union $V = \bigcup_{\mathcal{C}^+ \in \Delta^+} T^\vee_{\mathcal{C}^+}$ of copies of the dual torus $T^\vee = M \otimes \mathbb{C}^\times$ indexed by the maximal cones $\mathcal{C}^+$ of the cluster complex Δ^+. We have the family $\mathcal{V} \to \operatorname{Spec} A = \mathbb{A}^r_{t_1,\dots,t_r}$, $\mathcal{V} = \bigcup_{\mathcal{C}^+ \in \Delta^+} T^\vee_{\mathcal{C}^+} \times \mathbb{A}^r$, with fiber V over the point $t_i = c_i^\vee = -1/\lambda_i^\vee$, and its formal completion $\hat{\mathcal{V}} \to \operatorname{Spf} \hat{A}$ over $0 \in \mathbb{A}^r$.

We now define theta functions ϑ_v for $v \in U^{\text{trop}}(\mathbb{Z}) \simeq N$ on $\hat{\mathcal{V}}$. We define $\vartheta_0 = 1$. Let $v \in N$ be a nonzero vector. For $p \in \operatorname{Supp} \Delta^+$ a general point, we define

$$\vartheta_{v,p} = \sum_\gamma M(\gamma) \in \widehat{A[N]},$$

where the sum is over broken lines γ for v with endpoint p. For general points $p, p' \in \operatorname{Supp} \Delta^+$, and γ a path from p to p', we have $\theta_{\mathfrak{D},\gamma}(\vartheta_{v,p}) = \vartheta_{v,p'}$ Gross, Hacking, Keel, and Kontsevich [ibid.], Theorem 3.5, Carl, Pumperla, and Siebert [2010], §4. So, by the definition of $\mathcal{V}/\mathbb{A}^r$, the $\vartheta_{v,p}$ for $p \in \operatorname{Supp} \Delta^+$ general define a global function ϑ_v on $\hat{\mathcal{V}}$.

Example 5-7. Consider the scattering diagram $\mathfrak{D}$ for the data $r = 1$, $v_1 = (1,0) \in N = \mathbb{Z}^2$. Write $z_1 = z^{(1,0)}$ and $z_2 = z^{(0,1)}$. The scattering diagram $\mathfrak{D} = \mathfrak{D}_{\text{in}}$ consists of the single wall $(\mathbb{R} \cdot (1,0), 1 + tz_1)$. Let $v = (0,1)$. For $p = (a,b) \in N_{\mathbb{R}} = \mathbb{R}^2$, if $b > 0$ there is a unique broken line for v with endpoint p given by $\gamma(t) = (a,b) - t(0,1)$ with attached monomial z_2. If $b < 0$ there are two broken lines, one described as before and the second given by $\gamma(t) = (a-b, b) - t(0,1)$ for $t \leq b$ with attached monomial z_2 and

$\gamma(t) = (a,b) - t(1,1)$ for $b \le t \le 0$, with attached monomial tz_1z_2. Thus $\vartheta_{v,p} = z_2$ for $b > 0$ and $\vartheta_{v,p} = z_2 + tz_1z_2 = z_2(1+tz_1)$ for $b < 0$. This is the tropical version of Example 4-6. See Cheung, Gross, Muller, Musiker, Rupel, Stella, and Williams [2017] for more examples.

Recall that $\mathcal{V}_0 = T^\vee$, and note that ϑ_v restricts to the character z^v on $\mathcal{V}_0$ (because $M(\gamma) \equiv 0 \bmod \mathfrak{m}$ for any broken line that bends). So the ϑ_v, $v \in U^{\text{trop}}(\mathbb{Z})$ restrict to a basis of $H^0(\mathcal{V}_0, \mathcal{O}_{\mathcal{V}_0})$. It follows that the ϑ_v, $v \in U^{\text{trop}}(\mathbb{Z})$ define a topological basis of $H^0(\hat{\mathcal{V}}, \mathcal{O}_{\hat{\mathcal{V}}})$. That is, for every element $f \in H^0(\hat{\mathcal{V}}, \mathcal{O}_{\hat{\mathcal{V}}})$ there is a unique expression $f = \sum_{v \in U^{\text{trop}}(\mathbb{Z})} a_v \vartheta_v$ where $a_v \in \hat{A}$ for each v and for all $l \in \mathbb{N}$ there are finitely many a_v such that $a_v \not\equiv 0 \bmod \mathfrak{m}^l$.

The formal function ϑ_v defines a function on $\mathcal{V}$ (and so on the fiber V) if and only if the local expressions $\vartheta_{v,p} \in \widehat{A[N]}$ lie in $A[N]$, that is, are Laurent polynomials with coefficients in A. This is not the case in general. However, one can show that if $\vartheta_{v,p}$ is a Laurent polynomial for some $p \in \operatorname{Supp} \Delta^+$, then the same is true for all p, so that ϑ_v lies in $H^0(\mathcal{V}, \mathcal{O}_{\mathcal{V}})$ Gross, Hacking, Keel, and Kontsevich [2018], Proposition 7.1.

Example 5-8. Let $\mathcal{C}^+$ be a chamber of Δ^+ and $v \in \mathcal{C}^+ \cap U^{\text{trop}}(\mathbb{Z})$ an integral point. Let $p \in \mathcal{C}^+$ be a general point. Then there is a unique broken line for v and p, given by $\gamma\colon (-\infty, 0] \to N_{\mathbb{R}}$, $\gamma(t) = p - tv$, with attached monomial z^v. See Gross, Hacking, Keel, and Kontsevich [ibid., Corollary 3.9]. It follows that ϑ_v is a global function on V such that $\vartheta_v|_{T^\vee_{\mathcal{C}^+}} = z^v$. In the terminology of Fomin–Zelevinsky, ϑ_v is a *cluster monomial*.

Example 5-9. For cluster algebras of *finite type* Fomin and Zelevinsky [2003], the cluster complex has finitely many cones and is a complete fan, that is, $\operatorname{Supp} \Delta^+ = U^{\text{trop}}(\mathbb{R}) \simeq N_{\mathbb{R}}$. In this case, every theta function is a cluster monomial, and the cluster monomials form a basis of $H^0(V, \mathcal{O}_V)$.

Cluster algebras of finite type correspond to finite root systems Fomin and Zelevinsky [ibid.]. The mirror U of the A_2-cluster variety V is described in Example 5-3. Let $\vartheta_1, \ldots, \vartheta_5$ be the theta functions on $\mathcal{V}/\mathbb{A}^2$ corresponding to the primitive generators of the rays of the cluster complex in cyclic order. We identify V with the fiber of $\mathcal{V}$ over $(1,1) \in \mathbb{A}^2$. The theta function basis of $H^0(V, \mathcal{O}_V)$ is given by the cluster monomials

$$\{\vartheta_i^a \vartheta_{i+1}^b \mid a, b \in \mathbb{Z}_{\ge 0},\ i \in \mathbb{Z}/5\mathbb{Z}\}.$$

The algebra structure is given by

$$V = (\vartheta_{i-1}\vartheta_{i+1} = \vartheta_i + 1,\ i \in \mathbb{Z}/5\mathbb{Z}) \subset \mathbb{A}^5_{\vartheta_1,\ldots,\vartheta_5}.$$

The closure of V in $\mathbb{P}^5$ is the del Pezzo surface of degree 5 (the blowup of 4 points in $\mathbb{P}^2$ in general position) with an anti-canonical cycle of 5 (-1)-curves at infinity. In this case, the mirror V of U is isomorphic to U (since U is rigid this is a special case of Remark 4-12).

Theorem 5-10. *(Gross, Hacking, Keel, and Kontsevich [2018], Proposition 0.7) Let $U^{\text{trop}}(\mathbb{R}) = N_{\mathbb{R}}$ be the identification associated to some toric model of U. Suppose that the support of the cluster complex Δ^+ is not contained in a half-space in $N_{\mathbb{R}}$ under this identification. Then each ϑ_v defines a global function on $\mathcal{V}$, and the ϑ_v, $v \in U^{\text{trop}}(\mathbb{Z})$ define a $\mathbb{C}$-basis of $H^0(V, \mathcal{O}_V)$.*

See Gross, Hacking, Keel, and Kontsevich [ibid., Sec. 8], for the relation between the hypothesis and positivity of U.

Example 5-11. (Gross, Hacking, Keel, and Kontsevich [ibid., Corollary 0.20], Magee [2017], cf. Goncharov and Shen [2015]). Let $G = SL_m$. Let $B \subset G$ be a Borel subgroup, $N \subset B$ the maximal unipotent subgroup, and $H \subset B$ a maximal torus. Let $F = G/B$ be the full flag variety, and $\tilde{F} = G/N$ its universal torsor, a principal $H = B/N$-bundle over F. The variety F is called the *base affine space*. By the Borel–Weil–Bott theorem,

$$H^0(\tilde{F}, \mathcal{O}_{\tilde{F}}) = \oplus_{L \in \operatorname{Pic} F} H^0(F, L) = \oplus_\lambda V_\lambda,$$

the direct sum of the irreducible representations of G (where $\lambda \in \operatorname{Lie}(H)^*$ denotes a dominant weight). Cf. Fulton and Harris [1991], p. 392–3.

Let $B_- \subset G$ be the opposite Borel subgroup such that $B \cap B_- = H$. Let $V \subset F$ be the open subset of flags transverse to the flags with stabilizers B and B_-. Let $\tilde{V} \subset \tilde{F}$ be its inverse image. Then $\tilde{V}$ is identified with the double Bruhat cell $G^{w_0,e} := Bw_0B \cap B^- \subset G$ where $w_0 \in W = S_m$, $w_0(i) = m + 1 - i$, is the longest element of the Weyl group. In particular, $\tilde{V}$ is a cluster variety in the sense of Fomin–Zelevinsky Berenstein, Fomin, and Zelevinsky [2005]. (From our point of view, there are algebraic tori T_1 and T_2, an action of T_1 on $\tilde{V}$ and a T_1 invariant fibration $\tilde{V} \to T_2$, such that the quotients $\tilde{V}_t/T_1$ of the fibers are cluster varieties in the sense of Definition 3-1. Thus $\tilde{V}$ is given by a combination of the two constructions in Section 5.4.) We remark that the cluster structure on $\tilde{V}$ is closely related to the Poisson structure on G associated to the choice $H \subset B \subset G$ Gekhtman, Shapiro, and Vainshtein [2010, Sec. 1.3], which is the first order term of the non-commutative deformation of G to the quantum group Chari and Pressley [1995],§7.3.

One can show using a generalization of Theorem 5-10 that the theta functions give a canonical basis of $H^0(\tilde{V}, \mathcal{O}_{\tilde{V}})$. The variety $\tilde{F}$ is a partial compactification of $\tilde{V}$, such that $\tilde{F} \setminus \tilde{V}$ is a union of $2(m-1)$ boundary divisors along which the holomorphic volume form Ω on $\tilde{V}$ has a pole. Using positivity properties of the theta function basis $\mathcal{B}$ of $H^0(\tilde{V}, \mathcal{O}_{\tilde{V}})$, one can further show that the subalgebra $H^0(\tilde{F}, \mathcal{O}_{\tilde{F}})$ has basis given by the subset of $\mathcal{B}$ consisting of theta functions which are regular on $\tilde{F}$. The set of such functions is indexed by the integral points of a polyhedral cone in $\tilde{U}^{\text{trop}}(\mathbb{R})$ (where $\tilde{U}$ denotes the Fock–Goncharov mirror of $\tilde{V}$). This polyhedral cone C is given by $C = (W^{\text{trop}} \geq 0)$ where $W : \tilde{U} \to \mathbb{A}^1$ is the regular function given by the sum of the theta functions on

$\tilde{U}$ corresponding to the boundary divisors of the partial compactification $\tilde{V} \subset \tilde{F}$. (Thus, according to general principles, $\tilde{F}$ is mirror to the *Landau–Ginzburg model* $W : \tilde{U} \to \mathbb{A}^1$, cf. Abouzaid, Auroux, and Katzarkov [2016], §2.2.) For a specific choice of toric model of $\tilde{U}$, the cone C is identified with the Gel'fand–Tsetlin cone Goncharov and Shen [2015].

The theta function basis is equivariant for the action of H on $\tilde{F}$. Thus the theta functions with weight λ give a canonical basis of the irreducible representation V_λ.

Remark 5-12. The construction of theta functions given here appears to depend on the choice of a toric model of U. However, one can show, using the behavior of the scattering diagram under mutation, that the families $\mathcal{V}/\mathbb{A}^r$ together with the theta functions for different toric models are compatible Gross, Hacking, Keel, and Kontsevich [2018], Theorem 6.8. In the terminology of mirror symmetry, they correspond to different large complex structure limits of the mirror family.

ALGEBRAIC SURFACES WITH MINIMAL BETTI NUMBERS

JONGHAE KEUM (금종해)

Abstract

These are algebraic surfaces with the Betti numbers of the complex projective plane, and are called $\mathbb{Q}$-homology projective planes. Fake projective planes and the complex projective plane are smooth examples. We describe recent progress in the study of such surfaces, singular ones and fake projective planes. We also discuss open questions.

1 $\mathbb{Q}$-homology Projective Planes and Montgomery-Yang problem

A normal projective surface with the Betti numbers of the complex projective plane $\mathbb{CP}^2$ is called a *rational homology projective plane* or a *$\mathbb{Q}$-homology* $\mathbb{CP}^2$. When a normal projective surface S has only rational singularities, S is a $\mathbb{Q}$-homology $\mathbb{CP}^2$ if its second Betti number $b_2(S) = 1$. This can be seen easily by considering the Albanese fibration on a resolution of S.

It is known that a $\mathbb{Q}$-homology $\mathbb{CP}^2$ with quotient singularities (and no worse singularities) has at most 5 singular points (cf. Hwang and Keum [2011b, Corollary 3.4]). The $\mathbb{Q}$-homology projective planes with 5 quotient singularities were classified in Hwang and Keum [ibid.].

In this section we summarize progress on the Algebraic Montgomery-Yang problem, which was formulated by J. Kollár.

Conjecture 1.1 (Algebraic Montgomery–Yang Problem Kollár [2008]). *Let S be a $\mathbb{Q}$-homology projective plane with quotient singularities. Assume that $S^0 := S \backslash Sing(S)$ is simply connected. Then S has at most* 3 *singular points.*

This is the algebraic version of Montgomery–Yang Problem Fintushel and Stern [1987], which was originated from pseudofree circle group actions on higher dimensional sphere.

MSC2010: primary 14J29; secondary 14F05, 14J17, 14J26, 32Q40, 32N15.
Keywords: fake projective planes, ball quotients, $\mathbb{Q}$-homology projective planes, singular 4-manifolds, Montgomery–Yang problem.

Pseudofree circle group actions are those that have no points fixed by the entire circle group but that have isolated circles that are pointwise fixed by finite cyclic subgroups.

- Work over the field $\mathbb{C}$ of complex numbers, except a few remarks in positive characteristic and in differentiable case.

Definition 1.2. A normal projective surface S is called a $\mathbb{Q}$-homology $\mathbb{CP}^2$ if it has the same Betti numbers as $\mathbb{CP}^2$, i.e. $(b_0, b_1, b_2, b_3, b_4) = (1, 0, 1, 0, 1)$.

Examples 1.3.

1. If S is smooth, then $S = \mathbb{CP}^2$ or a fake projective plane(fpp).
2. If S is singular and has only A_1-singularities, then S is isomorphic to the quadric cone $(xy = z^2)$ in $\mathbb{CP}^3$, i.e., the weighted projective plane $\mathbb{CP}^2(1, 1, 2)$ (cf. Keum [2010]).
3. Cubic surfaces with $3A_2$ in $\mathbb{CP}^3$ (such surfaces can be shown to be isomorphic to $(w^3 = xyz)$).
4. If S has A_2-singularities only, then S has $3A_2$ or $4A_2$ and $S = \mathbb{CP}^2/G$ or fpp$/G$, where $G \cong \mathbb{Z}/3$ or $(\mathbb{Z}/3)^2$.
5. If S has A_1 or A_2-singularities only, then $S = \mathbb{CP}^2(1, 2, 3)$ or one of the above (see Keum [2015] for details).

In this section, S has at worst quotient singularities. Then it is easy to see that

- S is a $\mathbb{Q}$-homology $\mathbb{CP}^2$ if and only if $b_2(S) = 1$.
- A minimal resolution of S has $p_g = q = 0$.

1.1 Trichotomy: K_S ample, $-$ample, numerically trivial. Let S a $\mathbb{Q}$-hom $\mathbb{CP}^2$ with quotient singularities, $f : S' \to S$ a minimal resolution. The canonical class K_S falls in one of the three cases.

1. $-K_S$ is ample (log del Pezzo surfaces of Picard number 1): their minimal resolutions have Kodaira dimension $\kappa(S') = -\infty$; typical examples are $\mathbb{CP}^2/G$, $\mathbb{CP}^2(a, b, c)$.
2. K_S is numerically trivial (log Enriques surfaces of Picard number 1): their minimal resolutions have Kodaira dimension $\kappa(S') = -\infty, 0$.

3. K_S is ample: : their minimal resolutions have Kodaira dimension $\kappa(S') = -\infty, 0, 1, 2$; typical examples are fake projective planes and their quotients, suitable contraction of a suitable blowup of some Enriques surface or $\mathbb{CP}^2$.

The following problem was raised by J. Kollár [2008].

Problem 1.4. Classify all $\mathbb{Q}$-homology projective planes with quotient singularities.

1.2 The Maximum Number of Quotient Singularities. Let S be a $\mathbb{Q}$-homology $\mathbb{CP}^2$ with quotient singularities. From the orbifold Bogomolov–Miyaoka–Yau inequality (Sakai [1980], Miyaoka [1984], and Megyesi [1999]), one can derive that S has at most 5 singular points (see Hwang and Keum [2011b, Corollary 3.4]). Many examples with 4 or less singular points were provided (Brenton [1977] and Brenton, Drucker, and Prins [1981]), but no example with 5 singular points until D. Hwang and the author characterised the case with 5 singular points.

Theorem 1.5 (Hwang and Keum [2011b]). *Let S be a $\mathbb{Q}$-homology projective plane with quotient singularities. Then S has at most 4 singular points except the following case which is supported by an example: S has 5 singular points of type $3A_1 + 2A_3$.*
In the exceptional case the minimal resolution of S is an Enriques surface.

In fact, our proof assumed the condition that K_S is nef to apply the orbifold Bogomolov–Miyaoka–Yau inequality. On the other hand, the case where $-K_S$ is ample was dealt with by Belousov [2008, 2009]. He proved that log del Pezzo surfaces of Picard number 1 with quotient singularities have at most 4 singular points.

Corollary 1.6. *The following hold true.*

1. *$\mathbb{Q}$-cohomology projective planes with quotient singularities have at most 4 singular points except the case given in the above theorem.*

2. *$\mathbb{Z}$-homology projective planes with quotient singularities have at most 4 singular points.*

Here, a $\mathbb{Q}$-cohomology projective plane is a normal projective complex surface having the same $\mathbb{Q}$-cohomology ring with $\mathbb{CP}^2$. A $\mathbb{Q}$-homology projective plane with quotient singularities is a $\mathbb{Q}$-cohomology projective plane.

The problem of determining the maximum number of singular points on $\mathbb{Q}$-homology projective planes with quotient singularities is related to the algebraic Montgomery–Yang problem (Montgomery and Yang [1972] and Kollár [2008]).

Remark 1.7. (1) Every $\mathbb{Z}$-cohomology $\mathbb{CP}^2$ with quotient singularities has at most 1 singular point, and, if it has, then the singularity must be of type E_8 (Bindschadler and Brenton [1984]).

(2) If a $\mathbb{Q}$-homology projective plane S is allowed to have rational singular points (quotient singular points are rational, but the converse does not holds), then there is no bound for the number of singular points. In fact, there are $\mathbb{Q}$-homology projective planes with an arbitrary number of rational singular points. Such examples can be constructed by modifying Example 5 from Kollár [2008]: take a minimal ruled surface $\mathbb{F}_e \to \mathbb{P}^1$ with negative section E, blow up m distinct fibres into m strings of 3 rational curves (-2)—(-1)—(-2), then contract the proper transform of E with the m adjacent (-2)-curves, and also the m remaining (-2)-curves. If $e = -E^2$ is sufficiently larger than m, then the big singular point is rational and yields a $\mathbb{Q}$-homology $\mathbb{CP}^2$ with $m+1$ rational singular points.

(3) In char 2 there is a rational example of Picard number 1 with seven A_1-singularities.

Theorem 1.8 (The orbifold BMY inequality)**.** *Let S be a normal projective surface with quotient singularities. Assume that K_S is nef. Then*

$$K_S^2 \leq 3e_{orb}(S).$$

Theorem 1.9 (The weak oBMY inequality, Keel and McKernan [1999])**.** *Let S be a normal projective surface with quotient singularities. Assume that $-K_S$ is nef. Then*

$$0 \leq e_{orb}(S).$$

Here the orbifold Euler characteristic is defined by

$$e_{orb}(S) := e(S) - \sum_{p \in Sing(S)} \left(1 - \frac{1}{|\pi_1(L_p)|}\right)$$

1.3 Smooth $\mathbf{S}^1$-actions on $\mathbf{S}^m$. Let $\mathbf{S}^1$ be the circle group. Consider a faithful $\mathcal{C}^\infty$ action of $\mathbf{S}^1$ on the m-dimensional sphere $\mathbf{S}^m$

$$\mathbf{S}^1 \subset Diff(\mathbf{S}^m).$$

The identity element $1 \in \mathbf{S}^1$ acts as the identity on $\mathbf{S}^m$. Each diffeomorphism $g \in \mathbf{S}^1$ is homotopic to the identity on $\mathbf{S}^m$. By Lefschetz Fixed Point Formula,

$$e(Fix(g)) = e(Fix(1)) = e(\mathbf{S}^m).$$

If m is even, then $e(\mathbf{S}^m) = 2$ and such an action has fixed points, so is not pseudofree. Pseudofree circle actions are those that have no points fixed by the entire circle group but that have isolated circles that are pointwise fixed by finite cyclic subgroups.

Assume $m = 2n - 1$ odd.

Definition 1.10. A faithful $\mathcal{C}^\infty$-action of $\mathbf{S}^1$ on $\mathbf{S}^{2n-1}$

$$\mathbf{S}^1 \times \mathbf{S}^{2n-1} \to \mathbf{S}^{2n-1}$$

is called *pseudofree* if it is free except for finitely many orbits whose isotropy groups $\mathbb{Z}/a_1\mathbb{Z}, \ldots, \mathbb{Z}/a_k\mathbb{Z}$ have pairwise prime orders.

1.4 Pseudofree $\mathbf{S}^1$-actions on $\mathbf{S}^{2n-1}$.

Example 1.11 (Linear action)**.** For $a_1, ..., a_n$ pairwise prime

$$\mathbf{S}^1 \times \mathbf{S}^{2n-1} \to \mathbf{S}^{2n-1}$$

$$(\lambda, (z_1, z_2, ..., z_n)) \mapsto (\lambda^{a_1} z_1, \lambda^{a_2} z_2, ..., \lambda^{a_n} z_n)$$

where

$$\mathbf{S}^{2n-1} = \{(z_1, z_2, ..., z_n) : |z_1|^2 + |z_2|^2 + ... + |z_n|^2 = 1\} \subset \mathbb{C}^n$$
$$\mathbf{S}^1 = \{\lambda : |\lambda| = 1\} \subset \mathbb{C}.$$

In such a linear action

- $$\mathbf{S}^{2n-1}/\mathbf{S}^1 \cong \mathbb{CP}^{n-1}(a_1, a_2, ..., a_n);$$
- The orbit of the i-th coordinate point $e_i = (0, ..., 0, 1, 0..., 0) \in \mathbf{S}^{2n-1}$ is an exceptional orbit iff $a_i \geq 2$;
- The orbit of a non-coordinate point of $\mathbf{S}^{2n-1}$ is NOT exceptional;
- This action has at most n exceptional orbits;
- The quotient map $\mathbf{S}^{2n-1} \to \mathbb{CP}^{n-1}(a_1, a_2, ..., a_n)$ is a Seifert fibration.

For Seifert fibrations we recall the following.

1. For $n = 2$ Seifert [1933] showed that every pseudofree $\mathbf{S}^1$-action on $\mathbf{S}^3$ is diffeomorphic to a diagonal one and hence has at most 2 exceptional orbits.

2. For $n = 4$ Montgomery and Yang [1972] showed that given arbitrary collection of pairwise prime positive integers $a_1, \ldots, a_k$, there is a pseudofree $\mathbf{S}^1$-action on a homotopy $\mathbf{S}^7$ whose exceptional orbits have exactly those orders.

3. Petrie [1975] generalised the result of Montgomery-Yang for all $n \geq 5$.

Conjecture 1.12 (Montgomery–Yang problem, Fintushel and Stern [1987])**.** *A pseudo-free $\mathbf{S}^1$-action on $\mathbf{S}^5$ has at most 3 exceptional orbits.*

The problem has remained unsolved since its formulation.

- Pseudo-free $\mathbf{S}^1$-actions on a manifold Σ have been studied in terms of the pseudofree orbifold $\Sigma/\mathbf{S}^1$ (see e.g., Fintushel and Stern [1985, 1987]).
- The orbifold $X = \mathbf{S}^5/\mathbf{S}^1$ is a 4-manifold with isolated singularities whose neighborhoods are cones over lens spaces corresponding to the exceptional orbits of the $\mathbf{S}^1$-action.
- Easy to check that X is simply connected and $H_2(X, \mathbb{Z})$ has rank 1 and intersection matrix $(1/a_1 a_2 \cdots a_k)$.
- An exceptional orbit with isotropy type $\mathbb{Z}/a$ has an equivariant tubular neighborhood which may be identified with $\mathbb{C} \times \mathbb{C} \times \mathbf{S}^1$ with a $\mathbf{S}^1$-action

$$\lambda \cdot (z, w, u) = (\lambda^r z, \lambda^s w, \lambda^a u)$$

  where r and s are relatively prime to a.

The following 1-1 correspondence was known to Montgomery–Yang, Fintushel–Stern, and revisited by Kollár [2005, 2008].

Theorem 1.13. *There is a one-to-one correspondence between:*

1. *Pseudofree $\mathbf{S}^1$-actions on $\mathbb{Q}$-homology 5-spheres Σ with $H_1(\Sigma, \mathbb{Z}) = 0$.*
2. *Compact differentiable 4-manifolds M with boundary such that*
   - *(a)* $\partial M = \bigcup_i L_i$ *is a disjoint union of lens spaces* $L_i = \mathbf{S}^3/\mathbb{Z}_{a_i}$,
   - *(b) the orders a_i's are pairwise prime,*
   - *(c)* $H_1(M, \mathbb{Z}) = 0$,
   - *(d)* $H_2(M, \mathbb{Z}) \cong \mathbb{Z}$.

Furthermore, Σ is diffeomorphic to $\mathbf{S}^5$ iff $\pi_1(M) = 1$.

1.5 Algebraic Montgomery-Yang Problem. This is the Montgomery-Yang Problem when the pseudofree orbifold $\mathbf{S}^5/\mathbf{S}^1$ attains a structure of a normal projective surface.

Conjecture 1.14 (Kollár [2008]). *Let S be a $\mathbb{Q}$-homology $\mathbb{CP}^2$ with at worst quotient singularities. If the smooth part S^0 has $\pi_1(S^0) = \{1\}$, then S has at most 3 singular points.*

What happens if the condition $\pi_1(S^0) = \{1\}$ is replaced by the weaker condition $H_1(S^0, \mathbb{Z}) = 0$?

Remark 1.15. If $H_1(S^0, \mathbb{Z}) = 0$, then
(1) K_S cannot be numerically trivial;
(2) it follows from the oBMY that $|Sing(S)| \leq 4$.

There are infinitely many examples S with

$$H_1(S^0, \mathbb{Z}) = 0, \quad \pi_1(S^0) \neq \{1\}, \quad |Sing(S)| = 4,$$

obtained from the classification of surface quotient singularities by Brieskorn [1967/1968].

Example 1.16 (Brieskorn quotients). Let $I_m \subset GL(2, \mathbb{C})$ be the $2m$-ary icosahedral group $I_m = \mathbb{Z}_{2m}.\mathfrak{A}_5$,

$$1 \to \mathbb{Z}_{2m} \to I_m \to \mathfrak{A}_5 \subset PSL(2, \mathbb{C}).$$

The action of I_m on $\mathbb{C}^2$ extends naturally to $\mathbb{CP}^2$. Then

$$S := \mathbb{CP}^2/I_m$$

is a $\mathbb{Q}$-homology $\mathbb{CP}^2$ such that

- $-K_S$ ample;
- S has 4 quotient singularities: one non-cyclic singularity of type I_m (the image of the origin $O \in \mathbb{C}^2$) and 3 cyclic singularities of order $2, 3, 5$ (on the image of the line at infinity);
- $\pi_1(S^0) = \mathfrak{A}_5$, hence $H_1(S^0, \mathbb{Z}) = 0$.

1.6 Progress on Algebraic Montgomery-Yang Problem. Algebraic Montgomery-Yang problem holds true if S has at least 1 non-cyclic singular point.

Theorem 1.17 (Hwang and Keum [2011a]). *Let S be a $\mathbb{Q}$-homology $\mathbb{CP}^2$ with quotient singular points, not all cyclic, such that $\pi_1(S^0) = \{1\}$. Then $|Sing(S)| \leq 3$.*

More precisely

Theorem 1.18. *Let S be a $\mathbb{Q}$-homology $\mathbb{CP}^2$ with 4 or more quotient singular points, not all cyclic, such that $H_1(S^0, \mathbb{Z}) = 0$. Then S is isomorphic to a Brieskorn quotient.*

Remark 1.19. In Hwang and Keum [2011a], though the proof was correct, a wrong conclusion was made in the statement (4) of Theorem 3 that the smooth part S^0 of such a surface S is deformation equivalent to the smooth part of a Brieskorn quotient. A corrected statement was given in Hwang and Keum [2009].

More Progress on the Algebraic Montgomery-Yang Problem:

Theorem 1.20 (Hwang and Keum [2013, 2014])**.** *Let S be a $\mathbb{Q}$-homology $\mathbb{CP}^2$ with cyclic singularities such that $H_1(S^0, \mathbb{Z}) = 0$. If either S is not rational or $-K_S$ is ample, then $|Sing(S)| \leq 3$.*

The Remaining Case of the Algebraic Montgomery-Yang Problem:

S is a $\mathbb{Q}$-homology $\mathbb{CP}^2$ such that

1. S has cyclic singularities only,
2. S is a rational surface with K_S ample.

Looking at the adjunction formula

$$K_{S'} = \pi^* K_S - \sum D_p,$$

where $S' \to S$ is a resolution, one sees that K_S, though ample, is "smaller than $\sum D_p$" so that no positive multiple of $K_{S'}$ is effective. Such surfaces were given by

Keel and McKernan [1999];
Kollár [2008]: infinite series of examples with $|Sing(S)| = 2$;
Hwang and Keum [2012]: infinite series of examples with $|Sing(S)| = 1, 2, 3$.
Urzúa and Yáñez [2016]: characterization of Kollár surfaces.

There is no known example with $|Sing(S)| = 4$, even if the condition $H_1(S^0, \mathbb{Z}) = 0$ is removed.

Problem 1.21. Is there a $\mathbb{Q}$-homology projective plane S which is a rational surface with K_S ample and $|Sing(S)| = 4$?

Another interesting line of research is to obtain surfaces with quotient singularities with small volume. Alexeev and Liu [2016] has constructed a surface S with log terminal singularities (quotient singularities) and ample canonical class that has $K_S^2 = 1/48983$ and a log canonical pair (S, B) with a nonempty reduced divisor B and ample $K_S + B$ that has $(K_S + B)^2 = 1/462$, both examples signifcantly improve known record.

1.7 Cascade structure on rational $\mathbb{Q}$-homology projective planes. A rational $\mathbb{Q}$-homology $\mathbb{CP}^2$ is obtained by blow-ups and downs from a "basic surface" which is a rational minimal surface with certain configuration of curves.
In the case where $-K_S$ ample, all basic surfaces have been classified by Hwang [n.d.].

1.8 Gorenstein $\mathbb{Q}$-homology projective planes. These are $\mathbb{Q}$-homology projective planes with ADE-singular points (i.e., rational double points).

Let R be the singularity type, i.e., the corresponding root sublattice of the cohomology lattice of S', the minimal resolution of S.
Since S is Gorenstein, rank(R) is bounded.

$$1 + \text{rank}(R) = b_2(S') = 10 - K_{S'}^2 = 10 - K_S^2 \leq 10,$$

$$\text{rank}(R) \leq 9$$

with equality iff K_S is numerically trivial iff S' is an Enriques surface.

With D. Hwang and H. Ohashi, we classified all possible singularity types of Gorenstein $\mathbb{Q}$-homology projective planes. There are 58 types total.

Theorem 1.22 (Hwang, Keum, and Ohashi [2015]). *The singularity type R of a Gorenstein $\mathbb{Q}$-homology $\mathbb{CP}^2$ is one of the following:*

(1) K_S *±ample* (27 *types*)*:*
A_8, A_7, D_8, E_8, E_7, E_6, D_5, A_4, A_1;
$A_7 \oplus A_1$, $A_5 \oplus A_2$, $A_5 \oplus A_1$, $2A_4$, $A_2 \oplus A_1$, $D_6 \oplus A_1$, $D_5 \oplus A_3$, $2D_4$, $E_7 \oplus A_1$, $E_6 \oplus A_2$;
$A_5 \oplus A_2 \oplus A_1$, $2A_3 \oplus A_1$, $A_3 \oplus 2A_1$, $3A_2$, $D_6 \oplus 2A_1$;
$2A_3 \oplus 2A_1$, $4A_2$, $D_4 \oplus 3A_1$,

(2) K_S *numerically trivial* (31 *types*)
A_9, D_9;
$A_8 \oplus A_1$, $A_7 \oplus A_2$, $A_5 \oplus A_4$, $D_8 \oplus A_1$, $D_6 \oplus A_3$, $D_5 \oplus A_4$, $D_5 \oplus D_4$, $E_8 \oplus A_1$, $E_7 \oplus A_2$, $E_6 \oplus A_3$;
$A_7 \oplus 2A_1$, $A_6 \oplus A_2 \oplus A_1$, $A_5 \oplus A_3 \oplus A_1$, $A_5 \oplus 2A_2$, $2A_4 \oplus A_1$, $3A_3$, $D_7 \oplus 2A_1$, $D_6 \oplus A_2 \oplus A_1$, $D_5 \oplus A_3 \oplus A_1$, $2D_4 \oplus A_1$, $E_7 \oplus 2A_1$, $E_6 \oplus A_2 \oplus A_1$;

$A_5 \oplus A_2 \oplus 2A_1$, $A_4 \oplus A_3 \oplus 2A_1$, $2A_3 \oplus A_2 \oplus A_1$, $A_3 \oplus 3A_2$, $D_6 \oplus 3A_1$, $D_4 \oplus A_3 \oplus 2A_1$; $2A_3 \oplus 3A_1$.

The 27 types with $-K_S$ ample were classified by Furushima [1986], Miyanishi and Zhang [1988], Ye [2002]. Our method uses only lattice theory, different from theirs.

Among the 31 types with $K_S \equiv 0$, 29 types are supported by Enriques surfaces with finite automorphism group. Enriques surfaces with $|Aut| < \infty$ must have finitely many (-2)-curves, and were classified by Nikulin and Kondō [1986] into 7 families, two families 1-dimensional and five 0-dimensional. Schütt [2015] has constucted explicitly, for each of the 31 types, the moduli space of such Enriques surfaces, all 1-dimensional.

Remark 1.23. In positive characteristic the case with $K_S \equiv 0$ has been classified by M. Schütt [2016, 2017], which build on recent deep results of Katsura and Kondō [2018], Martin [2017], and Katsura, Kondō, and Martin [2017], also on a unpublished work of Dolgachev-Liedtke.

1.9 The differentiable case. Let M be a smooth, compact 4-manifold whose boundary components are spherical, that is, lens spaces $L_i = \mathbf{S}^3$. One can then attach cones to each boundary component to get a 4-dimensional orbifold S. As in the algebraic case, there is a minimal resolution $f : S' \to S$, where S' is a smooth, compact 4-manifold without boundary.

To each singular point $p \in S$ (the vertex of each cone), we assign a uniquely defined class $\mathfrak{D}_p = \sum(a_j E_j) \in H^2(S', \mathbb{Q})$ such that

$$\mathfrak{D}_p \cdot E_i = 2 + E_i^2$$

for each component E_i of $f^{-1}(p)$. We always assume that S and S' satisfy the following two conditions:

(1) S is a $\mathbb{Q}$-homology $\mathbb{CP}^2$, i.e. $H^1(S, \mathbb{Q}) = 0$ and $H^2(S, \mathbb{Q}) \cong \mathbb{Q}$.

(2) The intersection form on $H^2(S', \mathbb{Q})$ is indefinite, and is negative definite on the subspace generated by the classes of the exceptional curves of f.

If there is a class $K_{S'} \in H^2(S', \mathbb{Q})$ satisfying both the Noether formula

$$K_{S'}^2 = 10 - b_2(S')$$

and the adjunction formula

$$K_{S'} \cdot E + E^2 = -2$$

for each exceptional curve E of f, we call it a *formal canonical class of* S', and the class $K_{S'} + \sum \mathfrak{D}_p \in H^2(S', \mathbb{Q})$ a *formal canonical class of* S.

Theorem 1.24 (Hwang and Keum [2011b] Theorem 8.1)**.** *Let M, S, and S' be the same as above satisfying the conditions* (1) *and* (2)*. Assume that S' admits a formal canonical class $K_{S'}$. Assume further that*

$$K_{S'}^2 - \sum_{p \in Sing(S)} \mathfrak{D}_p^2 \leq 3e_{orb}(S).$$

Then M has at most 4 boundary components except the following two cases: M has 5 boundary components of type $3A_1 + 2A_3$ or $4A_1 + D_5$.

Note that the assumptions in Theorem 1.24 all hold for algebraic $\mathbb{Q}$-homology projective planes with quotient singularities such that the canonical divisor is nef.

Theorem 1.25 (Hwang and Keum [ibid.] Theorem 8.2)**.** *Let M, S, and S' be the same as above satisfying the conditions* (1) *and* (2)*. Assume that S' admits a formal canonical class $K_{S'}$. Assume further that*

$$0 \leq e_{orb}(S).$$

Then M has at most 5 boundary components. The bound is sharp.

The assumptions in Theorem 1.25 all hold for algebraic $\mathbb{Q}$-homology projective planes with quotient singularities.

1.10 The symplectic case. If S is a symplectic orbifold, then S' is a symplectic manifold and the symplectic canonical class $K_{S'}$ gives a formal canonical class.

Problem 1.26. Is there a Bogomolov–Miyaoka–Yau type inequality for symplectic 4-manifolds?
Is there an orbifold Bogomolov–Miyaoka–Yau type inequality for symplectic orbifolds?

The following question is also interesting in view of Sasakian geometry.

Problem 1.27 (Muñoz, Rojo, and Tralle [2016])**.** There does not exist a Kähler manifold or a Kähler orbifold with $b_1 = 0$ and $b_2 \geq 2$ having b_2 disjoint complex curves all of genus $g \geq 1$ which generate $H_2(S, \mathbb{Q})$.

A ruled surface over a curve of genus g has two disjoint curves, the negative section and a general section, of genus g, but has $b_1 \neq 0$ if $g \geq 1$.

2 Fake projective planes

A compact complex surface with the same Betti numbers as the complex projective plane is called *a fake projective plane* if it is not biholomorphic to the complex projective plane.

A fake projective plane has ample canonical divisor, so it is a smooth proper (geometrically connected) surface of general type with geometric genus $p_g = 0$ and self-intersection of canonical class $K^2 = 9$ (this definition extends to arbitrary characteristic.) The existence of a fake projective plane was first proved by Mumford [1979] based on the theory of 2-adic uniformization, and later two more examples by Ishida and Kato [1998] 1998) in a similar method. Keum [2006] gave a construction of a fake projective plane with an order 7 automorphism, which is birational to an order 7 cyclic cover of a Dolgachev surface. This surface and Mumford fake projective plane belong to the same class, in the sense that their fundamental groups are both contained in the same maximal arithmetic subgroup of the isometry group of the complex 2-ball.

Fake projective planes have Chern numbers $c_1^2 = 3c_2 = 9$ and are complex 2-ball quotients by Aubin [1976] and Yau [1977]. Such ball quotients are strongly rigid by Mostow's rigidity theorem (Mostow [1973]), that is, determined by fundamental group up to holomorphic or anti-holomorphic isomorphism. Fake projective planes come in complex conjugate pairs by Kulikov and Kharlamov [2002] and have been classified as quotients of the two-dimensional complex ball by explicitly written co-compact torsion-free arithmetic subgroups of $\mathrm{PU}(2,1)$ by Prasad and Yeung [2007, 2010] and Cartwright and Steger [2010, n.d.]. The arithmeticity of their fundamental groups was proved by Klingler [2003]. There are exactly 100 fake projective planes total, corresponding to 50 distinct fundamental groups. Cartwright and Steger also computed the automorphism group of each fake projective plane X, which is given by $\mathrm{Aut}(X) \cong N(X)/\pi_1(X)$, where $N(X)$ is the normalizer of $\pi_1(X)$ in its maximal arithmetic subgroup of $\mathrm{PU}(2,1)$. In particular $\mathrm{Aut}(X) \cong \{1\}$, $\mathbb{Z}_3$, $\mathbb{Z}_3^2$ or G_{21} where $\mathbb{Z}_n$ is the cyclic group of order n and G_{21} is the unique non-abelian group of order 21. Among the 50 pairs exactly 33 admit non-trivial automorphisms: 3 pairs have $\mathrm{Aut} \cong G_{21}$, 3 pairs have $\mathrm{Aut} \cong \mathbb{Z}_3^2$ and 27 pairs have $\mathrm{Aut} \cong \mathbb{Z}_3$.

For each pair of fake projective planes Cartwright and Steger [n.d.] also computed the torsion group

$$H_1(X,\mathbb{Z}) = \mathrm{Tor}(H^2(X,\mathbb{Z})) = \mathrm{Tor}(\mathrm{Pic}(X))$$

which is the abelianization of the fundamental group. According to their computation exactly 29 pairs of fake projective planes have a 3-torsion in $H_1(X,\mathbb{Z})$.

In this section we summarize recent progress on these fascinating objects.

2.1 Picard group of a fake projective plane. Since $p_g(X) = q(X) = 0$, the long exact sequence induced by the exponential sequence gives $\mathrm{Pic}(X) = H^2(X,\mathbb{Z})$. By the universal coefficient theorem, $\mathrm{Tor}H^2(X,\mathbb{Z}) = \mathrm{Tor}H_1(X,\mathbb{Z})$. This implies that

$$\mathrm{Pic}(X) = H^2(X,\mathbb{Z}) \cong \mathbb{Z} \times H_1(X,\mathbb{Z}).$$

Two ample line bundles with the same self-intersection number on a fake projective plane differ by a torsion.

It can be shown (cf. Keum [2017, Lemma 1.5]) that if a fake projective plane X has no 3-torsion in $H_1(X,\mathbb{Z})$ (21 pairs of fake projective planes satisfy this property), then the canonical class K_X is divisible by 3 and has a unique cube root, i.e., a unique line bundle L_0 up to isomorphism such that $3L_0 \equiv K_X$.

By a result of Kollár [1995, p. 96] the 3-divisibility of K_X is equivalent to the liftability of the fundamental group to $\mathrm{SU}(2,1)$. Except 4 pairs of fake projective planes the fundamental groups lift to $\mathrm{SU}(2,1)$ (Prasad and Yeung [2010, Section 10.4], Cartwright and Steger [2010, n.d.]). In the notation of Cartwright and Steger [2010], these exceptional 4 pairs are the 3 pairs in the class $(\mathcal{C}_{18}, p=3, \{2\})$, whose automorphism groups are of order 3, and the one in the class $(\mathcal{C}_{18}, p=3, \{2I\})$, whose automorphism group is trivial. There are fake projective planes with a 3-torsion and with canonical class divisible by 3 Cartwright and Steger [n.d.].

2.2 Quotients of fake projective planes. Let X be a fake projective plane with a nontrivial group G acting on it. In Keum [2008], all possible structures of the quotient surface X/G and its minimal resolution were classified:

Theorem 2.1 (Keum [ibid.]). *1. If $G=\mathbb{Z}_3$, then X/G is a $\mathbb{Q}$-homology projective plane with 3 singular points of type $\frac{1}{3}(1,2)$ and its minimal resolution is a minimal surface of general type with $p_g=0$ and $K^2=3$.*

2. If $G=\mathbb{Z}_3^2$, then X/G is a $\mathbb{Q}$-homology projective plane with 4 singular points of type $\frac{1}{3}(1,2)$ and its minimal resolution is a minimal surface of general type with $p_g=0$ and $K^2=1$.

3. If $G=\mathbb{Z}_7$, then X/G is a $\mathbb{Q}$-homology projective plane with 3 singular points of type $\frac{1}{7}(1,5)$ and its minimal resolution is a $(2,3)$- or $(2,4)$- or $(3,3)$-elliptic surface.

4. If $G=\mathbb{Z}7:\mathbb{Z}3=G_{21}$, then X/G is a $\mathbb{Q}$-homology projective plane with 4 singular points, where three of them are of type $\frac{1}{3}(1,2)$ and one of them is of type $\frac{1}{7}(1,5)$, and its minimal resolution is a $(2,3)$- or $(2,4)$- or $(3,3)$-elliptic surface.

A fake projective plane is a nonsingular $\mathbb{Q}$-homology projective plane, hence every quotient is again a $\mathbb{Q}$-homology projective plane. An (a,b)-elliptic surface is a relatively minimal elliptic surface over $\mathbb{P}^1$ with $c_2 = 12$ having two multiple fibres of multiplicity a and b respectively. It has Kodaira dimension 1 if and only if $a \geq 2, b \geq 2, a+b \geq 5$. It is an Enriques surface iff $a = b = 2$. It is rational iff $a = 1$ or $b = 1$. All (a,b)-elliptic surfaces have $p_g = q = 0$, and by van Kampfen theorem its fundamental group is the cyclic group $\mathbb{Z}_d$ (see Dolgachev [2010]), where d is the greatest common divisor of a and b. A simply connected (a,b)-elliptic surface is called a Dolgachev surface.

Remark 2.2. The possibility of $(3,3)$-elliptic surface was further removed by the computation of Cartwright-Steger. In Cartwright and Steger [n.d.] they also computed the fundamental group of each quotient X/G, which is by the result of Armstrong [1968] isomorphic to the quotient group of the augmented fundamental group $\langle \pi_1(X), G' \rangle$ by the normal subgroup generated by elements with nonempty fixed locus on the complex 2-ball, where G' is a lifting of G onto the ball. According to their computation, $\pi_1(X/G) = \{1\}$ or $\mathbb{Z}_2$ if $G = \mathbb{Z}_7$.

2.3 Vanishing theorem for some fake projective planes. For an ample line bundle M on a fake projective plane X, M^2 is a square integer. When $M^2 \geq 9$, $H^0(X,M) \neq 0$ if and only if $M \not\cong K_X$. This follows from the Riemann-Roch and the Kodaira vanishing theorem. When $M^2 \leq 4$, $H^0(X,M)$ may not vanish, though no example of non-vanishing so far has been known. If it does not vanish, then it gives an effective curve of small degree. The non-vanishing of $H^0(X,M)$ is equivalent to the existence of certain automorphic form on the 2-ball.

Theorem 2.3 (Keum [2017]). *Let X be a fake projective plane with* $\mathrm{Aut}(X) \cong \mathbb{Z}_7 : \mathbb{Z}_3$. *Then for every $\mathbb{Z}_7$-invariant ample line bundle M with $M^2 = 4$ we have the vanishing*

$$H^0(X,M) = 0.$$

In particular, for each line bundle L with $L^2 = 1$

$$H^0(X,2L) = 0.$$

Remark 2.4.

1. A fake projective plane with $\mathrm{Aut}(X) \cong \mathbb{Z}_7 : \mathbb{Z}_3$ has only 2-torsions Cartwright and Steger [n.d.], more precisely

$$H_1(X,\mathbb{Z}) = \mathbb{Z}_2^3,\ \mathbb{Z}_2^4,\ \mathbb{Z}_2^6.$$

2. Thus K_X of such a surface has a unique cube root L_0.

3. For such a surface two ample line bundles with the same self-intersection number differ by a 2-torsion. If $M^2 = m^2$, then $M \equiv mL_0 + t$ for a 2-torsion t, hence $2M \equiv 2mL_0$ and is invariant under every automorphism.

4. The above theorem in Keum [2017] was stated only for the case $M = 2L$, but the proof used only the invariance of M under the order 7 automorphism.

5. If $M = 2L_0 + t$ is invariant under an automorphism iff so is t.

6. By Catanese and Keum [2018] the $\mathbb{Z}_7$ action on $H_1(X,\mathbb{Z})$ fixes no 2-torsion element in the case of $H_1(X,\mathbb{Z}) \cong \mathbb{Z}_2^3,\ \mathbb{Z}_2^6$, and one in the case of $H_1(X,\mathbb{Z}) \cong \mathbb{Z}_2^4$.

Theorem 2.5 (Keum [2017])**.** *Let X be a fake projective plane with* $\mathrm{Aut}(X) \cong \mathbb{Z}_3^2$*. Then for every* $\mathrm{Aut}(X)$*-invariant ample line bundle M with $M^2 = 4$ we have the vanishing*

$$H^0(X, M) = 0.$$

In particular, for the cubic root L_0 of K_X

$$H^0(X, 2L_0) = 0.$$

Remark 2.6. 1. A fake projective plane with $\mathrm{Aut}(X) \cong \mathbb{Z}_3^2$ has

$$H_1(X,\mathbb{Z}) = \mathbb{Z}_{14},\ \ \mathbb{Z}_7,\ \ \mathbb{Z}_2^2 \times \mathbb{Z}_{13}.$$

2. Thus K_X of such a surface has a unique cube root L_0.

3. For such a surface two ample line bundles with the same self-intersection number differ by a torsion.

4. The above theorem in Keum [ibid.] was stated only for the case $M = 2L_0$, but the proof used only the invariance of M under $\mathrm{Aut}(X) \cong \mathbb{Z}_3^2$.

5. If $M = 2L_0 + t$ is invariant under an automorphism iff so is t.

6. By Catanese and Keum [2018] no torsion element is $\mathbb{Z}_3^2$-invariant in the case of $H_1(X,\mathbb{Z}) \cong \mathbb{Z}_7,\ \mathbb{Z}_2^2 \times \mathbb{Z}_{13}$, and only the unique 2-torsion is $\mathbb{Z}_3^2$-invariant in the case of $H_1(X,\mathbb{Z}) \cong \mathbb{Z}_{14}$.

Both proofs used the structure of the quotients of X given in the previous subsection. The key idea of proof is that if $H^0(X, M) \neq 0$, then $\dim H^0(X, 2M) \geq 4$, contradicting the Riemann-Roch which yields $\dim H^0(X, 2M) = 3$.

2.4 Exceptionl collections of line bundles. Let $D^b(coh(W))$ denote the bounded derived category of coherent sheaves on a smooth variety W. It is a triangulated category. An object E in a triangulated category is called exceptional if $Hom(E, E[i]) = \mathbb{C}$ if $i = 0$, and $= 0$ otherwise. A sequence $E_1, \ldots, E_n$ of exceptional objects is called an exceptional sequence if $Hom(E_j, E_k[i]) = 0$ for any $j > k$, any i. When W is a smooth surface with $p_g = q = 0$, every line bundle is an exceptional object in $D^b(coh(W))$.

Let X be a fake projective plane and L be an ample line bundle with $L^2 = 1$. The three line bundles

$$2L,\ L,\ \mathcal{O}_X$$

form an exceptional sequence if and only if $H^j(X, 2L) = H^j(X, L) = 0$ for all j. Write

$$D^b(coh(X)) = \langle 2L,\ L,\ \mathcal{O}_X,\ \mathcal{A}\rangle$$

where $\mathcal{A}$ is the orthogonal complement of the admissible triangulated subcategory generated by $2L,\ L,\ \mathcal{O}_X$. Then the Hochshield homology

$$HH_*(\mathcal{A}) = 0.$$

This can be read off from the Hodge numbers. In fact, the Hochshield homology of X is the direct sum of Hodge spaces $H^{p,q}(X)$, and its total dimension is the sum of all Hodge numbers. The latter is equal to the topological Euler number $c_2(X)$, as a fake projective plane has Betti numbers $b_1(X) = b_3(X) = 0$.

The Grothendieck group $K_0(X)$ has filtration

$$K_0(X) = F^0K_0(X) \supset F^1K_0(X) \supset F^2K_0(X)$$

with

$$F^0K_0(X)/F^1K_0(X) \cong CH^0(X) \cong \mathbb{Z},$$

$$F^1K_0(X)/F^2K_0(X) \cong \mathrm{Pic}(X),$$

$$F^2K_0(X) \cong CH^2(X).$$

If the Bloch conjecture holds for X, i.e. if $CH^2(X) \cong \mathbb{Z}$, then $K_0(\mathcal{A})$ is finite.

Corollary 2.7. *Let X be a fake projective plane with $\mathrm{Aut}(X) \cong \mathbb{Z}_7 : \mathbb{Z}_3$ or $\mathbb{Z}_3^2$. Let L_0 be the unique cubic root of K_X. Then the three line bundles*

$$\mathcal{O}_X,\ -L_0,\ -2L_0$$

form an exceptional collection on X. If t is a $\mathbb{Z}_7$- or $\mathbb{Z}_3^2$-invariant torsion line bundle, then the three line bundles

$$\mathcal{O}_X,\ -(L_0+t),\ -2L_0$$

form another exceptional collection.

Such a torsion line bundle t exists for only one pair of fake projective planes in each case $\mathrm{Aut}(X) \cong \mathbb{Z}_7 : \mathbb{Z}_3$ or $\mathbb{Z}_3^2$ by Catanese and Keum [2018] (see Remark 2.4, Remark 2.6).

This is equivalent to that $H^i(X, 2L_0) = H^i(X, L_0) = H^i(X, L_0 + t) = 0$ for all i, hence follows from Theorem 2.3 and 2.5. Indeed, since L_0 is a cubic root of K_X, these vanishings are equivalent to the vanishing $H^0(X, 2L_0) = H^0(X, 2L_0 + t) = 0$. This confirms, for fake projective planes with enough automorphisms, the conjecture raised by Galkin, Katzarkov, Mellit, and Shinder [2013] that predicts the existence of an exceptional sequence of length 3 on every fake projective plane. Disjoint from our cases, Fakhruddin [2015] confirmed the conjecture for the case of three 2-adically uniformized fake projective planes found by Mumford [1979] and Ishida and Kato [1998].

2.5 Bicanonical map of fake projective planes. By Reider's theorem Reider [1988] (see Barth, Hulek, Peters, and Van de Ven [2004] for a slightly refined version) on adjoint linear systems the bicanonical system $|2K_X|$ of a ball quotient X is base point free, thus it defines a morphism.

If the ball quotient X has $\chi(X) \geq 2$, then $K_X^2 \geq 9\chi(X) \geq 10$, and since a ball quotient cannot contain a curve of geometric genus 0 or 1, the bicanonical map embeds X unless X contains a smooth genus 2 curve C with $C^2 = 0$, and $CK_X = 2$.

In the case $\chi(X) = 1$, for instance if we have a fake projective plane, we are below the Reider inequality $K_X^2 \geq 10$, and the question of the very-ampleness of the bicanonical system is interesting.

Conjecture 2.8. *For each fake projective plane its bicanonical map is an embedding into* $\mathbb{P}^9$.

Every fake projective plane X with automorphism group of order 21 cannot contain an effective curve with self-intersection 1 (Theorem 2.3), as was first proved in Keum [2013] (see Keum [2017], also Galkin, Katzarkov, Mellit, and Shinder [2015]). Thus by applying I. Reider's theorem, one sees that the bicanonical map of such a fake projective plane is an embedding into $\mathbb{P}^9$ (see also Di Brino and Di Cerbo [2018]).

Including these 3 pairs of fake projective planes, for 10 pairs the conjecture has been confirmed by Catanese and Keum [2018]. For nine pairs this follows from the vanishing result of Keum [2013, 2017], Catanese and Keum [2018]. For one pair we do not have the vanishing theorem, and the surface possesses either none or 3 curves D with $D^2 = 1$. But even in the latter case we manage to prove the very-ampleness of the bicanonical system.

2.6 Explicit equations of fake projective planes. It has long been of great interest since Mumford to find equations of a projective model of a fake projective plane.

In a recent joint work Borisov and Keum [2017, 2018] we find equations of a projective model (the bicanonical image) of a conjugate pair of fake projective planes by studying the geometry of the quotient of such surface by an order seven automorphism. The equations are given explicitly as 84 cubics in 10 variables with coefficients in the field $\mathbb{Q}[\sqrt{-7}]$. The complex conjugate equations define the bicanonical image of the complex conjugate of the surface,

This pair has the most geometric symetries among the 50 pairs, in the sense that it has the large automorphism group $G_{21} = \mathbb{Z}_7 : \mathbb{Z}_3$ and the $\mathbb{Z}_7$-quotient has a smooth model of a $(2, 4)$-elliptic surface which is not simply connected. For several pairs of fake projective planes including this pair the bicanonical map gives an embedding into the 9-dimensional projective space.

FROM CONTINUOUS RATIONAL TO REGULOUS FUNCTIONS

Wojciech Kucharz and Krzysztof Kurdyka

Abstract

Let X be an algebraic set in $\mathbb{R}^n$. Real-valued functions, defined on subsets of X, that are continuous and admit a rational representation have some remarkable properties and applications. We discuss recently obtained results on such functions, against the backdrop of previously developed theories of arc-symmetric sets, arc-analytic functions, approximation by regular maps, and algebraic vector bundles.

1 Introduction

Our purpose is to report on some new developments in real algebraic geometry, focusing on functions that have a rational representation. Let us initially consider the simplest case. A function $f : \mathbb{R}^n \to \mathbb{R}$ of class $\mathcal{C}^k$, where k is a nonnegative integer, is said to have a *rational representation* if there exist two polynomial functions p, q on $\mathbb{R}^n$ such that q is not identically 0 and $f = p/q$ on $\{q \neq 0\}$. A typical example is

(1.1) $f_k : \mathbb{R}^2 \to \mathbb{R}$ defined by

$$f_k(x, y) = \frac{x^{3+k}}{x^2 + y^2} \text{ for } (x, y) \neq (0, 0) \text{ and } f(0, 0) = 0.$$

To the best of our knowledge, Kucharz [2009] was the first paper devoted to the systematic study of such functions. This line of research was continued by several mathematicians Bilski, Kucharz, A. Valette, and G. Valette [2013], Fichou, Huisman, Mangolte, and Monnier [2016], Fichou, Monnier, and Quarez [2017], Kollár, Kucharz, and

W. Kucharz was partially supported by the National Science Center (Poland) under grant number 2014/15/ST1/00046. K. Kurdyka was partially supported by the ANR project LISA (France).

Keywords: Real algebraic set, semialgebraic set, regular function, rational function, regulous function, arc-symmetric set, arc-analytic function, approximation, vector bundle.

Kurdyka [2018], Kollár and Nowak [2015], Kucharz [2013b, 2014a,b, 2015b, 2016a,b], Kucharz and Kurdyka [2016a,b, 2017, 2015], Kucharz and Zieliński [2018], Monnier [2018], Zieliński [2016], frequently with $k = 0$, where the functions admitting a rational representation are only continuous. Let us note that the complex case is quite different. Any continuous function from $\mathbb{C}^n$ into $\mathbb{C}$ that has a rational representation is a polynomial function.

Henceforth we work with real algebraic sets, which is equivalent to the approach adopted in Bochnak, Coste, and Roy [1998]. By a *real algebraic set* we mean an algebraic subset of $\mathbb{R}^n$ for some n. One can realize real projective d-space $\mathbb{P}^d(\mathbb{R})$ as a real algebraic set using the embedding

$$\mathbb{P}^d(\mathbb{R}) \ni (x_0 : \cdots : x_d) \mapsto \left(\frac{x_i x_j}{x_0^2 + \cdots + x_d^2} \right) \in \mathbb{R}^{(d+1)^2}. \tag{1.2}$$

Thus any algebraic subset of $\mathbb{P}^d(\mathbb{R})$ is an algebraic subset of $\mathbb{R}^{(d+1)^2}$. Consequently, many useful constructions can be performed within the class of real algebraic sets, blowing-up being an important example. One can also view any real algebraic set as the set of real points $V(\mathbb{R})$ of a quasiprojective variety V defined over $\mathbb{R}$.

Unless explicitly stated otherwise, we always assume that real algebraic sets and their subsets are endowed with the Euclidean topology, which is induced by the usual metric on $\mathbb{R}$. For a real algebraic set X, its singular locus $\operatorname{Sing}(X)$ is an algebraic, Zariski nowhere dense subset of X. We say that X is *smooth* if $\operatorname{Sing}(X)$ is empty. The following examples illustrate some phenomena that do not occur in the complex setting.

(1.3) The algebraic curve

$$C := (x^4 - 2x^2 y - y^3 = 0) \subset \mathbb{R}^2$$

is irreducible and $\operatorname{Sing}(C) = \{(0,0)\}$. Actually, C is an analytic submanifold of $\mathbb{R}^2$.

(1.4) The algebraic curve

$$C := (x^3 - x^2 - y^2 = 0) \subset \mathbb{R}^2$$

is irreducible and $\operatorname{Sing}(C) = \{(0,0)\}$. It has two connected components, the singleton $\{(0,0)\}$ and the unbounded branch $C \setminus \{(0,0)\}$.

(1.5) The algebraic curve

$$C := (x^2(x^2 - 1)(x^2 - 4) + y^2 = 0) \subset \mathbb{R}^2$$

is irreducible and $\operatorname{Sing}(C) = \{(0,0)\}$. It has three connected components, the singleton $\{(0,0)\}$ and two ovals.

(1.6) The Cartan umbrella

$$S \coloneqq (x^3 - z(x^2 + y^2) = 0) \subset \mathbb{R}^3$$

is an irreducible algebraic surface with $\operatorname{Sing}(S) = (z\text{-axis})$. The surface S is connected and $S \setminus \operatorname{Sing}(S)$ is not dense in S. Furthermore, S is not coherent when regarded as an analytic subset of $\mathbb{R}^3$.

It will be convenient to consider regular functions in a more general setting than usual. Let $X \subset \mathbb{R}^n$ be an algebraic set and let $f: W \to \mathbb{R}$ be a function defined on some subset W of X. We say that f is *regular at a point* $x \in W$ if there exist two polynomial functions p, q on $\mathbb{R}^n$ such that $q(x) \neq 0$ and $f = p/q$ on $W \cap \{q \neq 0\}$. We say that f is a *regular function* if it is regular at each point of W. For any algebraic set $Y \subset \mathbb{R}^p$, a map $\varphi = (\varphi_1, \ldots, \varphi_p): W \to Y$ is *regular* if all the components $\varphi_i: W \to \mathbb{R}$ are regular functions. These notions are independent of the algebraic embeddings $X \subset \mathbb{R}^n$ and $Y \subset \mathbb{R}^p$.

Any rational function R on X determines a regular function $R: X \setminus \operatorname{Pole}(R) \to \mathbb{R}$, where $\operatorname{Pole}(R)$ stands for the polar set of R.

Contents. In Section 2 we recall briefly main facts about arc-symmetric sets and arc-analytic functions. These notions, introduced 30 years ago by the second-named author, describe some rigidity phenomena (of an analytic type) of real algebraic sets. They form a background for the subsequent sections in which we present recent developments in the context of rational functions.

Section 3 contains presentation of new results on the geometry defined by regulous functions, that is, continuous functions which admit a strong version of rational representation.

In Section 4 we recall some theorems on approximation of continuous maps with values in spheres by regular maps and give new results in which approximating maps are allowed to be regulous.

In Section 5 we discuss topological, algebraic and regulous vector bundles. Regulous vector bundles have many desirable properties of algebraic vector bundles but are more flexible.

2 Arc-symmetric sets and arc-analytic functions

Arc-symmetric sets and arc-analytic functions were introduced in Kurdyka [1988]. They were further investigated and applied in Adamus and Seyedinejad [2017], Bierstone and Milman [1990], Bierstone, Milman, and Parusiński [1991], Fichou [2005], Koike and

Parusiński [2003], Kucharz [2005], Kurdyka [1991, 1994, 1999], Kurdyka and Parusiński [2007, 2012], Kurdyka and Rusek [1988], McCrory and Parusiński [2003], Parusiński [1994, 2001, 2004], Parusiński and Păunescu [2017].

2.1 Arc-symmetric sets. We say that a subset $E \subset \mathbb{R}^n$ is *arc-symmetric* if for every analytic arc $\gamma\colon (-1,1) \to \mathbb{R}^n$ with $\gamma((-1,0)) \subset E$, we have $\gamma((-1,1)) \subset E$. We are mostly interested in semialgebraic arc-symmetric sets.

Recall that a topological space is called *Noetherian* if every descending chain of its closed subsets is stationary. In particular, $\mathbb{R}^n$ with the Zariski topology is a Noetherian topological space. In Kurdyka [1988], the following is proved.

Theorem 2.1. *The semialgebraic arc-symmetric subsets of $\mathbb{R}^n$ are precisely the closed sets of a certain Noetherian topology on $\mathbb{R}^n$.*

Following Kurdyka [ibid.], we call this topology on $\mathbb{R}^n$ the $\mathfrak{AR}$ *topology*. Thus a subset of $\mathbb{R}^n$ is $\mathfrak{AR}$-closed if and only if it is semialgebraic and arc-symmetric. It follows from the curve selection lemma that each $\mathfrak{AR}$-closed subset of $\mathbb{R}^n$ is closed (in the Euclidean topology), cf. Kurdyka [ibid.]. Clearly, any connected component of an $\mathfrak{AR}$-closed subset of $\mathbb{R}^n$ is also $\mathfrak{AR}$-closed. Furthermore, any irreducible analytic component of an algebraic subset of $\mathbb{R}^n$ is $\mathfrak{AR}$-closed. However, an $\mathfrak{AR}$-closed set need not be analytic at every point.

Example 2.2. The set

$$E = \{(x,y,z) \in \mathbb{R}^3 : x^3 - z(x^2+y^2) = 0,\ x^2+y^2 \neq 0\} \cup \{(0,0,0)\}$$

(the “cloth” of the Cartan umbrella (1.6)) is $\mathfrak{AR}$-closed, but it is not analytic at the origin of $\mathbb{R}^3$.

Given a semialgebraic subset $E \subset \mathbb{R}^n$, we say that a point $x \in E$ is *regular in dimension d* if for some open neighborhood $U_x \subset \mathbb{R}^n$ of x, the intersection $E \cap U_x$ is a d-dimensional analytic submanifold of U_x. We let $\mathrm{Reg}_d(E)$ denote the locus of regular points of E in dimension d. The dimension of E, written $\dim E$, is the maximum d with $\mathrm{Reg}_d(E)$ nonempty. If V is the Zariski closure of E in $\mathbb{R}^n$, then $\dim E = \dim V$, cf. Bochnak, Coste, and Roy [1998].

By a *resolution of singularities* of a real algebraic set X we mean a proper regular map $\pi : \tilde{X} \to X$ where $\tilde{X}$ is a smooth real algebraic set and π is birational.

The following is the key result of Kurdyka [1988].

Theorem 2.3. *Let $X \subset \mathbb{R}^n$ be a d-dimensional real algebraic set and let $E \subset \mathbb{R}^n$ be an $\mathfrak{AR}$-closed irreducible subset with $E \subset X$ and* $\dim E = d$. *If $\pi : \tilde{X} \to X$ is a resolution of singularities of X, then there exists a unique connected component $\tilde{E}$ of $\tilde{X}$ such that $\pi(\tilde{E})$ is the closure (in the Euclidean topology) of* $\mathrm{Reg}_d(E)$.

This is illustrated by an example below.

Example 2.4. The real cubic $C := (x^3 - x - y^2 = 0) \subset \mathbb{R}^2$ is smooth and irreducible. It has two connected components, C_1 which is compact and C_2 which is noncompact. Consider the cone $X := (x^3 - xz^2 - y^2 z = 0) \subset \mathbb{R}^3$ over C. Note that X is irreducible and $\operatorname{Sing}(X) = \{(0,0,0)\}$. Clearly,

$$\pi\colon \tilde{X} := C \times \mathbb{R} \to X, \quad (x, y, z) \mapsto (xz, yz, z)$$

is a resolution of singularities of X. The connected components $C_1 \times \mathbb{R}$ and $C_2 \times \mathbb{R}$ of $\tilde{X}$ correspond via π to the $\mathfrak{AR}$-irreducible components of X.

The notion of arc-symmetric set turns out to be related to a notion introduced by Nash in his celebrated paper Nash [1952]. We adapt his definition to the case of $\mathfrak{AR}$-closed sets.

Definition 2.5. Let E be an $\mathfrak{AR}$-closed subset of $\mathbb{R}^n$. We say that a subset $S \subset E$ is a (Nash) *sheet* of E if the following conditions are satisfied:

(i) for any two points x_0, x_1 in S there exists an analytic arc $\gamma\colon [0,1] \to \mathbb{R}^n$ with $\gamma(0) = x_0$, $\gamma(1) = x_1$, and $\gamma([0,1]) \subset S$;

(ii) S is maximal in the class of subsets satisfying the condition (i);

(iii) the interior of S in X is nonempty.

The following result of Kurdyka [1988] gives a positive and precise answer to Nash's conjecture on sheets of an algebraic set Nash [1952].

Theorem 2.6. *Let X be an algebraic subset or more generally an $\mathfrak{AR}$-closed subset of $\mathbb{R}^n$. Then:*

(i) *There are finitely many sheets in X.*

(ii) *Each sheet in X is semialgebraic and closed (in the Euclidean topology).*

(iii) *X is the union of its sheets.*

The proof of this theorem is based on Theorem 2.3 and the notion of *immersed component* of an $\mathfrak{AR}$-closed set. An immersed component of X is an $\mathfrak{AR}$-irreducible subset of X with nonempty interior in X. In general, X may have more immersed components than $\mathfrak{AR}$-irreducible components. For instance, the Whitney umbrella $(xy^2 - z^2 = 0) \subset \mathbb{R}^3$ is $\mathfrak{AR}$-irreducible, but it has two immersed components.

Compact $\mathfrak{AR}$-closed sets share with compact real algebraic sets all known local and global topological properties. In particular, each compact $\mathfrak{AR}$-closed set carries the mod 2 fundamental class. It is conjectured that any compact $\mathfrak{AR}$-closed set is semialgebraically homeomorphic to a real algebraic set.

Recall that a Nash manifold $X \subset \mathbb{R}^n$ is an analytic submanifold which is a semialgebraic set. Building on Thom's representability theorem Thom [1954] and Theorem 2.3, the following was established in Kucharz [2005].

Theorem 2.7. *Let $X \subset \mathbb{R}^n$ be a compact Nash manifold, and d an integer satisfying $0 \leq d \leq \dim X$. Then each homology class in $H_d(X;\mathbb{Z}/2)$ can be represented by an $\mathfrak{AR}$-closed subset of $\mathbb{R}^n$, contained in X.*

Now we recall a result of Kurdyka and Rusek [1988] which was motivated by the problem of surjectivity of injective selfmaps.

Theorem 2.8. *Let $X \subset \mathbb{R}^n$ be an $\mathfrak{AR}$-closed subset of dimension d, with $0 \leq d \leq n-1$. Then the homotopy group $\pi_{n-d-1}(\mathbb{R}^n \setminus X)$ is nontrivial.*

As demonstrated in Kurdyka and Rusek [ibid.], Theorem 2.8 implies the following result of Białynicki-Birula and Rosenlicht [1962].

Theorem 2.9. *Any injective polynomial map from $\mathbb{R}^n$ into itself is surjective.*

One should mention that Theorem 2.9, with $n = 2$, was established earlier by Newman [1960]. Ax [1969] proved that any injective regular map of a complex algebraic variety into itself is surjective. Ax's proof is based on the Lefschetz principle and a reduction to the finite field case. By extending the idea of Białynicki-Birula and Rosenlicht [1962], Borel [1969] gave a topological proof of Ax's theorem that works also for injective regular maps of a smooth real algebraic set into itself. Finally, combining Borel's argument with the geometry of $\mathfrak{AR}$-closed sets, the second-named author proved in Kurdyka [1999] the following.

Theorem 2.10. *Let X be a real algebraic set (possibly singular) and let $f : X \to X$ be an injective regular map. Then f is surjective.*

In fact, there is a more general version of Theorem 2.10 due to Parusiński [2004], cf. also Kurdyka and Parusiński [2007].

2.2 Arc-analytic maps. Let $X \subset \mathbb{R}^n$ and $Y \subset \mathbb{R}^p$ be some subsets. A map $f : X \to Y$ is said to be *arc-analytic* if for every analytic arc $\gamma : (-1,1) \to \mathbb{R}^n$ with $\gamma((-1,1)) \subset X$, the composite $f \circ \gamma : (-1,1) \to \mathbb{R}^p$ is an analytic map. We are mostly interested in the case where X and Y are $\mathfrak{AR}$-closed, and f is semialgebraic.

The function $f_k\colon \mathbb{R}^2 \to \mathbb{R}$ in (1.1) is arc-analytic and of class $\mathcal{C}^k$, but it is not of class $\mathcal{C}^{k+1}$. The following fact is recorded in Kurdyka [1988].

Proposition 2.11. *Let $X \subset \mathbb{R}^n$ and $Y \subset \mathbb{R}^p$ be $\mathcal{AR}$-closed subsets, and let $f\colon X \to Y$ be a semialgebraic arc-analytic map. Then:*

(i) *The graph of f is an $\mathcal{AR}$-closed subset of $\mathbb{R}^n \times \mathbb{R}^p$.*

(ii) *If $Z \subset Y$ is an $\mathcal{AR}$-closed set, then so is $f^{-1}(Z)$.*

(iii) *f is continuous (in the Euclidean topology).*

Arc-analytic functions do not have nice properties without some additional assumptions. For instance, an arc-analytic function on $\mathbb{R}^n$ need not be subanalytic Kurdyka [1991] or continuous Bierstone, Milman, and Parusiński [1991], and even for $n = 2$ it may have a nondiscrete singular set Kurdyka [1994].

In complex algebraic geometry, the image of an algebraic set by a proper regular map is again an algebraic set. This is trivially false in the real case; consider $\mathbb{R} \to \mathbb{R}$, $x \mapsto x^2$. There is also a more interesting example. Let

$$X := (x - y^2 - 1 = 0) \subset \mathbb{R}^2 \text{ and } Y := (x^3 - x^2 - y^2 = 0) \subset \mathbb{R}^2.$$

Then $f\colon X \to Y$, $(x, y) \mapsto (x, xy)$ is an injective, proper regular map. However, $f(X)$ is not an algebraic set. Therefore the following embedding theorem of Kurdyka [1988] is of interest.

Theorem 2.12. *Let $X \subset \mathbb{R}^n$ be an $\mathcal{AR}$-closed subset and let $f\colon X \to \mathbb{R}^p$ be a semialgebraic arc-analytic map that is injective and proper. Then $f(X) \subset \mathbb{R}^p$ is an $\mathcal{AR}$-closed subset.*

Given an $\mathcal{AR}$-closed subset $X \subset \mathbb{R}^n$, we denote by $\mathcal{A}_a(X)$ the ring of semialgebraic arc-analytic functions on X. According to Kurdyka [ibid.], the ring $\mathcal{A}_a(X)$ is not Noetherian if $\dim X \geq 2$. However, any ascending chain of prime ideals of $\mathcal{A}_a(X)$ is stationary. Furthermore, by Kurdyka [ibid.], there exists a function $f \in \mathcal{A}_a(\mathbb{R}^n)$ such that $X \subset f^{-1}(0)$ and $\dim(f^{-1}(0) \setminus X) < \dim X$. This latter result has been recently strengthened by Adamus and Seyedinejad [2017], who proved that actually $X = f^{-1}(0)$ for some $f \in \mathcal{A}_a(\mathbb{R}^n)$. This enabled them to obtain the Nullstellensatz for the ring $\mathcal{A}_a(X)$, generalizing thereby the weak Nullstellensatz of Kurdyka [1988].

2.3 Blow-Nash and blow-analytic functions.

Let X be a smooth real algebraic set. A *Nash function* on X is an analytic function which is semialgebraic. A function on X is said to be *blow-Nash* if it becomes a Nash function after composing with a finite sequence of blowups with smooth nowhere dense centers. It was conjectured by K. Kurdyka (1987) that a function is blow-Nash if and only if it is arc-analytic and semialgebraic. The first proof of this conjecture was published by Bierstone and Milman [1990]. They developed techniques which later turned out to be useful in their approach to the resolution of singularities Bierstone and Milman [1997]. There is also a second proof due to Parusiński [1994]. It is based on the rectilinearization theorem for subanalytic functions Parusiński [ibid.], which is a prototype of the preparation theorem for subanalytic functions, cf. for example Parusiński [2001].

Less is known on arc-analytic functions which are subanalytic. Any such function is continuous and can be made analytic after composing with finitely many local blowups with smooth centers, cf. Bierstone and Milman [1990] and Parusiński [1994]. It is not known whether one can use global blowups, that is, whether arc-analytic subanalytic functions coincide with *blow-analytic* functions of T. C. Kuo [1985], cf. also Fukui, Koike, and T.-C. Kuo [1998]. In Kurdyka and Parusiński [2012] it is proved that the locus of nonanalyticity of an arc-analytic subanalytic function is arc-symmetric and subanalytic. Another result of Kurdyka and Parusiński [ibid.] asserts that in the blow-Nash case, the centers of blowups can be chosen in the locus of nonanalyticity.

2.4 Some applications. Recently arc-symmetric sets were used in the construction of new invariants in the singularity theory. These invariants include the virtual Betti numbers of real algebraic sets McCrory and Parusiński [2003] and arc-symmetric sets Fichou [2005]. Other invariants, analogous to the zeta function of Denef and Loeser, proved to be useful in the classification of germs of functions with respect to blow-analytic and blow-Nash equivalence, cf. Koike and Parusiński [2003] and Fukui, Koike, and T.-C. Kuo [1998]. Arc-analytic homeomorphisms were recently used in Parusiński and Păunescu [2017] to construct nice trivializations in the stratification theory.

3 Regulous functions

3.1 Functions regular on smooth algebraic arcs. All results presented in this subsection come from our joint paper Kollár, Kucharz, and Kurdyka [2018].

Let X be a real algebraic set. A subset $A \subset X$ is called a *smooth algebraic arc* if its Zariski closure C is an irreducible algebraic curve, $A \subset C \setminus \operatorname{Sing}(C)$, and A is homeomorphic to $\mathbb{R}$.

An open subset $U \subset X$ is said to be *smooth* if it is contained in $X \setminus \operatorname{Sing}(X)$.

Theorem 3.1. *Let X be a real algebraic set and let $f : U \to \mathbb{R}$ be a function defined on a connected smooth open subset $U \subset X$. Assume that the restriction of f is regular on* *each smooth algebraic arc contained in* U. *Then there exists a rational function* R *on* X *such that* $P := U \cap \operatorname{Pole}(R)$ *has codimension at least* 2 *and* $f|_{U\setminus P} = R|_{U\setminus P}$.

There are two main steps in the proof of Theorem 3.1. Assuming that f is a semialgebraic function (so U is a semialgebraic set), one first obtains a local variant of the assertion by means of Bertini's theorem, and then extends it along smooth algebraic arcs. The general case is reduced to the semialgebraic one via some subtle Hartogs-like results on analytic functions due to Błocki [1992] and Siciak [1990].

A function regular on smooth algebraic arcs need not be continuous.

Example 3.2. The function $f : \mathbb{R}^2 \to \mathbb{R}$ defined by

$$f(x,y) = \frac{x^8 + y(x^2 - y^3)^2}{x^{10} + (x^2 - y^3)^2} \text{ for } (x,y) \neq (0,0) \text{ and } f(0,0) = 0$$

is regular on each smooth algebraic arc in $\mathbb{R}^2$, but it is not locally bounded on the curve $x^2 - y^3 = 0$.

Let $X = X_1 \times \cdots \times X_n$ be the product of real algebraic sets and let $\pi_i : X \to X_i$ be the projection on the ith factor. A subset $K \subset X$ is said to be *parallel to the* i*th factor of* X if $\pi_j(K)$ consists of one point for each $j \neq i$.

Theorem 3.3. *Let* $X = X_1 \times \cdots \times X_n$ *be the product of real algebraic sets and let* $f : U \to \mathbb{R}$ *be a function defined on a connected smooth open subset* $U \subset X$. *Assume that the restriction of* f *is regular on each smooth algebraic arc contained in* U *and parallel to one of the factors of* X. *Then there exists a rational function* R *on* X *such that* $P := U \cap \operatorname{Pole}(R)$ *has codimension at least* 2 *and* $f|_{U\setminus P} = R|_{U\setminus P}$.

Theorem 3.3, for $n = 1$, coincides with Theorem 3.1. The general case is proved by induction on n, but a detailed argument is fairly long.

As a direct consequence, we get the following.

Corollary 3.4. *Let* $f : U \to \mathbb{R}$ *be a function defined on a connected open subset* $U \subset \mathbb{R}^n$. *Assume that the restriction of* f *is regular on each open interval contained in* U *and parallel to one of the coordinate axes. Then there exists a rational function* R *on* $\mathbb{R}^n$ *such that* $P := U \cap \operatorname{Pole}(R)$ *has codimension at least* 2 *and* $f|_{U\setminus P} = R|_{U\setminus P}$.

Results similar to Corollary 3.4 have been known earlier, but they were obtained under the restrictive assumption that f is an analytic function on U, cf. Bochner and Martin [1948].

3.2 Introducing regulous functions. Let X be a real algebraic set, $f : W \to \mathbb{R}$ a function defined on some subset $W \subset X$, and Y the Zariski closure of W in X.

Definition 3.5. A rational function R on Y is said to be a *rational representation* of f if there exists a Zariski open dense subset $Y^0 \subset Y \setminus \operatorname{Pole}(R)$ such that $f|_{W \cap Y^0} = R|_{W \cap Y^0}$.

While the definition makes sense for an arbitrary subset W, it is sensible only if W contains a sufficiently large portion of Y. The key examples of interest are open subsets and semialgebraic subsets, with $W = X$ being the most important case.

One readily checks that the following conditions are equivalent:

(3.6) For every algebraic subset $Z \subset X$ the restriction $f|_{W \cap Z}$ has a rational representation.

(3.7) There exists a sequence of algebraic subsets

$$X = X_0 \supset X_1 \supset \cdots \supset X_{m+1} = \varnothing$$

such that the restriction of f is regular on $W \cap (X_i \setminus X_{i+1})$ for $i = 0, \dots, m$.

(3.8) There exists a finite stratification $\mathcal{S}$ of X, with Zariski locally closed strata, such that the restriction of f is regular on $W \cap S$ for every $S \in \mathcal{S}$.

Definition 3.9. We say that f is a *regulous function* if it is continuous and the equivalent conditions (3.6), (3.7), (3.8) are satisfied.

In some papers, regulous functions are called *hereditarily rational* Kollár, Kucharz, and Kurdyka [2018] and Kollár and Nowak [2015] or *stratified-regular* Kucharz [2015b], Kucharz and Kurdyka [2016b, 2015], and Zieliński [2016]. The short name "regulous", derived from "regular" and "continuous", was introduced in Fichou, Huisman, Mangolte, and Monnier [2016]. A continuous function that has a rational representation is often called simply a *continuous rational function* Kollár, Kucharz, and Kurdyka [2018], Kollár and Nowak [2015], Kucharz [2009, 2013b, 2014b,a, 2016a], and Kucharz and Kurdyka [2016a, 2017].

Evidently, any regulous function is continuous and has a rational representation. The converse holds in an important special case.

Proposition 3.10. *Let X be a real algebraic set and let $W \subset X$ be a smooth open subset. For a function $f : W \to \mathbb{R}$, the following conditions are equivalent:*

(a) *f is regulous.*

(b) *f is continuous and has a rational representation.*

The nontrivial implication (b)⇒(a) is proved in Kollár and Nowak [2015]. Suppose that (b) holds, and let R be a rational representation of f. Since f is continuous and W

is smooth, one gets $f|_{W\setminus P} = R|_{W\setminus P}$, where $P = W \cap \operatorname{Pole}(R)$. Furthermore, it is not hard to see that P has codimension at least 2. Finally, condition (3.6) can be verified by induction on $\operatorname{codim} Z$.

As demonstrated in Kollár and Nowak [ibid.] and recalled below, the smoothness assumption in Proposition 3.10 cannot be dropped.

Example 3.11. Consider the algebraic surface

$$S := (x^3 - (1+z^2)y^3 = 0) \subset \mathbb{R}^3$$

and the function $f : S \to \mathbb{R}$ defined by $f(x,y,z) = (1+z^2)^{1/3}$. Note that $\operatorname{Sing}(S) =$ z-axis and $f(x,y,z) = x/y$ on $S \setminus (z\text{-axis})$. In particular, f is continuous and has a rational representation. However, f is not regulous since $f|_{z\text{-axis}}$ does not have a rational representation. It is also interesting that S is an analytic submanifold of $\mathbb{R}^3$.

The main result of Kollár and Nowak [ibid.] can be stated as follows.

Theorem 3.12. *Let X be a smooth real algebraic set and let $f : W \to \mathbb{R}$ be a function defined on an algebraic subset $W \subset X$. Then the following conditions are equivalent:*

(a) *f is regulous.*

(b) *$f = \tilde{f}|_W$, where $\tilde{f} : X \to \mathbb{R}$ is a continuous function that has a rational representation.*

The proof of (a)⇒(b) by induction on $\dim W$ is tricky. Roughly speaking, one first finds a function on X that extends f and has a rational representation. However, such an extension may not be continuous and has to be corrected. This is achieved by analyzing liftings of functions to the blowup of X at a suitably chosen ideal. The argument relies on a version of the Łojasiewicz inequality given in Bochnak, Coste, and Roy [1998, Theorem 2.6.6].

The implication (b)⇒(a) follows from Proposition 3.10.

As it was noted on various occasions (see for example Kucharz [2009, p. 528] or Fichou, Huisman, Mangolte, and Monnier [2016, Théorème 3.11]), Hironaka's theorem on resolution of indeterminacy points Hironaka [1964] implies immediately the following.

Proposition 3.13. *Let X be a smooth real algebraic set. For a function $f : X \to \mathbb{R}$, the following conditions are equivalent:*

(a) *f is continuous and has a rational representation.*

(b) *There exists a regular map $\pi : X' \to X$, which is the composite of a finite sequence of blowups with smooth Zariski nowhere dense centers, such that the function $f \circ \pi : X' \to \mathbb{R}$ is regular.*

Fefferman and Kollár [2013] study the following problem. Consider a linear equation

$$f_1 y_1 + \cdots + f_r y_r = g,$$

where g and the f_i are regular (or polynomial) functions on $\mathbb{R}^n$. Assume that it admits a solution where the y_i are continuous functions on $\mathbb{R}^n$. Then, according to Fefferman and Kollár [ibid., Section 2], it has also a continuous semialgebraic solution. One could hope to prove that it has a regulous solution. This is indeed the case for $n = 2$ Kucharz and Kurdyka [2017, Corollary 1.7], but fails for any $n \geq 3$ Kollár and Nowak [2015, Example 6]. It would be interesting to decide which linear equations have regulous solutions. Of course, the problem can be considered in a more general setting, replacing $\mathbb{R}^n$ by a real algebraic set.

3.3 Curve-regulous and arc-regulous functions.

All results discussed in this subsection come from our joint paper Kollár, Kucharz, and Kurdyka [2018], where it is proved that regulous functions can be characterized by restrictions to algebraic curves or algebraic arcs.

Definition 3.14. Let X be a real algebraic set and let $f : W \to \mathbb{R}$ be a function defined on some subset $W \subset X$.

We say that f is *regulous on algebraic curves* or *curve-regulous* for short if for every irreducible algebraic curve $C \subset X$ the restriction $f|_{W \cap C}$ is regulous (equivalently, $f|_{W \cap C}$ is continuous and has a rational representation).

Furthermore, we say that f is *regulous on algebraic arcs* or *arc-regulous* for short if for every irreducible algebraic curve $C \subset X$ and every point $x \in W \cap C$ there exists an open neighborhood $U_x \subset W$ of x such that the restriction $f|_{U_x \cap C}$ is regulous (equivalently, $f|_{U_x \cap C}$ is continuous and has a rational representation).

Obviously, any curve-regulous function is arc-regulous. The converse does not hold for a rather obvious reason. For instance, consider the hyperbola $H \subset \mathbb{R}^2$ defined by $xy - 1 = 0$. Any function on H that is constant on each connected component of H is arc-regulous, but it must be constant to be regulous.

In Kollár, Kucharz, and Kurdyka [ibid.], curve-regulous (resp. arc-regulous) functions are called *curve-rational* (resp. *arc-rational*).

Our main result on curve-regulous functions is the following.

Theorem 3.15. *Let X be a real algebraic set and let $W \subset X$ be a subset that is either open or semialgebraic. For a function $f : W \to \mathbb{R}$, the following conditions are equivalent:*

(a) *f is regulous.*

(b) *f is curve-regulous.*

The corresponding result for arc-regulous functions takes the following form.

Theorem 3.16. *Let X be a real algebraic set and let $W \subset X$ be a connected smooth open subset. For a function $f : W \to \mathbb{R}$, the following conditions are equivalent:*

(a) *f is regulous.*

(b) *f is arc-regulous.*

The crucial ingredient in the proofs of Theorems 3.15 and 3.16 is Theorem 3.1. In both cases, only the implication (b)⇒(a) is not obvious. It is essential that testing curves and arcs are allowed to have singularities.

The main properties of arc-regulous functions on semialgebraic sets can be summarized as follows.

Theorem 3.17. *Let X be a real algebraic set and let $f : W \to \mathbb{R}$ be an arc-regulous function defined on a semialgebraic subset $W \subset X$. Then f is continuous and there exists a sequence of semialgebraic sets*

$$W = W_0 \supset W_1 \supset \cdots \supset W_{m+1} = \varnothing,$$

which are closed in W, such that the restriction of f is a regular function on each connected component of $W_i \setminus W_{i+1}$ for $i = 0, \ldots, m$. In particular, f is a semialgebraic function.

We also establish a connection between arc-regulous functions and, discussed in Section 2, arc-analytic functions.

Theorem 3.18. *Let X be a real algebraic set and let $f : W \to \mathbb{R}$ be an arc-regulous function defined on an open subset $W \subset X$. Then f is continuous and arc-analytic.*

In Kollár, Kucharz, and Kurdyka [ibid.] there are several other related results.

3.4 Constructible topology and k-regulous functions. We consider regulous functions of class $\mathcal{C}^k$.

Definition 3.19. Let X be a smooth real algebraic set and let $f : U \to \mathbb{R}$ be a function defined on an open subset $U \subset X$.

We say that f is a *k-regulous* function, where k is a nonnegative integer, if it is of class $\mathcal{C}^k$ and regulous; or equivalently, by Proposition 3.10, if it is of class $\mathcal{C}^k$ and has a rational representation.

The set $\mathcal{R}^k(U)$ of all k-regulous functions on U forms a ring. An example of a k-regulous function on $\mathbb{R}^2$ is provided by (1.1).

A function on U which is of class $\mathcal{C}^\infty$ and regulous is actually regular, cf. Kucharz [2009]. Therefore one gains no new insight by considering such functions.

All results discussed in the remainder of this subsection come from the paper of Fichou, Huisman, Mangolte, and Monnier [2016], where they are stated for functions defined on $\mathbb{R}^n$. The ring $\mathcal{R}^k(\mathbb{R}^n)$ is not Noetherian if $n \geq 2$. Nevertheless it has some remarkable properties.

Given a collection F of real-valued functions on $\mathbb{R}^n$, we set

$$Z(F) := \{x \in \mathbb{R}^n : f(x) = 0 \text{ for all } f \in F\}$$

and write $Z(f)$ for $Z(F)$ if $F = \{f\}$.

The following is a variant of the classical Nullstellensatz for the ring $\mathcal{R}^k(\mathbb{R}^n)$.

Theorem 3.20. *Let I be an ideal of the ring $\mathcal{R}^k(\mathbb{R}^n)$. If a function f in $\mathcal{R}^k(\mathbb{R}^n)$ vanishes on $Z(I)$, then f^m belongs to I for some positive integer m.*

Recall that the Nullstellensatz for the ring of polynomial or regular functions on $\mathbb{R}^n$ requires an entirely different formulation, cf. Bochnak, Coste, and Roy [1998].

The subsets of $\mathbb{R}^n$ of the form $Z(I)$ for some ideal I of $\mathcal{R}^k(\mathbb{R}^n)$ can be characterized in terms of constructible sets. A subset of $\mathbb{R}^n$ is said to be *constructible* if it belongs to the Boolean algebra generated by the algebraic subsets of $\mathbb{R}^n$; or equivalently if it is a finite union of Zariski locally closed subsets of $\mathbb{R}^n$.

Theorem 3.21. *For a subset $E \subset \mathbb{R}^n$, the following conditions are equivalent:*

(a) *$E = Z(I)$ for some ideal I of $\mathcal{R}^k(\mathbb{R}^n)$.*

(b) *$E = Z(f)$ for some function f in $\mathcal{R}^k(\mathbb{R}^n)$.*

(c) *E is closed and constructible.*

Theorem 3.21 can be illustrated as follows.

Example 3.22. Consider the Cartan umbrella $S \subset \mathbb{R}^3$ defined in (1.6), and let E be the closure of $S \setminus (z\text{-axis})$. It is clear that E is a closed constructible set. Moreover, $E = Z(f)$, where $f : \mathbb{R}^3 \to \mathbb{R}$ is the regulous function defined by

$$f(x, y, z) = z - \frac{x^3}{x^2 + y^2} \text{ on } \mathbb{R}^3 \setminus (z\text{-axis}) \text{ and } f(x, y, z) = z \text{ on the } z\text{-axis}.$$

The collection of all closed constructible subsets of $\mathbb{R}^n$ forms the family of closed subsets for a Noetherian topology on $\mathbb{R}^n$, called the *constructible topology*. Any subset of $\mathbb{R}^n$ which is constructible-closed is actually $\mathcal{AR}$-closed. The converse does not hold if $n \geq 2$.

In what follows we consider $\mathbb{R}^n$ endowed with the constructible topology. The assignment $\mathcal{R}^k : U \mapsto \mathcal{R}^k(U)$, where U runs through the open subsets of $\mathbb{R}^n$, is a sheaf of rings on $\mathbb{R}^n$, and $(\mathbb{R}^n, \mathcal{R}^k)$ is a locally ringed space. Sheaves of $\mathcal{R}^k$-modules on $\mathbb{R}^n$ are called *k-regulous sheaves*.

It follows from Theorem 3.20 that the ringed space $(\mathbb{R}^n, \mathcal{R}^k)$ carries essentially the same information as the affine scheme $\operatorname{Spec}(\mathcal{R}^k(\mathbb{R}^n))$. In particular, Cartan's theorems A and B are available for k-regulous sheaves.

Theorem 3.23. *For any quasi-coherent k-regulous sheaf $\mathcal{F}$ on $\mathbb{R}^n$, the following hold:*

(A) *$\mathcal{F}$ is generated by global sections.*

(B) *$H^i(\mathbb{R}^n, \mathcal{F}) = 0$ for $i \geq 1$.*

As is well-known, Cartan's theorems A and B fail for coherent algebraic sheaves on $\mathbb{R}^n$.

Let $V \subset \mathbb{R}^n$ be a constructible-closed subset. The sheaf $\mathcal{J}_V \subset \mathcal{R}^k$ of ideals of k-regulous functions vanishing on V is a quasi-coherent k-regulous sheaf on $\mathbb{R}^n$, and the quotient sheaf $\mathcal{R}^k/\mathcal{J}_V$ has support V. Endow V with the induced (constructible) topology, and let $\mathcal{R}^k_V$ be the restriction of the sheaf $\mathcal{R}^k_V/\mathcal{J}_V$ to V. The locally ringed space $(V, \mathcal{R}^k_V)$ is called a *closed k-regulous subvariety of* $(\mathbb{R}^n, \mathcal{R}^k)$. One can consider k-regulous sheaves on V, which are just sheaves of $\mathcal{R}^k_V$-modules. By a standard argument, Theorem 3.23 implies that Cartan's theorems A and B hold also for quasi-coherent k-regulous sheaves on V.

An *affine k-regulous variety* is a locally ringed space isomorphic to a closed k-regulous subvariety of $\mathbb{R}^n$ for some n. An *abstract k-regulous variety* can be defined in the standard way. The geometry of k-regulous varieties is to be developed.

4 Homotopy and approximation

In this section we discuss some homotopy and approximation results in the framework of real algebraic geometry, focusing on maps with values in the unit p-sphere

$$\mathbb{S}^p = (u_0^2 + \cdots + u_p^p - 1 = 0) \subset \mathbb{R}^{p+1}.$$

Approximation of continuous maps means approximation in the compact-open topology.

4.1 Approximation by regular maps. The theory of regular maps between real algebraic sets was developed by J. Bochnak and the first-named author Bochnak and Kucharz

[1987a,b, 1988, 1989b, 1991b, 1993, 1999, 2007] who joined forces with R. Silhol working on Bochnak, Kucharz, and Silhol [1997]. Regular maps are studied also in Ghiloni [2006, 2007], Joglar-Prieto and Mangolte [2004], Kucharz [2010, 2013a, 2015a], Loday [1973], Ozan [1995], Peng and Tang [1999], Turiel [2007], and Wood [1968]. We make no attempt to survey this theory, but give instead a sample of results that motivated later work described in the next subsection.

Problem 4.1. Let X be a compact real algebraic set. For a continuous map

$$f : X \to \mathbb{S}^p,$$

consider the following questions:

(i) Is f homotopic to a regular map?

(ii) Can f be approximated by regular maps?

It is expected that questions (i) and (ii) are equivalent, however, the proof is available only for special values of p, cf. Bochnak and Kucharz [1987a].

Theorem 4.2. *Let X be a compact real algebraic set. For a continuous map*

$$f : X \to \mathbb{S}^p,$$

where $p \in \{1, 2, 4\}$, the following conditions are equivalent:

(a) *f is homotopic to a regular map.*

(b) *f can be approximated by regular maps.*

Basic topological properties of regular maps between unit spheres still remain mysterious.

Conjecture 4.3. *For any pair (n, p) of positive integers, the following assertions hold:*

(i) *Each continuous map from $\mathbb{S}^n$ into $\mathbb{S}^p$ is homotopic to a regular map.*

(ii) *Each continuous map from $\mathbb{S}^n$ into $\mathbb{S}^p$ can be approximated by regular maps.*

Conjecture 4.3 (i) is known to be true in several cases Bochnak, Coste, and Roy [1998], Bochnak and Kucharz [1987a,b], Peng and Tang [1999], Turiel [2007], and Wood [1968]; for example if $n = p$ or $(n, p) = (2q + 14, 2q + 1)$ with $q \geq 7$.

Conjecture 4.3 (ii) holds if either $n < p$ (trivial) or $p \in \{1, 2, 4\}$ Bochnak and Kucharz [1987a]. Nothing is known for other pairs (n, p).

However, a complete solution to Problem 4.1 is known in several cases. The simplest one, noted in Bochnak and Kucharz [ibid.], is the following.

Proposition 4.4. *Let X be a compact smooth real algebraic curve. Then each continuous map from X into $\mathbb{S}^1$ can be approximated by regular maps.*

Going beyond curves is a lot harder. Nevertheless, it can happen also in higher dimension that the behavior of regular maps is determined entirely by the topology of the real algebraic sets involved.

Consider a compact $\mathcal{C}^\infty$ manifold M. A smooth real algebraic set diffeomorphic to M is called an *algebraic model* of M. By the Nash–Tognoli theorem Nash [1952] and Tognoli [1973], M has algebraic models. Actually, according to Bochnak and Kucharz [1991a], there exists an uncountable family of pairwise birationally nonequivalent algebraic models of M, provided that $\dim M \geq 1$. If $\dim M \leq 2$, the existence of algebraic models of M follows easily from the well-known classification of such manifolds. As X runs through the class of all algebraic models of M, the topological properties of regular maps from X into $\mathbb{S}^p$ may vary; this phenomenon is extensively investigated in Bochnak and Kucharz [1987b, 1988, 1989b, 1990, 1993] and Kucharz [2010].

A detailed study of regular maps into $\mathbb{S}^1$ is contained in Bochnak and Kucharz [1989b] where in particular the following result is proved.

Theorem 4.5. *Let M be a compact $\mathcal{C}^\infty$ manifold. Then there exists an algebraic model X of M such that each continuous map from X into $\mathbb{S}^1$ can be approximated by regular maps.*

For simplicity, we state the next result of Bochnak and Kucharz [ibid.] only for surfaces.

Theorem 4.6. *Let M be a connected, compact $\mathcal{C}^\infty$ surface. Then the following conditions are equivalent:*

(a) *For any algebraic model X of M, each continuous map from X into $\mathbb{S}^1$ can be approximated by regular maps.*

(b) *M is homeomorphic to the unit 2-sphere or the real projective plane or the Klein bottle.*

In Bochnak and Kucharz [1987b], one finds the following.

Theorem 4.7. *Let M be a compact $\mathcal{C}^\infty$ manifold of dimension p. Then there exists an algebraic model X of M such that each continuous map from X into $\mathbb{S}^p$ is homotopic to a regular map.*

Theorem 4.7, for $p = 1$, is of course weaker than Proposition 4.4. The cases $p = 2$ and $p = 4$ are of particular interest in view of Theorem 4.2.

Numerous results on algebraic models and regular maps into even-dimensional spheres are included in Bochnak and Kucharz [1988, 1990, 1993] and Kucharz [2010]. The following comes from Bochnak and Kucharz [1988].

Theorem 4.8. *Let M be a connected, compact $\mathcal{C}^\infty$ surface. Then the following conditions are equivalent:*

(a) *For any algebraic model X of M, each continuous map from X into $\mathbb{S}^2$ can be approximated by regular maps.*

(b) *M is nonorientable of odd genus.*

The true complexity of Problem 4.1 becomes apparent for surfaces of other types.

Consider smooth cubic curves in $\mathbb{P}^2(\mathbb{R})$. Each such cubic is either connected or has two connected components, and its Zariski closure in $\mathbb{P}^2(\mathbb{C})$ is also smooth. If C_1 and C_2 are smooth cubic curves in $\mathbb{P}^2(\mathbb{R})$, then $C_1 \times C_2$ can be oriented in such a way that for each regular map $\varphi\colon C_1 \times C_2 \to \mathbb{S}^2$, the topological degree $\deg(\varphi|_A)$ of the restriction of φ to a connected component A of $C_1 \times C_2$ does not depend on the choice of A. Moreover, the set

$$\mathrm{Deg}_{\mathcal{R}}(C_1, C_2) := \{m \in \mathbb{Z} \colon m = \deg(\psi|_A) \text{ for some regular map } \psi\colon C_1 \times C_2 \to \mathbb{S}^2\}$$

is a subgroup of $\mathbb{Z}$. These assertions are proved in Bochnak and Kucharz [1993, Theorem 3.1]. Define $b(C_1, C_2)$ to be the unique nonnegative integer satisfying

$$\mathrm{Deg}_{\mathcal{R}}(C_1, C_2) = b(C_1, C_2)\mathbb{Z}.$$

According to Hopf's theorem and Theorem 4.2, a continuous map $f\colon C_1 \times C_2 \to \mathbb{S}^2$ is homotopic to a regular map (or equivalently can be approximated by regular maps) if and only if for every connected component A of $C_1 \times C_2$, one has $\deg(f|_A) = b(C_1, C_2)r$ for some integer r independent of A. Thus, in this context, Problem 4.1 is reduced to the computation of the numerical invariant $b(C_1, C_2)$.

For any real number α in $\mathbb{R}^* := \mathbb{R} \setminus \{0\}$, set

$$\tau_\alpha = \frac{1}{2}(1 + \alpha\sqrt{-1}) \text{ if } \alpha > 0 \text{ and } \tau_\alpha = \alpha\sqrt{-1} \text{ if } \alpha < 0.$$

The lattice $\Lambda_\alpha := \mathbb{Z} + \mathbb{Z}\tau_\alpha$ in $\mathbb{C}$ is stable under complex conjugation. Hence the numbers

$$g_2(\tau_\alpha) = 60 \sum_\omega \omega^{-4}, \quad g_3(\tau_\alpha) = 140 \sum_\omega \omega^{-6}$$

(summation over $\omega \in \Lambda_\alpha \setminus \{0\}$) are real and

$$D_\alpha := \{(x : y : z) \in \mathbb{P}^2(\mathbb{R}) \colon y^2 z = 4x^3 - g_2(\tau_\alpha)xz^2 - g_3(\tau_\alpha)z\}$$

is a smooth cubic curve in $\mathbb{P}^2(\mathbb{R})$. Each smooth cubic curve in $\mathbb{P}^2(\mathbb{R})$ is biregularly isomorphic to exactly one cubic D_α. Thus $\mathbb{R}^*$ can be regarded as a moduli space of smooth cubic curves in $\mathbb{P}^2(\mathbb{R})$. For $\alpha > 0$ (resp. $\alpha < 0$) the cubic D_α is connected (resp. has two connected components).

The invariant $b(D_{\alpha_1}, D_{\alpha_2})$ is explicitly computed in Bochnak and Kucharz [ibid.] for all pairs (α_1, α_2). In particular, it can take any nonnegative integer value. We recall only two cases.

First we deal with generic pairs (α_1, α_2).

Theorem 4.9. *For (α_1, α_2) in $\mathbb{R}^* \times \mathbb{R}^*$, the following conditions are equivalent:*

(a) *Each regular map from $D_{\alpha_1} \times D_{\alpha_2}$ into $\mathbb{S}^2$ is null homotopic.*

(b) $b(D_{\alpha_1}, D_{\alpha_2}) = 0$.

(c) *The product $\alpha_1\alpha_2$ is an irrational number.*

From the viewpoint of approximation, the following case is of greatest interest.

Theorem 4.10. *For (α_1, α_2) in $\mathbb{R}^* \times \mathbb{R}^*$, the following conditions are equivalent:*

(a) *Each continuous map from $D_{\alpha_1} \times D_{\alpha_2}$ into $\mathbb{S}^2$ can be approximated by regular maps.*

(b) $\alpha_1 > 0$, $\alpha_2 > 0$, *and* $b(D_{\alpha_1}, D_{\alpha_2}) = 1$.

(c) $\alpha_i = (p_i/q_i)\sqrt{d}$ *for* $i = 1, 2$, *where* p_i, q_i, d *are positive integers,* p_i *and* q_i *are relatively prime,* d *is square free,* $d \equiv 3 \pmod 4$, $p_1p_2q_1q_2 \equiv 1 \pmod 2$, *and* p_1p_2d *is divisible by* q_1q_2.

Theorems 4.9 and 4.10 show that a small perturbation of (α_1, α_2) can drastically change topological properties of regular maps from $D_{\alpha_1} \times D_{\alpha_2}$ into $\mathbb{S}^2$. Thus, in general, one cannot hope to find a comprehensive solution to Problem 4.1, even for X smooth with $\dim X = p$. It is therefore desirable to introduce maps which have good features of regular maps but are more flexible.

4.2 Approximation by regulous maps. Let X and $Y \subset \mathbb{R}^q$ be smooth real algebraic sets, and let k be a nonnegative integer. A map $f = (f_1, \dots, f_q) \colon X \to Y$ is said to be *k-regulous* if its components $f_i : X \to \mathbb{R}$ are k-regulous functions; 0-regulous maps are called *regulous*.

If f is a regulous map, we denote by $P(f)$ the smallest algebraic subset of X such that $f|_{X \setminus P(f)} \colon X \setminus P(f) \to Y$ is a regular map. Obviously, $P(f)$ is Zariski nowhere dense in X. We say that f is *nice* if $f(P(f)) \neq Y$.

We state the next result for $\mathcal{C}^\infty$ maps. This is convenient since such maps have regular values by Sard's theorem.

Theorem 4.11. *Let X be a compact smooth real algebraic set, $f : X \to \mathbb{S}^p$ a $\mathcal{C}^\infty$ map with $p \geq 1$, and $y \in \mathbb{S}^p$ a regular value of f. Assume that the $\mathcal{C}^\infty$ submanifold $f^{-1}(y)$ of X is isotopic to a smooth Zariski locally closed subset of X. Then:*

(i) *f is homotopic to a nice k-regulous map, where k is an arbitrary nonnegative integer.*

(ii) *f can be approximated by nice regulous maps.*

Theorem 4.11 is due to the first-named author. Part (i) is a simplified version of Kucharz [2009, Theorem 2.4]. The proof is based on the Pontryagin construction (framed cobordism), Łojasiewicz inequality, and Hironaka's resolution of singularities. In turn (ii) follows from Kucharz [2014a, Theorem 1.2] since, by Kucharz [1985, Theorem 2.1], $f^{-1}(y)$ can be approximated by smooth Zariski locally closed subsets of X.

Theorem 4.11 provides information also on continuous maps since they can be approximated by $\mathcal{C}^\infty$ maps.

According to Akbulut and King [1992, Theorem A], any compact $\mathcal{C}^\infty$ submanifold of $\mathbb{R}^n$ (resp. $\mathbb{S}^n$) is isotopic to a smooth Zariski locally closed subset of $\mathbb{R}^n$ (resp. $\mathbb{S}^n$). In particular, Theorem 4.11 yields the following.

Corollary 4.12. *Let (n, p) be a pair of positive integers. Then:*

(i) *Each continuous map from $\mathbb{S}^n$ into $\mathbb{S}^p$ is homotopic to a nice k-regulous map, where k is an arbitrary nonnegative integer.*

(ii) *Each continuous map from $\mathbb{S}^n$ into $\mathbb{S}^p$ can be approximated by nice regulous maps.*

With notation as in Theorem 4.11 we have $\dim f^{-1}(y) = \dim X - p$. Hence we get immediately the following.

Corollary 4.13. *Let X be a compact smooth real algebraic set of dimension p. Then:*

(i) *Each continuous map from X into $\mathbb{S}^p$ is homotopic to a nice k-regulous map, where k is an arbitrary nonnegative integer.*

(ii) *Each continuous map from X into $\mathbb{S}^p$ can be approximated by nice regulous maps.*

Comparing Theorems 4.8, 4.9 and 4.10 with Corollary 4.13 we see that k-regulous maps are indeed more flexible than regular ones. However, for each integer $p \geq 1$ there exist a compact smooth real algebraic set Y and a continuous map $g : Y \to \mathbb{S}^p$ such that $\dim Y = p + 1$ and g is not homotopic to any regulous map, cf. Kucharz and Kurdyka [2016b, Theorem 7.9]. In particular, Theorem 4.11 does not hold without some assumption on the $\mathcal{C}^\infty$ submanifold $f^{-1}(y) \subset X$. It would be very useful to formulate an appropriate assumption in terms of bordism. This is related to a certain conjecture, which has nothing to do with regulous maps and originates from the celebrated paper of Nash [1952] and the subsequent developments due to Tognoli [1973], Akbulut and King [1992], and other mathematicians.

For a real algebraic set X, a bordism class in the unoriented bordism group $\mathfrak{N}_*(X)$ is said to be *algebraic* if it can be represented by a regular map from a compact smooth real algebraic set into X.

Conjecture 4.14. *For any smooth real algebraic set X, the following holds: If M is a compact $\mathcal{C}^\infty$ submanifold of X and the unoriented bordism class of the inclusion map $M \hookrightarrow X$ is algebraic, then M is ε-isotopic to a smooth Zariski locally closed subset of X.*

Here "ε-isotopic" means isotopic via a $\mathcal{C}^\infty$ isotopy that can be chosen arbitrarily close, in the $\mathcal{C}^\infty$ topology, to the inclusion map. A slightly weaker assertion than the one in Conjecture 4.14 is known to be true: If the unoriented bordism class of the inclusion map $M \hookrightarrow X$ is algebraic, then the $\mathcal{C}^\infty$ submanifold $M \times \{0\}$ of $X \times \mathbb{R}$ is ε-isotopic to a smooth Zariski locally closed subset of $X \times \mathbb{R}$, cf. Akbulut and King [ibid., Theorem F].

Remark 4.15. Let X be a compact smooth real algebraic set and let $f : X \to \mathbb{S}^p$ be a continuous map. According to Kucharz and Kurdyka [2016a, Proposition 1.4], if Conjecture 4.14 holds, then the following conditions are equivalent:

(a) f is homotopic to a nice regulous map.

(b) f can be approximated by nice regulous maps.

Using a method independent of Conjecture 4.14, the first-named author proved in Kucharz [2016a] the following weaker result.

Theorem 4.16. *Let X be a compact smooth real algebraic set and let p be an integer satisfying* $\dim X + 3 \leq 2p$. *For a continuous map $f : X \to \mathbb{S}^p$, the following conditions are equivalent:*

(a) *f is homotopic to a nice regulous map.*

(b) *f can be approximated by nice regulous maps.*

Other results on topological properties of regulous maps can be found in Kucharz [2013b, 2014b, 2016a], Kucharz and Kurdyka [2016b], and Zieliński [2016].

5 Vector bundles

Let $\mathbb{F}$ stand for $\mathbb{R}$, $\mathbb{C}$ or $\mathbb{H}$ (the quaternions). We consider only left $\mathbb{F}$-vector spaces. When convenient, $\mathbb{F}$ will be identified with $\mathbb{R}^{d(\mathbb{F})}$, where $d(\mathbb{F}) = \dim_{\mathbb{R}} \mathbb{F}$.

5.1 Algebraic versus topological vector bundles. Let X be a real algebraic set. For any nonnegative integer n, let

$$\varepsilon_X^n(\mathbb{F}) = (X \times \mathbb{F}^n, p, X)$$

denote the product $\mathbb{F}$-vector bundle of rank n on X, where $X \times \mathbb{F}^n$ is regarded as a real algebraic set and $p\colon X \times \mathbb{F}^n \to X$ is the canonical projection.

An *algebraic* $\mathbb{F}$*-vector bundle on* X is an algebraic $\mathbb{F}$-vector subbundle of $\varepsilon_X^n(\mathbb{F})$ for some n (cf. Bochnak, Coste, and Roy [1998] for various characterizations of algebraic $\mathbb{F}$-vector bundles). The category of algebraic $\mathbb{F}$-vector bundles on X is equivalent to the category of finitely generated projective left $\mathcal{R}(X, \mathbb{F})$-modules, where $\mathcal{R}(X, \mathbb{F})$ is the ring of $\mathbb{F}$-valued regular functions on X.

Any algebraic $\mathbb{F}$-vector bundle on X can be regarded also as a topological $\mathbb{F}$-vector bundle. A topological $\mathbb{F}$-vector bundle is said to *admit an algebraic structure* if it is topologically isomorphic to an algebraic $\mathbb{F}$-vector bundle.

Problem 5.1. Which topological $\mathbb{F}$-vector bundles on X admit an algebraic structure?

It is convenient to bring into play the reduced Grothendieck group $\tilde{K}_{\mathbb{F}}(X)$ of topological $\mathbb{F}$-vector bundles on X. Since X has the homotopy type of a compact polyhedron Bochnak, Coste, and Roy [ibid.], the Abelian group $\tilde{K}_{\mathbb{F}}(X)$ is finitely generated Atiyah and Hirzebruch [1961] and Dyer [1969]. We let $\tilde{K}_{\mathbb{F}\text{-alg}}(X)$ denote the subgroup of $\tilde{K}_{\mathbb{F}}(X)$ generated by the classes of all topological $\mathbb{F}$-vector bundles on X that admit an algebraic structure.

If X is compact, then Problem 5.1 is equivalent to providing a description of $\tilde{K}_{\mathbb{F}\text{-alg}}(X)$. More precisely, the following holds.

Theorem 5.2. *Let X be a compact real algebraic set. Then:*

(i) *Two algebraic $\mathbb{F}$-vector bundles on X are algebraically isomorphic if and only if they are topologically isomorphic.*

(ii) *A topological $\mathbb{F}$-vector bundle on X admits an algebraic structure if and only if its class in $\tilde{K}_{\mathbb{F}}(X)$ belongs to $\tilde{K}_{\mathbb{F}\text{-alg}}(X)$.*

Theorem 5.2 follows from Swan [1977, Theorem 2.2], and a geometric proof is given in Bochnak, Coste, and Roy [1998]. Note that $\tilde{K}_{\mathbb{F}\text{-alg}}(X) = 0$ if and only if each algebraic $\mathbb{F}$-vector bundle on X is algebraically stably trivial. In turn, $\tilde{K}_{\mathbb{F}\text{-alg}}(X) = \tilde{K}_{\mathbb{F}}(X)$ if and only if each topological $\mathbb{F}$-vector bundle on X admits an algebraic structure.

According to Fossum [1969] and Swan [1977], we have the following.

Theorem 5.3. *For the unit n-sphere $\mathbb{S}^n$, the equality $\tilde{K}_{\mathbb{F}\text{-alg}}(\mathbb{S}^n) = \tilde{K}_{\mathbb{F}}(\mathbb{S}^n)$ holds.*

Benedetti and Tognoli [1980] proved that algebraization of topological vector bundles on a compact $\mathcal{C}^\infty$ manifold is always possible.

Theorem 5.4. *Let M be a compact $\mathcal{C}^\infty$ manifold. Then there exists an algebraic model X of M such that $\tilde{K}_{\mathbb{F}\text{-alg}}(X) = \tilde{K}_{\mathbb{F}}(X)$ for $\mathbb{F} = \mathbb{R}$, $\mathbb{F} = \mathbb{C}$ and $\mathbb{F} = \mathbb{H}$.*

The groups $\tilde{K}_{\mathbb{F}\text{-alg}}(-)$ have been extensively investigated by Bochnak and Kucharz [1989a, 1990, 1992] and Bochnak, Buchner, and Kucharz [1989]. In many cases, $\tilde{K}_{\mathbb{F}\text{-alg}}(-)$ are "small" subgroups of $\tilde{K}_{\mathbb{F}}(-)$. The following is a simplified version of Bochnak, Buchner, and Kucharz [ibid., Theorem 7.1].

Theorem 5.5. *Let M be a compact $\mathcal{C}^\infty$ submanifold of $\mathbb{R}^{n+1}$, with* $\dim M = n \geq 1$. *Then M is ε-isotopic to a smooth algebraic subset X of $\mathbb{R}^{n+1}$ such that the group $\tilde{K}_{\mathbb{F}\text{-alg}}(X)$ is finite for $\mathbb{F} = \mathbb{R}$, $\mathbb{F} = \mathbb{C}$ and $\mathbb{F} = \mathbb{H}$.*

The conclusion of Theorem 5.5 can be strengthened in some cases.

Example 5.6. Recall that $\tilde{K}_{\mathbb{F}}(\mathbb{S}^{4d}) = \mathbb{Z}$ for every positive integer d, cf. Husemoller [1975]. Hence, by Theorem 5.5, $\mathbb{S}^{4d}$ is ε-isotopic in $\mathbb{R}^{4d+1}$ to a smooth algebraic subset Σ^{4d} such that

$$\tilde{K}_{\mathbb{F}\text{-alg}}(\Sigma^{4d}) = 0 \text{ and } \tilde{K}_{\mathbb{F}}(\Sigma^{4d}) = \mathbb{Z}$$

for $\mathbb{F} = \mathbb{R}$, $\mathbb{F} = \mathbb{C}$ and $\mathbb{F} = \mathbb{H}$.

One readily sees that each topological $\mathbb{R}$-vector bundle on a smooth real algebraic curve admits an algebraic structure. Next we discuss some results on vector bundles on a product of real algebraic curves.

Example 5.7. Let $X = C_1 \times \cdots \times C_n$, where $C_1, \ldots, C_n$ are connected, compact smooth real algebraic curves. Then $\tilde{K}_{\mathbb{R}\text{-alg}}(X) = \tilde{K}_{\mathbb{R}}(X)$ if $n = 2$ or $n = 3$. This assertion is a special case of Bochnak and Kucharz [1989a, Theorem 1.6].

In Example 5.7, one cannot take $n \geq 4$.

Example 5.8. Let $\mathbb{T}^n := \mathbb{S}^1 \times \cdots \times \mathbb{S}^1$ be the n-fold product of $\mathbb{S}^1$. According to Bochnak and Kucharz [1987b], $\tilde{K}_{\mathbb{C}\text{-alg}}(\mathbb{T}^n) = 0$. Furthermore, by Kucharz and Kurdyka [2016b, Example 1.11], we have $\tilde{K}_{\mathbb{R}\text{-alg}}(\mathbb{T}^n) \neq \tilde{K}_{\mathbb{R}}(\mathbb{T}^n)$ and $\tilde{K}_{\mathbb{H}\text{-alg}}(\mathbb{T}^n) \neq \tilde{K}_{\mathbb{H}}(\mathbb{T}^n)$ for $n \geq 4$.

Let $\mathbb{K}$ be a subfield of $\mathbb{F}$, where $\mathbb{K}$ (as $\mathbb{F}$) stands for $\mathbb{R}$, $\mathbb{C}$ or $\mathbb{H}$. Any $\mathbb{F}$-vector bundle ξ can be regarded as a $\mathbb{K}$-vector bundle, which is indicated by $\xi_{\mathbb{K}}$.

Example 5.9. Let λ be a nontrivial topological $\mathbb{C}$-line bundle on $\mathbb{T}^2$. By Example 5.7, the $\mathbb{R}$-vector bundle $\lambda_{\mathbb{R}}$ on $\mathbb{T}^2$ admits an algebraic structure. However, in view of Example 5.8, λ does not admit an algebraic structure. The rth tensor power $\lambda^{\otimes r}$ is a nontrivial $\mathbb{C}$-line bundle, hence it does not admit an algebraic structure.

The next two theorems come from Bochnak and Kucharz [1992]. We use smooth real cubic curves $D_\alpha \subset \mathbb{P}^2(\mathbb{R})$, with $\alpha \in \mathbb{R}^*$, introduced in Section 4.1.

Theorem 5.10. *Let $X = D_\alpha \times \cdots \times D_\alpha$ be the n-fold product of D_α, where α is in $\mathbb{R}^*$ and $n \geq 2$. Then the following conditions are equivalent:*

(a) $\tilde{K}_{\mathbb{C}\text{-alg}}(X) = 0$.

(b) *The number α^2 is irrational.*

In this context, the equality $\tilde{K}_{\mathbb{C}\text{-alg}}(-) = \tilde{K}_{\mathbb{C}}(-)$ is characterized as follows.

Theorem 5.11. *Let $X = D_{\alpha_1} \times \cdots \times D_{\alpha_n}$, where $\alpha_1, \dots, \alpha_n$ are in $\mathbb{R}^*$ and $n \geq 2$. Then the following conditions are equivalent:*

(a) $\tilde{K}_{\mathbb{C}\text{-alg}}(X) = \tilde{K}_{\mathbb{C}}(X)$.

(b) $\alpha_i > 0$ *for all i, and* $b(D_{\alpha_i}, D_{\alpha_j}) = 1$ *for* $i \neq j$.

The pairs (α_i, α_j) with $b(D_{\alpha_i}, D_{\alpha_j}) = 1$ are explicitly described in Theorem 4.10.

In the next subsection we deal with vector bundles of a new type, which occupy an intermediate position between algebraic and topological vector bundles.

5.2 Regulous versus topological vector bundles. Let X be a real algebraic set. As in (3.8), by a stratification of X we mean a finite collection $\mathcal{S}$ of pairwise disjoint Zariski locally closed subsets whose union is X. An $\mathcal{S}$-*algebraic* $\mathbb{F}$-*vector bundle on* X is a topological $\mathbb{F}$-vector subbundle of $\varepsilon^n_X(\mathbb{F})$, for some n, such that the restriction $\xi|_S$ of ξ to each stratum $S \in \mathcal{S}$ is an algebraic $\mathbb{F}$-vector subbundle of $\varepsilon^n_S(\mathbb{F})$. If ξ and η are $\mathcal{S}$-algebraic $\mathbb{F}$-vector bundles on X, then an $\mathcal{S}$-*algebraic morphism* $\varphi\colon \xi \to \eta$ is a morphism of topological $\mathbb{F}$-vector bundles which induces a morphism of algebraic $\mathbb{F}$-vector bundles $\varphi_S\colon \xi|_S \to \eta|_S$ for each stratum $S \in \mathcal{S}$.

Definition 5.12. A *regulous* $\mathbb{F}$-*vector bundle on* X is an $\mathcal{S}$-algebraic $\mathbb{F}$-vector bundle for some stratification $\mathcal{S}$ of X. If ξ and η are regulous $\mathbb{F}$-vector bundles on X, then a *regulous morphism* $\varphi\colon \xi \to \eta$ is an $\mathcal{S}$-algebraic morphism for some stratification $\mathcal{S}$ of X such that both ξ and η are $\mathcal{S}$-algebraic $\mathbb{F}$-vector bundles.

In our joint paper Kucharz and Kurdyka [2016b], we introduced and investigated regulous (= stratified-algebraic) vector bundles. The main focus of Kucharz and Kurdyka [ibid.] and the subsequent papers Kucharz [2015b, 2016b], Kucharz and Kurdyka [2015], Kucharz and Zieliński [2018] is on comparison of algebraic, regulous, and topological vector bundles.

Regulous $\mathbb{F}$-vector bundles on X (together with regulous morphisms) form a category, which is equivalent to the category of finitely generated projective left $\mathcal{R}^0(X, \mathbb{F})$-modules, where $\mathcal{R}^0(X, \mathbb{F})$ is the ring of $\mathbb{F}$-valued regulous functions on X, cf. Kucharz and Kurdyka [2016b, Theorem 3.9].

A topological $\mathbb{F}$-vector bundle on X is said to *admit a regulous structure* if it is topologically isomorphic to a regulous $\mathbb{F}$-vector bundle. We let $\tilde{K}_{\mathbb{F}\text{-reg}}(X)$ denote the subgroup of $\tilde{K}_{\mathbb{F}}(X)$ generated by the classes of all topological $\mathbb{F}$-vector bundles on X that admit a regulous structure.

We have the following counterpart of Theorem 5.2, cf. Kucharz and Kurdyka [ibid.].

Theorem 5.13. *Let X be a compact real algebraic set. Then:*

(i) *Two regulous $\mathbb{F}$-vector bundles on X are regulously isomorphic if and only if they are topologically isomorphic.*

(ii) *A topological $\mathbb{F}$-vector bundle on X admits a regulous structure if and only if its class in $\tilde{K}_{\mathbb{F}}(X)$ belongs to $\tilde{K}_{\mathbb{F}\text{-reg}}(X)$.*

Hence $\tilde{K}_{\mathbb{F}\text{-reg}}(X) = \tilde{K}_{\mathbb{F}}(X)$ if and only if each topological $\mathbb{F}$-vector bundle on X admits a regulous structure.

The following result of Kucharz and Kurdyka [ibid.] should be compared with Theorem 5.3 and Example 5.6.

Theorem 5.14. *Let X be a compact real algebraic set that is homotopically equivalent to the unit n-sphere $\mathbb{S}^n$. Then $\tilde{K}_{\mathbb{F}\text{-reg}}(X) = \tilde{K}_{\mathbb{F}}(X)$.*

In contrast to Example 5.8 and Theorems 5.10 and 5.11, we proved in Kucharz and Kurdyka [ibid.] the following.

Theorem 5.15. *Let $X = X_1 \times \cdots \times X_n$, where X_i is a compact real algebraic set that is homotopically equivalent to the unit d_i-sphere $\mathbb{S}^{d_i}$ for $1 \leq i \leq n$. Then*

$$2\tilde{K}_{\mathbb{R}}(X) \subset \tilde{K}_{\mathbb{R}\text{-reg}}(X),\ \tilde{K}_{\mathbb{C}\text{-reg}}(X) = \tilde{K}_{\mathbb{C}}(X) \text{ and } \tilde{K}_{\mathbb{H}\text{-reg}}(X) = \tilde{K}_{\mathbb{H}}(X).$$

It is possible that $\tilde{K}_{\mathbb{R}\text{-reg}}(X) = \tilde{K}_{\mathbb{R}}(X)$ in Theorem 5.15, but no proof is available even for $X = \mathbb{T}^n$ with $n \geq 4$.

Our next result comes from Kucharz and Kurdyka [2015].

Theorem 5.16. *Let X be a compact real algebraic set that is homotopically equivalent to $\mathbb{S}^{d_1} \times \cdots \times \mathbb{S}^{d_n}$. Then the quotient group $\tilde{K}_{\mathbb{F}}(X)/\tilde{K}_{\mathbb{F}\text{-reg}}(X)$ is finite.*

If $n \geq 5$, then there exists an algebraic model X of $\mathbb{T}^n$ with $\tilde{K}_{\mathbb{F}}(X)/\tilde{K}_{\mathbb{F}\text{-reg}}(X) \neq 0$ for $\mathbb{F} = \mathbb{R}$, $\mathbb{F} = \mathbb{C}$ and $\mathbb{F} = \mathbb{H}$, cf. Kucharz and Kurdyka [2016b, Example 7.10].

For any real algebraic set X, we let $\tilde{K}_{\mathbb{F}}^{(\mathrm{crk})}(X)$ denote the subgroup of $\tilde{K}_{\mathbb{F}}(X)$ generated by the classes of all topological $\mathbb{F}$-vector bundles of constant rank. Define $\Gamma_{\mathbb{F}}(X)$ to be the quotient group

$$\Gamma_{\mathbb{F}}(X) := \tilde{K}_{\mathbb{F}}^{(\mathrm{crk})}(X)/(\tilde{K}_{\mathbb{F}\text{-reg}}(X) \cap \tilde{K}_{\mathbb{F}}^{(\mathrm{crk})}(X))$$

(cf. Kucharz and Kurdyka [2015] for an equivalent description). Evidently, $\Gamma_{\mathbb{F}}(X) = \tilde{K}_{\mathbb{F}}(X)/\tilde{K}_{\mathbb{F}\text{-reg}}(X)$ if X is connected. Note, however, that for the real algebraic curve C of (1.5), one has $\Gamma_{\mathbb{R}}(C) = 0$, while the group $\tilde{K}_{\mathbb{R}}(C)/\tilde{K}_{\mathbb{R}\text{-reg}}(C)$ is infinite.

Conjecture 5.17. *For any compact real algebraic set X, the group $\Gamma_{\mathbb{F}}(X)$ is finite.*

In Kucharz and Kurdyka [ibid.], we proved that Conjecture 5.17 holds in low dimensions.

Theorem 5.18. *If X is a compact real algebraic set of dimension at most 8, then the group $\Gamma_{\mathbb{F}}(X)$ is finite.*

For $\mathbb{C}$-line bundles, the following is expected.

Conjecture 5.19. *For any compact real algebraic set X and any topological $\mathbb{C}$-line bundle λ on X, the $\mathbb{C}$-line bundle $\lambda^{\otimes 2}$ admits a regulous structure.*

According to Kucharz [2015b], Conjecture 4.14 implies Conjecture 5.19. If $\dim X \leq 8$, then for some positive integer r, the $\mathbb{C}$-line bundle $\lambda^{\otimes r}$ admits a regulous structure, cf. Kucharz and Kurdyka [2015]. This should be compared with Example 5.9.

The key role in the proofs of the results presented in this subsection plays the following theorem of Kucharz and Kurdyka [2016b].

Theorem 5.20. *Let X be a compact real algebraic set. A topological $\mathbb{F}$-vector bundle ξ on X admits a regulous structure if and only if the $\mathbb{R}$-vector bundle $\xi_{\mathbb{R}}$ admits a regulous structure.*

By Example 5.9, one cannot substitute "algebraic" for "regulous" in Theorem 5.20.

PAIRS OF INVARIANTS OF SURFACE SINGULARITIES

András Némethi

Abstract

We discuss several invariants of complex normal surface singularities with a special emphasis on the comparison of analytic–topological pairs of invariants. Additionally we also list several open problems related with them.

1 Introduction

Singularity theory aims to study the singular points of algebraic/analytic varieties. It was born together with the classical algebraic geometry, but step by step became an independent discipline within algebraic and complex geometry. Furthermore, it also created formidable connections with other fields, like topology or differential equations. By crucial classification projects in mainstream mathematics (e.g. the Mori program in algebraic geometry targeting classification of varieties, or developments in low-dimensional topology) singularities theory became even more a central area.

In both local and global case the study of surfaces became central. In the global case, after the 'classical' classification of Enriques and the Italian school, a 'modern' classification was provided by Kodaira in 60's based on sheaves, cohomologies and characteristic classes with special emphasis on the relationships of the analytic structures with invariants of the underlying smooth 4–manifolds: e.g. Hodge or Riemann–Roch–Hirzebruch formulas. Crucial open questions were formulated targeting this type of ties: e.g. the purely topological characterization of rational surfaces (as an addendum of Castelnuovo's criterion) or of K3 surfaces (asked by Kodaira). The appearance of Donaldson and Seiberg–Witten theories gave a powerful impetus of such comparison results, and generated a series of new open questions. These were inherited by local singularity theory too. The lack of

Keywords: normal surface singularities, rational singularities, elliptic singularities, $\mathbb{Q}$–homology spheres, geometric genus, link of singularities, divisorial filtration, Poincaré series, Seiberg–Witten invariants of 3–manifolds, Casson Invariant Conjecture, Seiberg–Witten Invariant Conjecture, Heegaard–Floer homology, graded roots, surgery 3-manifolds, unicuspidal rational projective plane curves.

classification results in 3 and 4 dimensional topology put even more in the highlight the possible analytic/algebraic connections.

This is the guiding principle of the present manuscript too: what are the ties between analytic and topological structures of a local complex normal surface singularity.

It is always exciting to understand such bridges between topology and rigid analytic/algebraic geometry. In this note by the style of the presentation we even try to emphasize more the existing parallel pairs of invariants, theorems and constructions from both sides. Though the presented list definitely is not exhaustive, it supports rather well the philosophical conviction that any result in the analytic part must have a topological counterpart, and vice versa.

The guiding pair is $\mathcal{P}(\mathbf{t}) \leftrightarrow Z(\mathbf{t})$, where $\mathcal{P}(\mathbf{t})$ is the multivariable Poincaré series associated with the divisorial filtration given by the irreducible curves of a resolution, while $Z(\mathbf{t})$ is a combinatorial 'zeta' function read from the corresponding resolution graph.

2 Normal surface singularities. Analytic Invariants

2.1 Definitions, notations. Let (X,o) be a complex normal surface singularity. Let $\pi : \widetilde{X} \to X$ be a good resolution with dual graph Γ whose vertices are denoted by $\mathcal{V}$. Set $E := \pi^{-1}(o)$. Let M be the link of (X,o), and we will assume that M is a rational homology sphere. This happens if and only if Γ is a tree and all the irreducible exceptional curves $\{E_v\}_{v\in\mathcal{V}}$ have genus 0.

Set $L := H_2(\widetilde{X},\mathbb{Z})$. It is freely generated by the classes of the irreducible exceptional curves. If L' denotes $H^2(\widetilde{X},\mathbb{Z})$, then the intersection form $(\,,\,)$ on L provides an embedding $L \hookrightarrow L'$ with factor the first homology group H of the link. (In fact, L' is the dual lattice of $(L,(\,,\,))$.) Moreover, $(\,,\,)$ extends to L'. L' is freely generated by the duals E_v^*, where $(E_v^*, E_w) = -1$ for $v = w$ and $= 0$ else.

Effective classes $l = \sum r_v E_v \in L'$ with all $r_v \in \mathbb{Q}_{\geq 0}$ are denoted by $L'_{\geq 0}$ and $L_{\geq 0} := L'_{\geq 0} \cap L$. Denote by $\mathcal{S}'$ the (Lipman's) anti-nef cone $\{l' \in L' \;:\; (l', E_v) \leq 0 \text{ for all } v\}$. It is generated over $\mathbb{Z}_{\geq 0}$ by the base-elements E_v^*. Since all the entries of E_v^* are strict positive, $\mathcal{S}'$ is a sub-cone of $L'_{\geq 0}$, and for any fixed $a \in L'$ the set $\{l' \in \mathcal{S}' \;:\; l' \ngeq a\}$ is finite. Set $\mathfrak{C} := \{\sum l'_v E_v \in L',\ 0 \leq l'_v < 1\}$. For any $l' \in L'$ write its class in H by $[l']$, and or any $h \in H$ let $r_h \in L'$ be its unique representative in $\mathfrak{C}$. Denote by $\theta : H \to \widehat{H}$ the isomorphism $[l'] \mapsto e^{2\pi i (l',\cdot)}$ of H with its Pontrjagin dual $\widehat{H}$.

Denote by $K \in L'$ the *canonical class* satisfying $(K+E_v, E_v) = -2$ for all $v \in \mathcal{V}$. We set $\chi(l') = -(l', l'+K)/2$; by Riemann-Roch theorem $\chi(l) = \chi(\mathcal{O}_l)$ for any $l \in L_{>0}$.

Most of the analytic geometry of $\widetilde{X}$ is described by its line bundles and their cohomology groups. E.g., the geometric genus of (X,o) is $p_g := h^1(\widetilde{X}, \mathcal{O}_{\widetilde{X}})$. In this note we mostly target the following numerical invariants (below $\mathcal{L} \in \mathrm{Pic}(\widetilde{X})$ and $l \in L_{>0}$):

$$(2.1.1)\qquad (a)\ \dim\ H^0(\mathcal{L})\,/\,H^0(\mathcal{L}(-l)) \quad \text{and} \quad (b)\ \dim H^1(\mathcal{L}).$$

Their behaviour for arbitrary line bundles is rather complicated, however for *natural line bundles* we have several (sometimes even topological) descriptions/characterizations. These line bundles are provided by the splitting of the cohomological exponential exact sequence Némethi [n.d.(b), §3]:

$$0 \to H^1(\widetilde{X}, \mathcal{O}_{\widetilde{X}}) \to \mathrm{Pic}(\widetilde{X}) \xrightarrow{c_1} L' \to 0.$$

The first Chern class c_1 has an obvious section on the subgroup L, namely $l \mapsto \mathcal{O}_{\widetilde{X}}(l)$. This section has a unique extension $\mathcal{O}(\cdot)$ to L'. We call a line bundle *natural* if it is in the image of this section.

One can recover these bundles via coverings as follows. Let $c : (Y, o) \to (X, o)$ be the universal abelian covering of (X, o), $\pi_Y : \widetilde{Y} \to Y$ the normalized pullback of π by c, and $\widetilde{c} : \widetilde{Y} \to \widetilde{X}$ the morphism which covers c. Then the action of H on (Y, o) lifts to $\widetilde{Y}$ and one has an H–eigensheaf decomposition (Némethi [ibid., (3.7)] or Okuma [2008, (3.5)]):

$$(2.1.2)\qquad \widetilde{c}_*\mathcal{O}_{\widetilde{Y}} = \bigoplus_{l' \in \mathfrak{C}} \mathcal{O}(-l') \quad (\mathcal{O}(-l') \text{ being the } \theta([l'])\text{-eigenspace of } \widetilde{c}_*\mathcal{O}_{\widetilde{Y}}).$$

Note that the geometric genus of Y is $h^1(\widetilde{Y}, \mathcal{O}_{\widetilde{Y}})$, hence, by Equation (2.1.2), $\{h^1(\widetilde{X}, \mathcal{O}_{\widetilde{X}}(-r_h))\}_{h\in H}$ are the dimensions of the H–eigenspaces; we call them equivariant geometric genera of (X, o).

2.2 Series associated with the divisorial filtration. For those natural line bundles which appear in Equation (2.1.2), the dimensions from Equation (2.1.1)(a) can be organized in a generating function. Indeed, once a resolution π is fixed, $\mathcal{O}_{Y,o}$ inherits the *divisorial multi-filtration* (cf. Némethi [2008b, (4.1.1)]):

$$(2.2.1)\qquad \mathcal{F}(l') := \{f \in \mathcal{O}_{Y,o} \mid \mathrm{div}(f \circ \pi_Y) \geq \widetilde{c}^*(l')\}.$$

Let $\mathfrak{h}(l')$ be the dimension of the $\theta([l'])$-eigenspace of $\mathcal{O}_{Y,o}/\mathcal{F}(l')$. Then, one defines the *equivariant divisorial Hilbert series* by

$$(2.2.2)\qquad \mathcal{H}(\mathbf{t}) = \sum_{l' \in L'} \mathfrak{h}(l') t_1^{l'_1} \cdots t_s^{l'_s} = \sum_{l' \in L'} \mathfrak{h}(l')\mathbf{t}^{l'} \in \mathbb{Z}[[L']] \ \ (l' = \sum_i l'_i E_i).$$

Notice that the terms of the sum reflect the H-eigenspace decomposition too: $\mathfrak{h}(l')\mathbf{t}^{l'}$ contributes to the $\theta([l'])$-eigenspace. For example, $\sum_{l\in L} \mathfrak{h}(l)\mathbf{t}^l$ corresponds to the H-invariants, hence it is the *Hilbert series* of $\mathcal{O}_{X,o}$ associated with the $\pi^{-1}(o)$-divisorial multi-filtration (considered and intensively studied, see e.g. Cutkosky, Herzog, and Reguera [2004] and the citations therein, or Campillo, Delgado, and Gusein-Zade [2004]).

The 'graded version' associated with the Hilbert series is defined (cf. Campillo, Delgado, and Gusein-Zade [2004] and Guseĭn-Zade, Delgado, and Kampil'o [2008]) as

$$\mathcal{P}(\mathbf{t}) = -\mathcal{H}(\mathbf{t}) \cdot \prod_v (1 - t_v^{-1}) \in \mathbb{Z}[[L']]. \tag{2.2.3}$$

Although the multiplication by $\prod_v (1 - t_v^{-1})$ in $\mathbb{Z}[[L']]$ is not injective, hence apparently $\mathcal{P}$ contains less information then $\mathcal{H}$, they, in fact, determine each other as we will see in Equation (2.4.2).

If we write the series $\mathcal{P}(\mathbf{t})$ as $\sum_{l'} \mathfrak{p}(l')\mathbf{t}^{l'}$, then

$$\mathfrak{p}(l') = \sum_{I \subseteq \mathcal{V}} (-1)^{|I|+1} \dim \frac{H^0(\widetilde{X}, \mathcal{O}(-l'))}{H^0(\widetilde{X}, \mathcal{O}(-l' - E_I))} \tag{2.2.4}$$

and $\mathcal{P}$ is supported in the cone $\mathcal{S}'$.

2.3 Quasipolynomials and the periodic constants associated with series. The following definitions are motivated by properties of Hilbert–Samuel functions and also by Ehrhart theory and the properties of its qusipolynomials. The periodic constant of one–variable series was introduced in Némethi and Okuma [2009], Okuma [2008], and Braun and Némethi [2010], the multivariable generalization is treated in László and Némethi [2014].

Let $S(t) = \sum_{l \geq 0} c_l t^l \in \mathbb{Z}[[t]]$ be a formal power series with one variable. Assume that for some $p \in \mathbb{Z}_{>0}$ the counting function $Q^{(p)}(n) := \sum_{l=0}^{pn-1} c_l$ is a polynomial $\mathfrak{Q}^{(p)}$ in n. Then the constant term $\mathfrak{Q}^{(p)}(0)$ is independent of p and it is called the *periodic constant* $\mathrm{pc}(S)$ of the series S. E.g., if $S(t)$ is a finite polynomial, then $\mathrm{pc}(S)$ exists and it equals $S(1)$. If the coefficients of $S(t)$ are given by a Hilbert function $l \mapsto c(l)$, which admits a Hilbert polynomial $H(l)$ with $c(l) = H(l)$ for $l \gg 0$, then $S^{reg}(t) = \sum_{l \geq 0} H(l)t^l$ has zero periodic constant and $\mathrm{pc}(S) = \mathrm{pc}(S - S^{reg}) + \mathrm{pc}(S^{reg}) = (S - S^{reg})(1)$, measuring the difference between the Hilbert function and Hilbert polynomial.

For the multivariable case we consider a (negative) definite lattice $L = \mathbb{Z}\langle E_v \rangle_v$, its dual lattice L', and a series $S(\mathbf{t}) \in \mathbb{Z}[[L']]$, $S(\mathbf{t}) = \sum_{l' \in L'} s(l')\mathbf{t}^{l'}$. We decompose S as $S = \sum_{h \in H} S_h$, where $S_h(\mathbf{t}) = \sum_{[l']=h} s(l')\mathbf{t}^{l'}$, and we consider the following 'counting function of the coefficients'

$$Q_h : L'_h := \{x \in L' : [x] = h\} \to \mathbb{Z}, \quad Q_h(x) = \sum_{l' \not\geq x,\, [l']=h} s(l'). \tag{2.3.1}$$

Assume that there exist a real cone $\mathcal{K} \subset L' \otimes \mathbb{R}$ whose affine closure is top–dimensional, $l'_* \in \mathcal{K}$, a sublattice $\widetilde{L} \subset L$ of finite index, and a quasipolynomial $\mathfrak{Q}_h(l)$ $(l \in \widetilde{L})$ such that $Q_h(l + r_h) = \mathfrak{Q}_h(l)$ for any $l + r_h \in (l'_* + \mathcal{K}) \cap (\widetilde{L} + r_h)$. Then we say that the counting function Q_h (or just $S_h(\mathbf{t})$) admits a quasipolynomial in $\mathcal{K}$, namely $\mathfrak{Q}_h(l)$, and also an (equivariant, multivariable) *periodic constant* associated with $\mathcal{K}$, which is defined by

$$\mathrm{pc}^{\mathcal{K}}(S_h(\mathbf{t})) := \mathfrak{Q}_h(0). \tag{2.3.2}$$

The definition does not depend on the choice of the sublattice $\widetilde{L}$, which corresponds to the choice of p in the one–variable case. This is responsible for the name 'periodic' in the definition. The definition is independent of the choice of l'_* as well.

By general theory of multivariable Ehrhart-type quasipolynomials, for a nicely defined series one can construct a conical chamber decomposition of the space $L' \otimes \mathbb{R}$, such that each cone satisfies the above definition (hence provides a periodic constant), for details see László and Némethi [ibid.] or Szenes and Vergne [2003]. However, it turns out, that in all our situations the whole $\mathcal{S}'_{\mathbb{R}}$ (the real Lipman cone) will be a unique chamber.

2.4 The quasipolynomial of $\mathcal{P}$. Let $\mathcal{P}$ and $\mathcal{H}$ be the series defined in SubSection 2.2.

Theorem 2.4.1. *For any $l' \in L'$ one has*

$$\mathfrak{h}(l') = \sum_{a \in L,\, a \ngeq 0} \mathfrak{p}(l' + a). \tag{2.4.2}$$

Furthermore, there exists a constant $\mathrm{const}_{[-l']}$, *depending only on the class of* $[-l'] \in H$, *such that*

$$-h^1(\widetilde{X}, \mathcal{O}(-l')) = \sum_{a \in L,\, a \ngeq 0} \mathfrak{p}(l' + a) + \mathrm{const}_{[-l']} + \frac{(K + 2l')^2 + |\mathcal{V}|}{8}. \tag{2.4.3}$$

By taking $l' = r_h$ one can identify $\mathrm{const}_{[-l']}$ with the equivariant geometric genus, that is $-h^1(\widetilde{X}, \mathcal{O}(-r_h)) = \mathrm{const}_{-h} + ((K + 2r_h)^2 + |\mathcal{V}|)/8$. In particular, the coefficients of the series $\mathcal{P}(\mathbf{t})$ determine the invariants Equation (2.1.1)((a)-(b)) for all natural line bundles.

Write $l' = l + r_h$ for $l \in L$. Note that if $l \in L_{\leq 0}$, then in Equation (2.4.3) the sum will not appear (check the support of $\mathcal{P}$). On the other hand, if in Equation (2.4.3) $l' \in -K + \mathcal{S}'$ then by the vanishing of $h^1(\mathcal{O}(-l'))$ we get that $\sum_{a \in L,\, a \ngeq 0} \mathfrak{p}(l' + a)$ is the multivariable quadratic function $\chi(l) - (r_h, l) + h^1(\widetilde{X}, \mathcal{O}(-r_h))$. This quadratic function is the quasipolynomial of $\mathcal{P}$ in $\mathcal{K} = \mathcal{S}'_{\mathbb{R}}$, and its periodic constant is $h^1(\widetilde{X}, \mathcal{O}(-r_h))$.

2.5 Reductions of $\mathcal{P}$. Let $\mathcal{U}$ be a nonempty subset of $\mathcal{V}$, and fix $h \in H$ as well. One can introduce the reduction of the series $\mathcal{P}_h$ to the variables $\{t_v\}_{v\in\mathcal{U}}$ in two different ways. First, we can consider the multivariable divisorial filtration induced by the exceptional divisors $\{E_v\}_{v\in\mathcal{U}}$, define the Hilbert series $\mathcal{H}_h^{\mathcal{U}}$ and $\mathcal{P}_h^{\mathcal{U}}$ in variables $\{t_v\}_{v\in\mathcal{U}}$ and associated with $\theta(h)$–eigendecomposition similarly as $\mathcal{H}_h$ and $\mathcal{P}_h$ was defined in Section 2.2. The second possibility is to reduced the variables in the original $\mathcal{P}_h$. The point is that the two constructions have the same output: $\mathcal{P}_h^{\mathcal{U}} = \mathcal{P}_h(\mathbf{t})|_{t_v=1 \text{ for all } v\notin\mathcal{U}}$. In this article we mostly discuss the case $\mathcal{U} = \{v\}$ for a certain vertex v, however all the discussions can be extended for arbitrary $\mathcal{U}$.

2.6 Surgery formulae for $h^1(\widetilde{X}, \mathcal{L})$. Let (X,o) and $\pi : \widetilde{X} \to X$ as above. We fix a vertex $v \in \mathcal{V}$. Let $\cup_{j\in J}\Gamma_j$ be the connected components of the graph obtained from Γ by deleting v and its adjacent edges. Let X' be the space obtained from $\widetilde{X}$ by contracting all irreducible exceptional curves except E_v to normal points. It has $|J|$ normal singular points $\{o_j\}_j$, the images of the connected components of $E - E_v$. Let X_j be a small Stein neighbourhood of o_j in X', $\widetilde{X}_j = \tau^{-1}(X_j)$ its pre-image via the contraction $\tau : \widetilde{X} \to X'$, and $\tau(E) = E' \subset X'$. We denote the local singularities by (X_j, o_j).

We say that the Assumption (*C*) is satisfied if $nE' \subset X'$ is a Cartier divisor for certain $n > 0$.

Theorem 2.6.1. *Okuma [2008] Set $\mathcal{U} = \{v\}$ and fix $h \in H$. Under the Assumption (C)*

$$h^1(\widetilde{X}, \mathcal{O}_{\widetilde{X}}(-r_h)) = \mathrm{pc}(\mathcal{P}_h^{\{v\}}(t_v)) + \sum_j h^1(\widetilde{X}_j, \mathcal{O}_{\widetilde{X}}(-r_h)|_{\widetilde{X}_j}).$$

E.g., this applied for $\mathcal{O}_{\widetilde{X}}$ gives $p_g(X,o) = \mathrm{pc}(\mathcal{P}_h^{\{v\}}(t_v)) + \sum_j p_g(X_j, o_j)$. In general, $\mathcal{O}_{\widetilde{X}}(-r_h)|_{\widetilde{X}_j}$ is not a natural line bundle on $\widetilde{X}_j$, however e.g. for splice quotient singularities it is the line bundle associated with the cohomology restriction of $-r_h$ (for details see Section 3.3). Hence, Theorem 2.6.1 provides an ideal inductive procedure for the computation of the cohomology of natural line bundles.

3 Topological invariants. The series $Z(\mathbf{t})$

3.1 The series $Z(\mathbf{t})$. The *multivariable topological series* is the Taylor expansion $Z(\mathbf{t}) = \sum_{l'} z(l')\mathbf{t}^{l'} \in \mathbb{Z}[[L']]$ at the origin of the rational function

$$f(\mathbf{t}) = \prod_{v\in\mathcal{V}} (1 - \mathbf{t}^{E_v^*})^{\delta_v - 2}. \tag{3.1.1}$$

It is supported in $\mathcal{S}'$. Similarly as $\mathcal{P}$, it decomposes as $Z(\mathbf{t}) = \sum_{h\in H} Z_h(\mathbf{t})$. In fact,

$$Z_h(\mathbf{t}) := \frac{1}{|H|} \cdot \sum_{\rho\in\widehat{H}} \rho(h)^{-1} \cdot \prod_{v\in\mathcal{V}} \left(1-\rho([E_v^*])\mathbf{t}^{E_v^*}\right)^{\delta_v-2}. \tag{3.1.2}$$

3.2 Seiberg–Witten invariants of the link M. Let $\widetilde{\sigma}_{can}$ be the *canonical $spin^c$–structure on $\widetilde{X}$* identified by $c_1(\widetilde{\sigma}_{can}) = -K$, and let $\sigma_{can} \in \mathrm{Spin}^c(M)$ be its restriction to M, called the *canonical $spin^c$–structure on M*. $\mathrm{Spin}^c(M)$ is an H–torsor with action denoted by $*$.

We denote by $\mathfrak{sw}_\sigma(M) \in \mathbb{Q}$ the *Seiberg–Witten invariant* of M indexed by the $spin^c$–structures $\sigma \in \mathrm{Spin}^c(M)$ (cf. Lim [2000] and Nicolaescu [2004]). We will use the sign convention of Braun and Némethi [2010] and Némethi [2011].

In the last years several combinatorial expressions were established for the Seiberg–Witten invariants. For rational homology spheres, Nicolaescu [2004] showed that $\mathfrak{sw}(M)$ is equal to the Reidemeister–Turaev torsion normalized by the Casson–Walker invariant. In the case when M is a negative definite plumbed rational homology sphere, combinatorial formula for Casson–Walker invariant in terms of the plumbing graph can be found in Lescop [1996], and the Reidemeister–Turaev torsion is determined by Némethi and Nicolaescu [2002] using Dedekind–Fourier sums. A different combinatorial formula of $\{\mathfrak{sw}_\sigma(M)\}_\sigma$ was proved in Némethi [2011] using qualitative properties of the coefficients of the series $Z(\mathbf{t})$.

Theorem 3.2.1. *Némethi [ibid.] The counting function of $Z_h(\mathbf{t})$ in the cone $S'_{\mathbb{R}}$ admits the (quasi)polynomial*

$$\mathfrak{Q}_h(l) = -\frac{(K+2r_h+2l)^2+|\mathcal{V}|}{8} - \mathfrak{sw}_{-h*\sigma_{can}}(M), \tag{3.2.2}$$

whose periodic constant is

$$\mathrm{pc}^{S'_{\mathbb{R}}}(Z_h(\mathbf{t})) = \mathfrak{Q}_h(0) = -\mathfrak{sw}_{-h*\sigma_{can}}(M) - \frac{(K+2r_h)^2+|\mathcal{V}|}{8}. \tag{3.2.3}$$

The right hand side of Equation (3.2.3) with opposite sign is called the *r_h–normalized Seiberg–Witten invariant* of M.

3.3 Surgery formulae for the normalized Seiberg–Witten invariants. Surgery formulae for a certain 3–manifold invariant, in general, compare the invariant of M with the invariants of different surgery modifications of M. In the case of plumbed 3–manifolds, one compares the invariants associated with 3–manifolds obtained by different modifications of the graph. The ‘standard’ topological surgery formulae for the Seiberg–Witten invariant (induced by exact triangles of certain cohomology theories, cf. Ozsváth and Szabó [2004a], Greene [2013], and Némethi [2011]) compare the invariants of three such 3–manifolds (see also Section 5.1 here). Furthermore, in these approaches, one cannot separate a certain fixed $spin^c$ structure, the theory mixes always several of them. (See also Turaev [2001].) The next formula is different: it compares the Seiberg–Witten invariant of two 3–manifolds via the periodic constant of a series, and they split according to the $spin^c$–structures.

Let us fix $v \in \mathcal{V}$ and consider the notations of Section 2.6. For each $j \in J$ we consider the inclusion operator $\iota_j : L(\Gamma_j) \to L(\Gamma)$, $E_v(\Gamma_j) \mapsto E_v(\Gamma)$; let $\iota_j^* : L'(\Gamma) \to L'(\Gamma_j)$ be its dual (the cohomological restriction defined by $\iota_j^*(E_v^*(\Gamma)) = E_v^*(\Gamma_j)$ if $v \in \mathcal{V}(\Gamma_j)$, and $= 0$ otherwise).

Next, consider an arbitrary $spin^c$–structure $\widetilde{\sigma}$ on $\widetilde{X}$. Since $\mathrm{Spin}^c(\widetilde{X})$ is an L'–torsor, there is a unique $l' \in L'$ such that $\widetilde{\sigma} = l' * \widetilde{\sigma}_{can}$. Its restriction to $\mathrm{Spin}^c(M)$ is $\sigma = [l'] * \sigma_{can}$. We write $\widetilde{\sigma}_j$ the restriction of $\widetilde{\sigma}$ to each $\widetilde{X}_j$. Since the canonical $spin^c$–structure of $\widetilde{X}$ restricts to the canonical $spin^c$–structure $\widetilde{\sigma}_{can,j}$ of $\widetilde{X}_j$, $\widetilde{\sigma} = l' * \widetilde{\sigma}_{can}$ restricts to $\widetilde{\sigma}_j := \iota_j^*(l') * \widetilde{\sigma}_{can,j} \in \mathrm{Spin}^c(\widetilde{X}_j)$, whose restriction to the boundary $M_j = M(X_j, o_j) = \partial \widetilde{X}_j$ is $\sigma_j = [\iota_j^*(l')] * \sigma_{can,j}$.

Theorem 3.3.1. *Braun and Némethi [2010] Fix $\mathcal{U} = \{v\}$ and $h \in H$. Extend $h * \sigma_{can} \in \mathrm{Spin}^c(M)$ as $\widetilde{\sigma} := r_h * \widetilde{\sigma}_{can} \in \mathrm{Spin}^c(\widetilde{X})$ and consider the corresponding restrictions. Then*

$$\mathfrak{sw}_{-h*\sigma_{can}}(M) + \frac{(K+2r_h)^2 + |\mathcal{V}|}{8} =$$
$$= \sum_j \Big(\mathfrak{sw}_{-[\iota_j^*(r_h)]*\sigma_{can,j}}(M_j) + \frac{(K(\Gamma_j) + 2\iota_j^*(r_h))^2 + |\mathcal{V}(\Gamma_j))|}{8} \Big) - \mathrm{pc}(Z_h^{\{v\}}(t_v)).$$

For a generalization to an arbitrary $\mathcal{U}$ and to an arbitrary extension $\widetilde{\sigma} := l' * \widetilde{\sigma}_{can}$ see László, Nagy, and Némethi [n.d.].

4 Topological invariants. The lattice cohomology of M

The $spin^c$–structures of M can also be indexed as follows. Set $\mathrm{Char} = \{k \in L' : (k + x, x) \in 2\mathbb{Z}$ for all $x \in L\}$, the set of characteristic elements of $\widetilde{X}$. Then L acts on Char by $l * k = k + 2l$, and the set of orbits $[k] = k + 2L$ is an H torsor identified with $\mathrm{Spin}^c(M)$.

For any $k \in \mathrm{Char}$ one also defines $\chi_k : L' \to \mathbb{Q}$ by $\chi_k(l') := -(l', l' + k)/2$. We write χ for χ_K.

The Seiberg–Witten invariant is the (normalized) Euler-characteristic of the Seiberg–Witten monopole Floer homology of Kronheimer–Mrowka, or equivalently, of the Heegaard–Floer homology of Ozsváth and Szabó. These theories had an extreme influence on the modern mathematics, solving (or disproving) a long list of old conjectures (e.g. Thom Conjecture, or conjectures regarding classification of 4-manifolds, or famous old problems in knot theory); see the long list of distinguished articles of Kronheimer–Mrowka or Ozsváth–Szabó. In Ozsváth and Szabó [2003b] Ozsváth and Szabó provided a computation of the Heegaard–Floer homology for some special plumbed 3-manifolds. This computation resonated incredibly with the theory of computation sequences used in Artin–Laufer program (see e.g. Laufer [1977] and Némethi [1999a,b]). These two facts influenced considerably the definition of the lattice cohomology.

4.1 Short review of Heegaard–Floer homology $HF^+(M)$. We assume that M is an oriented rational homology 3–sphere, and we restrict ourselves to the $+$–theory of Ozsváth and Szabó. The Heegaard–Floer homology $HF^+(M)$ is a $\mathbb{Z}[U]$–module with a $\mathbb{Q}$–grading compatible with the $\mathbb{Z}[U]$–action, where $\deg(U)=-2$. Additionally, $HF^+(M)$ has another $\mathbb{Z}_2$–grading; $HF^+(M)_{even}$, respectively $HF^+(M)_{odd}$ denote the graded parts. Moreover, $HF^+(M)$ has a natural direct sum decomposition of $\mathbb{Z}[U]$–modules (compatible with all the gradings): $HF^+(M)=\oplus_\sigma HF^+(M,\sigma)$ indexed by the $spin_c$–structures σ of M. For any σ one has

$$HF^+(M,\sigma)=\mathcal{T}^+_{d(M,\sigma)}\oplus HF^+_{red}(M,\sigma),$$

a graded $\mathbb{Z}[U]$–module isomorphism, where $\mathcal{T}^+_r$ denotes $\mathbb{Z}[U^{-1}]$ as a $\mathbb{Z}[U]$–module, in which the degree of 1 is r; and $HF^+_{red}(M,\sigma)$ has finite $\mathbb{Z}$–rank and an induced $\mathbb{Z}_2$–grading. One also considers

$$\chi(HF^+(M,\sigma)) := \operatorname{rank}_{\mathbb{Z}} HF^+_{red,even}(M,\sigma)-\operatorname{rank}_{\mathbb{Z}} HF^+_{red,odd}(M,\sigma).$$

Then via $\chi(HF^+(M,\sigma))-d(M,\sigma)/2$ one gets the Seiberg–Witten invariant of (M,σ). By changing the orientation one has $\chi(HF^+(M,\sigma))=-\chi(HF^+(-M,\sigma))$ and $d(M,\sigma)=-d(-M,\sigma)$.

4.2 Lattice cohomology of M. Now we review some facts from the lattice cohomology theory, introduced by the author in Némethi [2008a]. The construction captures the structure of lattice points inside of some real ellipsoids. $L\otimes\mathbb{R}$ has a natural cellular decomposition into cubes. The set of zero–dimensional cubes is provided by the lattice points L. Any $l\in L$ and subset $I\subset\mathcal{V}$ of cardinality q defines a q–dimensional cube (l,I), which has its vertices in the lattice points $(l+\sum_{i\in I'}E_j)_{I'}$, where I' runs over all subsets of I.

Next, we fix $k \in \mathrm{Char}$, we set $\chi_k(l) = -(l, l+k)/2$ and $m_k := \min_{l \in L} \chi_k(l)$. Finally, for any fixed integer $n \geq m_k$ we denote by S_n the union of all q–cubes in the real ellipsoid $\{l \in L \otimes \mathbb{R} \,:\, \chi_k(l) \leq n\}$. Then one defines

$$\mathbb{H}^p(\Gamma, k) := \oplus_{n \geq m_k} H^p(S_n, \mathbb{Z}).$$

For each fixed p, the module $\mathbb{H}^p$ is in a natural way $\mathbb{Z}$– (in fact, $2\mathbb{Z}$)–graded: $H^p(S_n, \mathbb{Z})$ consists of the $2n$–homogeneous elements. Also, it is a $\mathbb{Z}[U]$–module; the U–action is induced by the restriction $H^p(S_{n+1}, \mathbb{Z}) \to H^p(S_n, \mathbb{Z})$. Moreover, there is an augmentation decomposition

$$\mathbb{H}^0(\Gamma, k) = (\oplus_{n \geq m_k} \mathbb{Z}) \oplus (\oplus_{n \geq m_k} \widetilde{H}^0(S_n, \mathbb{Z})) = \mathcal{T}^+_{2m_k} \oplus \mathbb{H}^0_{red}(\Gamma, k).$$

This module $\mathbb{H}^*(\Gamma, k)$ is independent of the choice of the resolution (or plumbing) graph Γ (hence depends only on the 3-manifold M), and it depends only on the class $[k] = k + 2L$ (i.e. only on the corresponding $spin^c$–structure) up to a shift in grading. In order to fix one module in each class we take one $k' \in [k]$ with $m_{k'} = 0$, and we set $\mathbb{H}^*(\Gamma, [k]) := \mathbb{H}(\Gamma, k')$ (which is independent of the choice). For any rational number r we denoted by $\mathbb{H}^*(\Gamma, [k])[r]$ the module isomorphic to $\mathbb{H}^*(\Gamma, [k])$, but whose grading is shifted by r. (The $(d+r)$–homogeneous part of $\mathbb{H}^*(\Gamma, [k])[r]$ is isomorphic with the d–homogeneous part of $\mathbb{H}^*(\Gamma, [k])$.) It is also convenient to redefine $\mathbb{H}^p_{red} := \mathbb{H}^p$ for $p \geq 1$; this is motivated by the fact that $\mathbb{H}^*_{red} = \oplus_{p \geq 0} \mathbb{H}^p_{red}$ has finite $\mathbb{Z}$–rank.

5 The relations of the lattice cohomology with other invariants

5.1 Exact sequence. Let us fix a vertex v_0, we consider the graphs $\Gamma \setminus v_0$ and $\Gamma^+_{v_0}$, where the first one is obtained from Γ by deleting the vertex v_0 and adjacent edges, while the second one is obtained from Γ by increasing the decoration of the vertex v_0 by 1. We will assume that $\Gamma^+_{v_0}$ is still negative definite. Then there exists an exact sequence of $\mathbb{Z}[U]$–modules of the following type:

$$\cdots \longrightarrow \mathbb{H}^q(\Gamma^+_{v_0}) \longrightarrow \mathbb{H}^q(\Gamma) \longrightarrow \mathbb{H}^q(\Gamma \setminus v_0) \longrightarrow \mathbb{H}^{q+1}(\Gamma^+_{v_0}) \longrightarrow \cdots$$

The first 3 terms of the exact sequence (i.e. the $\mathbb{H}^0$–part) appeared in Ozsváth and Szabó [2003b] and Némethi [2005], the exact sequence over $\mathbb{Z}_2$–coefficients was proved in Greene [2013], the general case in Némethi [2011]. For more properties see Némethi [ibid.].

5.2 Rational singularities. By definition, (X, o) is rational if $p_g(X, o) = 0$. This is an analytic property, however, Artin replaced the vanishing of p_g by a topological criterion formulated in terms of χ: (X, o) is rational if and only if $\chi(l) > 0$ for any $l \in L_{>0}$ (independently of the resolution) Artin [1962, 1966]. For a different, the so–called 'Laufer's rationality criterion', see Laufer [1972]. Any connected negative definite graph with this property is called rational graph. The set of rational graphs include e.g. all the graphs with the following property: if e_v and δ_v denote the Euler decoration and the valency of a vertex, then one requires $-e_v \geq \delta_v$ for any $v \in \mathcal{V}$. Hence, if we decrease sufficiently the Euler decorations of any graph we get a rational graph. The class of rational graphs is closed while taking subgraphs and decreasing the Euler numbers.

Rationality in terms of the lattice cohomology is characterized as follows:

Theorem 5.2.1. *Némethi [2005] The following facts are equivalent:*

(a) Γ *is rational;*

(b) $\mathbb{H}^0(\Gamma, K) = \mathcal{T}_0^+$*;*

(c) $\mathbb{H}^0(\Gamma, K) = \mathcal{T}_m^+$ *for some* $m \in \mathbb{Z}$*; or equivalently,* $\mathbb{H}^0_{red}(\Gamma, K) = 0$*;*

(d) $\mathbb{H}^*_{red}(\Gamma, k) = 0$ *for all* $k \in \text{Char}$.

Moreover, if Γ *is rational then* $\min \chi_{k_r} = 0$.

5.3 (Weakly) elliptic singularities. A normal surface singularity (X, o) is called *elliptic*, if (one of its) resolution graph is elliptic. A graph Γ is elliptic if $\min_{l>0} \chi(l) = 0$ (cf. Wagreich [1970] and Laufer [1977], see also Némethi [1999b]).

The set of elliptic singularities includes all the singularities with $p_g = 1$, and all the Gorenstein singularities with $p_g = 2$. But an elliptic singularity might have arbitrary large p_g.

Ellipticity in terms of the lattice cohomology is characterized as follows:

Theorem 5.3.1. *The following facts are equivalent:*

(a) Γ *is elliptic;*

(b) $\mathbb{H}^0(\Gamma, K) = \mathcal{T}_0^+ \oplus \big(\mathcal{T}_0(1)\big)^{\oplus \ell}$ *for some* $\ell \geq 1$*. Here* $\mathcal{T}_0(1)$ *is a free* $\mathbb{Z}$*–module of rank one with trivial U–action and concentrated at degree 0. The integer* ℓ *above can be identified with the length of the elliptic sequence. In particular, if the graph* Γ *is minimally elliptic then* $\ell = 1$.

5.4 'Bad' vertices, AR graphs. We fix an integer $n \geq 0$. We say that a negative definite graph has at most n 'bad' vertices if we can find n vertices $\{v_k\}_{1 \leq k \leq n}$, such that by decreasing their Euler decorations we get a rational graph (this fact makes sense because of Section 5.2). In general, the choice of the bad vertices is not unique. A graph with at most one bad vertex is called *almost rational*, or AR, cf. Némethi [2005, 2008a]. Here are some AR graphs:

1) All rational and elliptic graphs are AR.

2) Any star-shaped graph is AR (modify the central vertex).

3) The rational surgery 3–manifolds $S^3_{-p/q}(\mathcal{K})$ ($\mathcal{K}$ algebraic knot, $p/q > 0$) are AR.

4) The class of AR graphs is closed while taking subgraphs and decreasing the Euler numbers.

Theorem 5.4.1. *Némethi [2011] If Γ has at most n bad vertices then $\mathbb{H}^q_{red}(\Gamma) = 0$ for $q \geq n$. In particular, if Γ is AR then $\mathbb{H}^0(\Gamma)$ is the only nonzero module.*

If Γ has at most $n \geq 2$ bad vertices $\{v_k\}_{1\leq k\leq n}$ such that $\Gamma \setminus v_1$ has at most $(n-2)$ bad vertices then $\mathbb{H}^q_{red}(\Gamma) = 0$ for $q \geq n-1$.

See Némethi [2005, (8.2)(5.b)] for a graph Γ with 2 bad vertices $\{v_1, v_2\}$ such that $\Gamma \setminus v_1$ has only rational components.

5.5 Relation with Heegaard–Floer theory. In Némethi [2008a] the author formulated the following

Conjecture 5.5.1. *For any plumbed rational homology sphere associated with a connected negative definite graph Γ, and for any $k \in$ Char, one has*

$$d(M,[k]) = \max_{k'\in[k]} \frac{(k')^2 + |\mathcal{V}|}{4} = \frac{k^2 + |\mathcal{V}|}{4} - 2\cdot \min \chi_k .$$

Furthermore,

$$HF^+_{red,even}(-M,[k]) = \bigoplus_{p\ even} \mathbb{H}^p_{red}(\Gamma,[k])[-d], \ and$$
$$HF^+_{red,odd}(-M,[k]) = \bigoplus_{p\ odd} \mathbb{H}^p_{red}(\Gamma,[k])[-d].$$

Both parts of the Conjecture were verified for almost rational graphs in Némethi [ibid.], for two bad vertices in Ozsváth, Stipsicz, and Szabó [2014], see Némethi [2008a, p. 8.4] too. Otherwise, the Conjecture is still open.

Note that (conjecturally) $\mathbb{H}^*$ has a richer structure: its p–filtration $\mathbb{H}^* = \oplus_p \mathbb{H}^p$ collapses at the level of HF^+ to a $\mathbb{Z}_2$ odd/even filtration.

5.6 Relation with Seiberg–Witten invariant. For any $k \in$ Char the (normalized) Euler characteristic of the lattice cohomology is defined as

$$\mathfrak{eu}(\mathbb{H}^*(\Gamma,k)) := -\min \chi_k + \sum_p (-1)^p \operatorname{rank} \mathbb{H}^p_{red}(\Gamma,k).$$

Then, it turns out that the (normalized) Euler characteristic of the lattice cohomology equals the (normalized) Seiberg–Witten invariant Némethi [2011] (this fact supports Conjecture 5.5.1 too):

$$-\mathfrak{sw}_{[k]}(M) - \frac{k^2 + |\mathcal{V}|}{8} = -\min \chi_k + \sum_p (-1)^p \operatorname{rank} \mathbb{H}^p_{red}(\Gamma, k).$$

5.7 Relation with L–spaces. By Section 5.2 Γ is rational if and only if $\mathbb{H}^*_{red}(\Gamma) = 0$. On the other hand, following Ozsváth and Szabó, M is an L–space by definition if and only if $HF^+_{red} = 0$. Their equivalence is predicted by Conjecture 5.5.1; in fact this 'tip of the iceberg' statement was proved in Némethi [2017]:

Theorem 5.7.1. *The following facts are equivalent:*
(i) (X, o) is a rational singularity (or, Γ is a rational graph),
(ii) the link M is an L–space.

$(i) \Rightarrow (ii)$ follows from lattice cohomology theory Némethi [2005, 2008a], while $(ii) \Rightarrow (i)$ uses partly the following equivalence $(ii) \Leftrightarrow (iii)$, where (iii) means that $\pi_1(M)$ is not a left–orderable group. The equivalence $(ii) \Leftrightarrow (iii)$ was proved in Hanselman, J. Rasmussen, S. D. Rasmussen, and Watson [n.d.] for any graph–manifolds. For arbitrary 3–manifolds was conjectured by Boyer, Gordon, and Watson [2013], for different developments and other references see Hanselman, J. Rasmussen, S. D. Rasmussen, and Watson [n.d.] and Némethi [2017].

Problem 5.7.2. Characterize elliptic singularities by a certain property of $\pi_1(M)$.

5.8 Reductions. In the lattice cohomology computations it is convenient to take a special representative k for the $spin^c$–structure $[k]$. Indeed, if $s_h \in L'$ is the minimal representative of $h \in H$ in $\mathcal{S}'$, and we take $k_r := K + 2s_h$ as representative for $[k]$, and we define the weighted cubes with the weight function χ_{k_r}, then one has the following 'homotopical identity': $H^p(S_n, \mathbb{Z}) = H^p(S_n \cap L_{\geq 0}, \mathbb{Z})$, where $S_n \cap L_{\geq 0}$ denotes the subset of S_n consisting of cubes with all vertices in $L_{\geq 0}$. Hence, with the natural notations (after notational modification $\mathbb{H}^*(L, k) = \mathbb{H}^*(\Gamma, k)$) we have

Theorem 5.8.1. *László and Némethi [2015]* $\mathbb{H}^*(L, \chi_{k_r}) = \mathbb{H}^*(L_{\geq 0}, \chi_{k_r})$.

This can be reduced even further. Fix k_r as above, that is $k_r = K + 2s_h$ for some h, and rewrite s_h as $s_{[k]}$. Assume that $\overline{\mathcal{V}} \subset \mathcal{V}$ is a set of bad vertices. Set also $\mathcal{V}^* := \mathcal{V} \setminus \overline{\mathcal{V}}$. Let $\overline{L}$ be the free $\mathbb{Z}$–submodule of L spanned by the (base elements of) $\overline{\mathcal{V}}$, and let $\overline{L}_{\geq 0}$ be its first quadrant. Next we introduce a special weight function for the points of $\overline{L}_{\geq 0}$ (which, in general, is not a Riemann–Roch type formula, it is not even quadratic).

For any $\mathbf{i} = (i_{v_1}, \dots) \in \overline{L}_{\geq 0}$ we define the element $x(\mathbf{i}) \in L$ by the following universal property:

(i) the coefficient of E_v in $x(\mathbf{i})$ is i_v for any $v \in \overline{\mathcal{V}}$,
(ii) $(x(\mathbf{i}) + s_{[k]}, E_v) \leq$ for every $v \in \mathcal{V}^*$,
(iii) $x(\mathbf{i})$ is minimal with the properties (i)-(ii).

The definition is motivated by the theory of generalized computation sequences used in singularity theory Laufer [1972, 1977] and Némethi [1999a,b].

Set $w_{k_r}(\mathbf{i}) := \chi_{k_r}(x(\mathbf{i}))$, the weight function of $\overline{L}_{\geq 0}$. Using this weight function, one defines the weight of any cube of $\overline{L}_{\geq 0}$ as the maximum of the weights of the vertices of the cube, and one also repeats the definition of S_n and of the lattice cohomology similarly as above.

Theorem 5.8.2. Reduction Theorem. *László and Némethi [2015]* $\mathbb{H}^*(L_{\geq 0}, \chi_{k_r}) = \mathbb{H}^*(\overline{L}_{\geq 0}, w_{k_r})$.

In particular, if Γ is AR (and $\mathbb{H}^p = 0$ for any $p > 0$ by Theorem 5.4.1) $\mathbb{H}^0(\Gamma, [k])$ for any $spin^c$–structure $[k]$ is determined by the sequence of integers $\{\tau(i)\}_{i \in \mathbb{Z}_{\geq 0}}$, $\tau(i) := \chi_{k_r}(x(i))$, where i is the coordinate of the bad vertex v. This was intensively used in concrete computations. The star–shaped graphs are AR, their τ–functions are described in terms of Seifert invariants in Némethi [2005].

If $\mathcal{K} \subset S^3$ is an algebraic knot (that is, one of its representative can be cut out by an isolated irreducible plane curve singularity germ $f_{\mathcal{K}}$), then the surgery 3–manifold $S^3_{-p/q}(\mathcal{K})$ for $p/q \in \mathbb{Q}_{>0}$ is a plumbed 3–manifold associated with a negative definite AR graph. For their τ–function see Némethi [2007]. This can be determined in terms of the semigroup of $f_{\mathcal{K}}$.

More generally, if $\{\mathcal{K}_i\}_{i=1}^N$ are algebraic knots then the graph of $S^3_{-p/q}(\#_i \mathcal{K})$ and the reduced weights together with the lattice cohomology in terms of the semigroups are determined in Némethi and Román [2012].

Theorem 3.2.1 has its 'reduction' as well. Indeed, one defines the reduction $Z^{\overline{\mathcal{V}}}$ of the series $Z(\mathbf{t})$ to the variables $\{t_v\}_{v \in \overline{\mathcal{V}}}$ (similarly as in Sections 2.5 and 3.3, by taking $t_v = 1$ for any $v \notin \overline{\mathcal{V}}$), and László and Némethi [2015] proves for it the analogue of Theorem 3.2.1. In particular, the Seiberg–Witten invariants can also be recovered as the periodic constants of the reduces series.

5.9 Ehrhart theory. In László and Némethi [2014] the Seiberg–Witten invariant (of a negative definite plumbed 3–manifold) is identified with the third coefficient of certain equivariant Ehrhart polynomial.

5.10 $Z(\mathbf{t})$ and $\mathfrak{eu}$ in terms of weighted cubes. Above in the definition of the lattice cohomology we used for each $spin^c$–structure a different weighted lattice. This can be unified in a common weighted lattice Némethi [2011] and Ozsváth, Stipsicz, and Szabó [2014]. Here we follow Némethi [2011]. The set of p–cubes consists of pairs (k, I), where $k \in \mathrm{Char}$ and $I \subset \mathcal{V}$, $|I| = p$. This pair can be identified with a cube in $L \otimes \mathbb{R}$ with vertices $\{k + 2E_{I'}\}_{I' \subset I}$. One defines the weight function induced by the intersection form $w : \mathrm{Char} \to \mathbb{Q}$ by $w(k) := -(k^2 + |\mathcal{V}|)/8$, which extends to a weight–function of the q–cubes via $w((k, I)) = \max_{I' \subset I}\{ w(k + 2E_{I'})\}$. (The correspondence between the two languages, for any fixed $[k]$, is realized by $k = K + 2s_{[k]} + 2l \leftrightarrow l$ and a universal constant shift in the weights.) The point is that in this language of weighted cubes the topological series $Z(\mathbf{t})$ can also be expressed Némethi [ibid.] as:

$$Z(\mathbf{t}) = \sum_{k \in \mathrm{Char}} \sum_{I \subset \mathcal{V}} (-1)^{|I|+1}\, w((k, I)) \cdot \mathbf{t}^{\frac{1}{2}(k-K)}. \tag{5.10.1}$$

Note that $\mathrm{Char} = K + 2L' \subset L'$, hence $(k - K)/2$ runs over L' when k runs over Char.

The normalized Seiberg–Witten invariant, or the normalized Euler characteristic of the lattice cohomology can also be determined directly by a weighted cube counting (this is really the analogue how Euler defined the classical Euler characteristic via alternating sum of p–cells/cubes). Since we have infinitely many cubes in $L \otimes \mathbb{R}$, we need to consider a 'truncation'.

Let us fix the class $[k]$. For any two $k_1, k_2 \in [k] \subset \mathrm{Char}$ with $k_1 \le k_2$ let $R(k_1, k_2)$ denote the rectangle $\{x \in L \otimes \mathbb{R} \ : \ k_1 \le x \le k_2\}$. Then we can consider the set of cubes (k, I) with $k \in [k]$ and situated with all vertices in $R(k_1, k_2)$ and the corresponding lattice cohomology $\mathbb{H}^*(R(k_1, k_2), w)$.

Theorem 5.10.2. *For 'good' choices of k_1, k_2 (with $k_1 \ll 0$ and $k_2 \gg 0$), and with the abridgment $R = R(k_1, k_2)$, one has the isomorphism of $\mathbb{Z}[U]$–modules $\mathbb{H}^*(\Gamma, k_r) = \mathbb{H}^*(R, w)$. Furthermore,*

$$\begin{aligned} \mathfrak{eu}(\mathbb{H}^*(\Gamma, k_r)) &= -\min(w|R) + \sum_p (-1)^p \,\mathrm{rank}_{\mathbb{Z}}\ \mathbb{H}^p_{red}(R, w) \\ &= \sum_{(k,I) \subset R} (-1)^{|I|+1} w((k, I)). \end{aligned}$$

Note that $Z(\mathbf{t})$ determines the intersection form $(\ ,\ )$ of the lattice L, hence the lattice cohomology as well (note also the direct 'periodic constant formula' for the Seiberg–Witten invariant).

Problem 5.10.3. Find a universal construction, which assigns to any series $S(\mathbf{t})$ a graded $\mathbb{Z}[U]$–module, such that it applied to $Z(\mathbf{t})$ we recover $\mathbb{H}^*$.

5.11 The fundamental group of M. In fact, the same question can be asked for the fundamental group of M. Note that $\pi_1(M)$ determines M in a unique way (except for lens spaces, a case which can be disregarded, since they have trivial $\mathbb{H}^*_{red}$).

Problem 5.11.1. Find a universal construction, which assigns to any group a graded $\mathbb{Z}[U]$–module, such that it applied to $\pi_1(M)$ we recover $\mathbb{H}^*$.

5.12 Another surgery formula for $\mathbb{H}^*$. Recall the surgery formulae 3.3.1 valid for the Seiberg–Witten invariant involving the periodic constant as a 'correction term'.

Problem 5.12.1. Find its analogue at the level of $\mathbb{H}^*$. (This is related with Problem 5.10.3 too).

5.13 Path lattice cohomology. Consider the situation of Section 4.2 with fixed Γ, and $k = K$ and weight function $\chi = \chi_K$. Furthermore, consider a sequence $\gamma := \{x_i\}_{i=0}^t$ so that $x_0 = 0$, $x_{i+1} = x_i + E_{v(i)}$ for certain $v(i) \in \mathcal{V}$ for each $0 \leq i < t$, and $x(t) \in -K + \mathcal{S}'$. Then for the union of 0–cubes marked by the points $\{x_i\}_i$ and segments (1–cubes) of type $[x_i, x_{i+1}]$ we can repeat the definition of the lattice cohomology (associated with χ_k), and we get a graded $\mathbb{Z}[U]$–module $\mathbb{H}^*(\gamma, K)$. In fact, only $\mathbb{H}^0$ is nonzero, and $\mathbb{H}^0(\gamma, K) = \mathcal{T}^+_{2\min_i\{\chi(x_i)\}} \oplus \mathbb{H}^0_{red}(\gamma, K)$. This is called the path–cohomology associated with the 'path' γ and χ. Similarly as in Section 5.6, we consider its normalized Euler characteristic

$$eu(\mathbb{H}^0(\gamma, K)) := -\min_i\{\chi(x_i)\} + \mathrm{rank}_{\mathbb{Z}}\, \mathbb{H}^0_{red}(\gamma, K).$$

One shows that

$$eu(\mathbb{H}^0(\gamma, K)) = \sum_{i=0}^{t-1} \max\{\chi(x_i), \chi(x_{i+1})\} - \chi(x_{i+1}) = \sum_{i=0}^{t-1} \max\{(x_i, E_{v(i)}) - 1, 0\}.$$

It is convenient to introdce the following notation as well (cf. Section 5.6):

$$eu(\mathbb{H}^0(\Gamma, K)) := -\min\chi + \mathrm{rank}\, \mathbb{H}^0_{red}(\Gamma, K).$$

It turns out (cf. Némethi and Sigurdsson [2016]) that

$$\min_\gamma\, eu(\mathbb{H}^0(\gamma, K)) \leq eu(\mathbb{H}^0(\Gamma, K)).$$

5.14 Graded roots. For each Γ and $k \in \mathrm{Char}$, the author in Némethi [2005] constructed a *graded root*, from which one recovers by a natural procedure $\mathbb{H}^0(\Gamma, k)$. This is tree whose vertices are $\mathbb{Z}$–graded, the weight n–vertices correspond to the connected components of S_n, and the edges of the tree to the possible inclusions of the components of S_n to the components of S_{n+1} (this at the $\mathbb{H}^0(\Gamma, k)$ level is codified in the U–action). For AR graphs it contains all the lattice cohomology (hence Heegaard–Floer) information, but it codifies completely the inclusions of the S_n–components (a fact, which from the U–action cannot be recovered).

There is a parallel characterization of rational and elliptic graphs in terms of graded roots too.

5.15 Classification of singularities. The ‘Artin-Laufer program’ starts the classification of singularities with the class of rational and elliptic singularities — it identifies topologically the families, and then (under certain analytic conditions in the elliptic case, e.g. Gorenstein property) determines certain analytic invariants (multiplicity, Hilbert function) by uniform formulae for each family.

In order to continue this program, we first have to identify subfamilies for which one can show that they share ‘common properties’. We propose to identify these subfamilies by graded roots, or by the (slightly weaker) $\mathbb{Z}[U]$–module $\mathbb{H}^0(\Gamma, K)$ (or, we can even consider the whole $\mathbb{H}^*(\Gamma, K)$) Némethi [2007].

Though we know all the possible topological types (namely, the singularity resolution graphs are exactly the connected negative definite graphs), it is not clear at all what graded tree might appear as a graded root associated with a resolution graph.

Problem 5.15.1. Classify all the possible graded roots associated with all (Γ, K) of normal surface singularities. Is there any hidden structure property carried by the $\mathbb{Z}[U]$–modules $\mathbb{H}^*(\Gamma, k)$ associated with topological type of singularities? It is possible to describe all the possible modules produced in this way?

6 Analytic – topological connections. The Seiberg–Witten Invariant Conjecture

In this section we treat a set of possible properties connecting the analytic invariants with the topological ones, namely, the equivariant geometric genera with the Seiberg–Witten invariants of the link. When they are valid they provide a topological description of the equivariant geometric genera. The identities are generalizations of the statement of the Casson Invariant Conjecture of Neumann and Wahl to the case of normal surface singularities with rational homology sphere links.

Conjecture 6.0.1. Seiberg–Witten Invariant Conjecture/Coincidence.

We say that (X,o) satisfy the equivariant SWIC if for any $h \in H$ the following identity holds

$$h^1(\widetilde{X}, \mathcal{O}(-r_h)) = -\mathfrak{sw}_{-h*\sigma_{can}}(M) - \frac{(K+2r_h)^2+|\mathcal{V}|}{8}. \tag{6.0.2}$$

Its validity automatically extends to arbitrary natural line bundles as follows:

$$h^1(\widetilde{X}, \mathcal{O}(l')) = -\mathfrak{sw}_{[l']*\sigma_{can}}(M) - \frac{(K-2l')^2+|\mathcal{V}|}{8}. \tag{6.0.3}$$

We say that (X,o) satisfies the SWIC if the above identity holds for $h=0$, that is, if

$$p_g(X,o) = -\mathfrak{sw}_{\sigma_{can}}(M) - \frac{K^2+|\mathcal{V}|}{8}. \tag{6.0.4}$$

The identity SWIC was formulated as a conjecture in Némethi and Nicolaescu [2002], while the equivariant case in Némethi [2007]: the expectation was that it holds for any $\mathbb{Q}$–Gorenstein singularity. Now we know that this is not true for this large class of singularities (see Luengo-Velasco, Melle-Hernández, and Némethi [2005]), although it is valid for large number of smaller families of singularities. But even in the case of those families when it fails, it still indicates interesting 'virtual' properties. The limits of the validity of the properties are not clarified at this moment. Having in mind the existence of cases when the identity does not hold, one might say that it is not totally justified the name SWI 'Conjecture', although this was its name in the literature in the last ten years. Hence, the reader might read the abbreviation SWIC as SWI 'Coincidence' too.

Example 6.0.5. CIC of Neumann and Wahl [1990] Assume that (X,o) is Gorenstein and it admits a smoothing with smooth nearby Milnor fiber F. Then the signature of F satisfies $\sigma(F)+8p_g+K^2+|\mathcal{V}|=0$, hence the SWIC for $h=0$ reads as $\sigma(F)/8 = \mathfrak{sw}_{\sigma_{can}}(M)$. (In this case, usually, $\sigma(F)/8$ is not an integer.) Additionally, if (X,o) is a complete intersection with integral homology sphere link, then $\mathfrak{sw}_{\sigma_{can}}(M)$ equals the Casson invariant $\lambda(M)$ of M, hence the above identity reads as $\sigma(F)/8=\lambda(M)$. This is the Casson Invariant Conjecture of Neumann and Wahl, predicted for any complete intersection with integral homology sphere link Neumann and Wahl [ibid.].

The CIC was solved for weighted homogeneous singularities and hypersurface suspension singularities ($(X,o)=\{f(x,y)+z^N=0\}$) in Neumann and Wahl [ibid.], for splice singularities (which includes the weighted homogeneous case as well) in Némethi and Okuma [2009]. The general case is still open.

6.1 Regarding the validity of SWIC.

We have the following statement:

Theorem 6.1.1. *The equivariant SWIC was verified in the following cases: rational singularities Némethi and Nicolaescu [2002], weighted homogeneous singularities Némethi and Nicolaescu [2002, 2004], splice quotient singularities Némethi and Okuma [2008].*

Additionally, the SWIC (for $h = 0$) was verified for suspensions $\{f(x, y) + z^N = 0\}$ with f irreducible Némethi and Nicolaescu [2005], for hypersurface Newton non–degenerate singularities Sigurdsson [2016] and superisolated singularities with one cusp Fernández de Bobadilla, Luengo-Velasco, Melle-Hernández, and Némethi [2006, 2007] and Borodzik and Livingston [2014]. Since the identity of the SWIC is stable with respect to equisingular deformations, the SWIC remains valid for such deformations of any of the above cases.

Recall that (X, o) is a hypersurface superisolated singularity if

$$(X, o) = \{f(x_1, x_2, x_3) = 0\}$$

where f is a hypersurface singularity with isolated singularity and the homogeneous terms $f_d + f_{d+1} + \cdots$ of f satisfy the following properties: $C := \{f_d = 0\}$ is reduced and it defines in $\mathbb{CP}^2$ an irreducible rational cuspidal curve C; furthermore, the intersection $\{f_{d+1} = 0\} \cap \mathrm{Sing}\{f_d = 0\}$ in $\mathbb{CP}^2$ is empty. The restriction regarding f_d implies that the link of (X, o) is a rational homology sphere. One shows that the minimal good graph of (X, o) has ν bad vertices, where ν is the number of cusps of C.

In all cases $p_g = d(d-1)(d-2)/6$, hence it depends only on d, however the Seiberg–Witten invariant (and the plumbing graph too) depend essentially on the type of cusps of C (see Section 6.4 below).

For superisolated singularities in certain cases when C is not unicuspidal the SWIC ($h = 0$ case) is not true Luengo-Velasco, Melle-Hernández, and Némethi [2005].

6.2 The path lattice cohomology bound of p_g. The failure of the SWIC in the case of superisolated singularities motivated a parallel deeper study of these germs. Surprisingly, in this case a rather natural universal bound of p_g will become equality.

Consider the set of paths $\mathfrak{P}$, $\gamma := \{x_i\}_{i=0}^t$ so that $x_0 = 0$, $x_{i+1} = x_i + E_{v(i)}$ for certain $v(i) \in \mathcal{V}$ for each $0 \leq i < t$, and $x(t) \in -K + \mathcal{S}'$. (If Γ is numerically Gorenstein we can even take $x(t) = -K$.) Then, considering the cohomology exact sequences $0 \to \mathcal{O}_{E_{v(i)}}(-x_i) \to \mathcal{O}_{x_{i+1}} \to \mathcal{O}_{x_i} \to 0$, we obtain that $p_g \leq \mathrm{eu}(\mathbb{H}^0(\gamma, K))$. Therefore,

$$p_g \leq \min_{\gamma \in \mathfrak{P}} \mathrm{eu}(\mathbb{H}^0(\gamma, K)). \tag{6.2.1}$$

This inequality is in the spirit of computational sequences initiated by Laufer and used intensively in Laufer [1972, 1977], Némethi [1999a], and László and Némethi [2015]. From this point of view, this relation, in some sense, is even more natural then that required by the SWIC. Note that in Equation (6.2.1) equality holds if and only if all the cohomology exact sequence (along a path which minimalizes the right hand side) split. The point is that this happens for certain key families.

Theorem 6.2.2 (Némethi and Sigurdsson [2016]). *The identity*

$$p_g = \min_{\gamma \in \mathfrak{P}} \mathfrak{eu}(\mathbb{H}^0(\gamma), K)$$

holds in the following cases:

(a) if $p_g = \mathfrak{eu}(\mathbb{H}^0(\Gamma, K))$ *(this happens e.g. if* $\mathbb{H}^q(\Gamma, K) = 0$ *for* $q \geq 1$ *and* (X, o) *satisfies the SWIC). In particular,* $p_g = \min_{\gamma \in \mathfrak{P}} \mathfrak{eu}(\mathbb{H}^0(\gamma), K)$ *holds for all weighted homogeneous and minimally elliptic singularities.*

(b) rational and Gorenstein elliptic singularities;

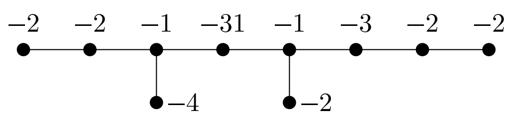
(c) for superisolated singularities (with arbitrary number of cusps);

(d) for hypersurface singularities with non-degenerate Newton principal part.

Again, since the identity is stable with respect to equisingular deformations, it remains valid for such deformations of any of the above cases.

The next example shows that in the case of superisolated singularities the non-vanishing of $\mathbb{H}^q(M)$ $(1 \leq q < \nu)$ obstructs the validity of the SWIC.

Example 6.2.3. Némethi and Sigurdsson [ibid.] Assume that (X, o) is a superisolated singularity with C of degree $d = 5$ and two cusps, both with one Puiseux pair: $(3, 4)$ and $(2, 7)$ respectively. The graph Γ is



We set $k = K$. One shows that $\min \chi = -5$, $\mathrm{rank}_{\mathbb{Z}}(\mathbb{H}^0_{red}) = 5$, $\mathrm{rank}_{\mathbb{Z}}(\mathbb{H}^1) = 2$. Hence $\mathfrak{eu}(\mathbb{H}^*) = 8$. Since for the superisolated germ with $d = 5$ one has $p_g = 10$, using Section 5.6 we get that the SWIC is not valid. On the other hand, $\min_\gamma \mathfrak{eu}(\mathbb{H}^0(\gamma, K)) = 10$ as well, hence $p_g = \min_\gamma \mathfrak{eu}(\mathbb{H}^0(\gamma, K))$, as it is predicted by the above theorem.

If we take any other analytic structure supported by Γ, by Equation (6.2.1) $p_g \leq 10$ still holds.

This graph (that is, topological type) supports another natural analytic structure as well, namely a splice quotient analytic type (compare with Section 7.2): it is the $\mathbb{Z}_5$–factor of the complete intersection $\{z_1^3 + z_2^4 + z_3^5 z_4 = z_3^7 + z_4^2 + z_1^4 z_2 = 0\} \subset (\mathbb{C}^4, 0)$ by the diagonal action $(\alpha^2, \alpha^4, \alpha, \alpha)$ $(\alpha^5 = 1)$. By Theorem 6.1.1 it satisfies the SWIC, hence $p_g = 8$.

In particular, in their choices of the topological characterization of their geometric genus, some analytic structures prefer $eu(\mathbb{H}^*(\Gamma, K))$, some of them the extremal

$$\min_{\gamma} eu(\mathbb{H}^0(\gamma, K))$$

(and there might exists even other choices, as parts/versions of the lattice cohomology). From this point of view the abridgement SWIC might also mean 'SWI Choice'.

6.3 What is the optimal topological lower/upper bounds of p_g? We are guided by the following key question: If one fixes a topological type (say, a minimal good resolution graph) and varies the possible analytic structures supported on this fixed topological type, then what are the possible values of the geometric genus p_g? A more concrete version is formulated as follows:

Problem 6.3.1. Associate combinatorially a concrete integer $\mathrm{MAX}(\Gamma)$ to any resolution graph Γ, such that for any analytic type supported by Γ one has $p_g \leq \mathrm{MAX}(\Gamma)$, and furthermore, for certain analytic structure one has equality.

Obviously, one can ask for the symmetric $\mathrm{MIN}(\Gamma)$ as well. But for the optimal lower bound we know the answer. A possible candidate is the 'artihmetical genus' $p_a(X, o) = 1 - \min \chi$ Wagreich [1970]. Indeed, for any analytic structure, whenever $p_g > 0$, one also has $1 - \min\chi \leq p_g$ Wagreich [ibid., p. 425].

The inequality looks not very sharp, however we have the following statement:

Theorem 6.3.2. *For any non–rational topological type $p_g = 1 - \min\chi$ for the generic analytic structure. (In particular, for non–rational graphs $\mathrm{MIN}(\Gamma)$ is exactly $1 - \min\chi$.)*

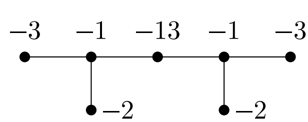
This was proved for elliptic singularities in Laufer [1977], the general case in Némethi and Nagy [n.d.].

A possible upper bound for p_g, hence a candidate for $\mathrm{MAX}(\Gamma)$, is $\min_{\gamma\in\mathfrak{P}} eu(\mathbb{H}^0(\gamma))$, cf. Equation (6.2.1).

However, for the next graph, $p_g \leq \min_{\gamma\in\mathfrak{P}} eu(\mathbb{H}^0(\gamma))$ is not sharp. Indeed

$$\min_{\gamma\in\mathfrak{P}} eu(\mathbb{H}^0(\gamma)) = 4$$

while for *any* analytic type $p_g \leq 3$ Némethi and Okuma [2017]. (For any Gorenstein structure one has $p_g = 3$, nevertheless, $p_g = 3$ can be realized by non–Gorenstein structure as well.)



6.4 Superisolated singularities revisited. Assume that the superisolated germ f is associated with the projective rational cuspidal curve C, as in Section 6.1. Here two main parts of the algebraic/analytic geometry meat: the classification of projective plane curves with the theory of local singularities. One of the aims of the classification of projective plane curves is to list the set of local topological types of plane curve singularities which can be realized as singularities of a degree d projective cuspidal curve. The strategy is to impose restrictions, obstructions for such realizations from the theory of singularities applied for the corresponding superisolated singularities. E.g., if $\{\mathcal{K}_i \subset S^3\}_{i=1}^{\nu}$ are the local algebraic knots of the plane curve singularities $\{(C,p_i)\}_{i=1}^{\nu}$ of C, and $\deg(C)=d$, then the link of the superisolated germ (X,o) is $M = S^2_{-d}(\#_i\mathcal{K}_i)$. Furthermore, if μ_i is the Milnor number of $(\mathcal{K}_i \subset S^3)$, then by the genus formula and the rationality of C implies $\sum_i \mu_i = (d-1)(d-2)$, hence d is uniquely determined by the local knot–types. The question whether we can impose any other restriction on M from the existence of C.

In the next presentation we follow Bodnár and Némethi [2016] and Fernández de Bobadilla, Luengo-Velasco, Melle-Hernández, and Némethi [2006, 2007]. Let us introduce the following notations. For each (C,p_i) (or $\mathcal{K}_i \subset S^3$) let Δ_i denote the Alexander polynomial (normalized as $\Delta_i(1)=1$) and $\Gamma_i \subset \mathbb{Z}_{\geq 0}$ the semigroup of (C,p_i). Recall that $\Delta_i(t) = (1-t)\cdot\sum_{k\in\Gamma_i} t^k$ Guseĭn-Zade, Delgado, and Kampil'o [1999], and $\#\{\mathbb{Z}_{\geq 0}\setminus\Gamma_i\} = \delta_i = \mu_i/2$ (the so-called delta–invariant, or genus of (C,p_i)), and write $\delta := \sum_i \delta_i = (d-1)(d-2)/2$.

Furthermore, consider the product of Alexander polynomials:

$$\Delta(t) := \Delta_1(t)\Delta_2(t)\cdots\Delta_\nu(t).$$

There is a unique polynomial Q for which $\Delta(t) = 1+\delta(t-1)+(t-1)^2Q(t)$. Write $Q(t) = \sum_{j=0}^{2\delta-2} q_j t^j$. For $\nu=1$ one shows

$$Q(t) = \sum_{s\notin\Gamma_1}(1+t+\cdots+t^{s-1}), \text{ hence } q_j = \#\{s\notin\Gamma_1 : s>j\} \quad (\text{if } \nu=1). \tag{6.4.1}$$

Next, set the rational function

$$R(t) := \frac{1}{d}\sum_{\xi^d=1}\frac{\Delta(\xi t^{1/d})}{(1-\xi t^{1/d})^2} - \frac{1-t^d}{(1-t)^3}. \tag{6.4.2}$$

In Fernández de Bobadilla, Luengo-Velasco, Melle-Hernández, and Némethi [2006, (2.4)] is proved that $R(t)$ is a symmetric polynomial ($R(t) = t^{d-3}R(1/t)$), and

$$R(t) = \sum_{j=0}^{d-3}\Big(q_{(d-3-j)d} - \frac{(j+1)(j+2)}{2}\Big)t^{d-3-j}. \tag{6.4.3}$$

In fact, if we reduce the variables of $Z(\mathbf{t})$ and $\mathcal{P}(\mathbf{t})$ to the variable t corresponding to $\mathfrak{U} := \{C\} \subset \mathcal{V}$ then $R(t) = Z^{\mathfrak{U}}_{h=0}(t) - \mathcal{P}^{\mathfrak{U}}_{h=0}(t)$, hence, by surgery formulae 2.6.1 and 3.3.1 we get that

$$(6.4.4) \qquad R(1) = -\mathfrak{sw}_{\sigma_{can}}(M) - (K^2 + |\mathcal{V}|)/8 - p_g(X,o).$$

Hence the vanishing of $R(1)$ is equivalent with the SWIC for (X,o). Moreover, in Fernández de Bobadilla, Luengo-Velasco, Melle-Hernández, and Némethi [ibid.] is also proved that for $\nu = 1$ all the coefficients of $R(t)$ are nonnegative, hence $(R(1) \leq 0) \Leftrightarrow (R(1) = 0) \Leftrightarrow$ all coefficients of $R(t)$ are zero. On the other hand, by Theorem 6.1.1, for $\nu = 1$ one has $R(1) = 0$ indeed. This implies the vanishing of all coefficients of $R(t)$; hence Equations (6.4.1) and (6.4.3) combined provide the strong *semigroup distribution property* of Γ_1, which must be satisfied by any collection of local knot types and degree d whenever the data is realized by a curve C.

In Fernández de Bobadilla, Luengo-Velasco, Melle-Hernández, and Némethi [ibid.] we conjectured that for any rational cuspidal plane curve $C \subset \mathbb{C}P^2$ of degree d with arbitrary number of cusps all the coefficients of $R(t)$ are non–positive. In Bodnár and Némethi [2016] is proved that this is indeed true for any $\nu \leq 2$, but it fails, in general, for $\nu \geq 3$. The corrected conjecture, as formulated in Bodnár and Némethi [ibid.] is the following:

Conjecture 6.4.5. Bodnár and Némethi [ibid.] For any superisolated germ

$$R(1) \leq 0, \quad \text{that is,} \quad p_g \geq -\mathfrak{sw}_{\sigma_{can}}(M) - (K^2 + |\mathcal{V}|)/8.$$

In Bodnár and Némethi [ibid.] this conjecture is proved for $\nu \leq 2$ and verified for all 'known' rational cuspidal curves with $\nu \geq 3$. The next reformulation of this conjecture in terms of the lattice cohomology emphasize once again the differences and resemblances between $\mathfrak{eu}(\mathbb{H}^*(\Gamma, K))$ and $\mathfrak{eu}(\mathbb{H}^0(\Gamma, K))$.

Conjecture 6.4.6. *Bodnár and Némethi [ibid.] For the link $M = S^3_{-d}(\#_i \mathcal{K}_i)$ of a superisolated surface singularity corresponding to a rational cuspidal projective plane curve of degree d we have:*

$$\mathfrak{eu}(\mathbb{H}^*(M,K)) \leq \mathfrak{eu}(\mathbb{H}^0(M,K)).$$

In fact, $\mathfrak{eu}(\mathbb{H}^0(M,K)) = d(d-1)(d-2)/6$ by Borodzik and Livingston [2014] and Bodnár and Némethi [2016]. From this reformulation it is clear its validity for $\nu \leq 2$, however a conceptual argument for its validity for $\nu \geq 3$ is still missing.

6.5 Coverings. Let (X,o) be a normal surface singularity with rational homology sphere link, and let (Y,o) be its universal abelian covering, cf. Section 2.1. Then, from Equation (2.1.2) automatically one has the analytic identity

$$p_g(Y,o) = \sum_{h\in H} h^1(\widetilde{X}, \mathcal{O}_{\widetilde{X}}(-r_h)), \tag{6.5.1}$$

that is, the sum of the equivariant geometric genera of (X,o) equals the geometric genus of (Y,o).

Let M and N be the links of (X,o) and (Y,o) respectively. Then N is the regular universal abelian covering of M (associated with the representation $\pi_1(M)\to H$). Let $\Gamma(M)$ and $\Gamma(N)$ be the corresponding negative definite resolution/plumbing graphs as well. In the next discussion we also assume that N is a rational homology sphere too.

Having in mind the equivariant SWIC identities for (X,o) and the SWIC for (Y,o), following Bodnár and Némethi [2017] we say that M and its universal abelian covering N satisfy the '*covering additivity property*' (CAP) if

$$\mathfrak{sw}_{\sigma_{can}}(N) + \frac{K(\Gamma(N))^2 + |\mathcal{V}(\Gamma(N))|}{8} =$$
$$= \sum_{h\in H} \mathfrak{sw}_{-h*\sigma_{can}}(M) + \frac{(K(\Gamma(M)) + 2r_h)^2 + |\mathcal{V}(\Gamma(N))|}{8}.$$

Clearly, if (X,o) satisfies the equivariant SWIC and (Y,o) the SWIC, then (CAP) for M and its universal abelian covering N holds. However, since (CAP) is a totally topological identity, we might ask its validity for any singularity link M (whose universal abelian covering N is a rational homology sphere), independently of the existence of any nice analytic structure, or independently of singularity theory.

The point is that the property (CAP) in general is not true Bodnár and Némethi [ibid.]. But, what is really surprising is that (CAP) is true for the surgery 3–manifolds $M = S^3_{-p/q}(\#_i \mathcal{K}_i)$, even though (some of) these 3–manifolds appear as the links of superisolated singularities, and the superisolated singularities are the basic couterexamples for SWIC.

Theorem 6.5.2. *Bodnár and Némethi [ibid.] Let $M = S^3_{-p/q}(K)$ be a manifold obtained by a negative rational Dehn surgery of S^3 along a connected sum of algebraic knots $\mathcal{K} = \mathcal{K}_1\#\dots\#\mathcal{K}_\nu$ ($p,q>0$, $\gcd(p,q)=1$). Assume that N, the universal abelian covering of M, is a rational homology sphere. Then (CAP) holds.*

Both statements Equation (6.5.1) and Theorem 6.5.2 remain valid for any abelian covering.

Problem 6.5.3. Characterize those 3–manifolds M (or, singularity links) for which (CAP) holds.

6.6 Newton non–degenerate germs revisited. Note that for a hypersurface Newton non–degenerate isolated singularity (X, o), with rational homology sphere link, both identities are true: $p_g = \mathfrak{eu}(\mathbb{H}^*(\Gamma, K))$ by Theorem 6.1.1, and

$$p_g = \min_{\gamma \in \mathfrak{P}} \mathfrak{eu}(\mathbb{H}^0(\gamma, K))$$

by Theorem 6.2.2. In particular, the link of such a singularity satisfy a very strong topological restiction: $\mathfrak{eu}(\mathbb{H}^*(\Gamma, K)) = \min_{\gamma \in \mathfrak{P}} \mathfrak{eu}(\mathbb{H}^0(\gamma, K))$. Though we know that such 3–manifolds are rather special (for the algorithm which determines the plumbing graph from the Newton diagram see Oka [1987, 1997], or Braun and Némethi [2010]), still, this topological identity is a mystery for us. (Maybe it is worth to mention that in this case, p_g also equals the lattice points of $(\mathbb{Z}_{>0})^3$ below the Newton diagram.)

Finally, we end this section with the following

Problem 6.6.1. Find the Heegaard–Floer theoretical interpretation of

$$\min_{\gamma \in \mathfrak{P}} \mathfrak{eu}(\mathbb{H}^0(\gamma, K))$$

7 Analytic – topological connections. $\mathcal{P}(\mathbf{t})$ versus $Z(\mathbf{t})$

7.1 The $\mathcal{P}(\mathbf{t}) = Z(\mathbf{t})$ identity. Recall that by Section 2.4 the periodic constant of $\mathcal{P}_h$ is the equivarint geometric genus $h^1(\widetilde{X}, \mathcal{O}(-r_h))$, while by Theorem 3.2.1 the periodic constant of Z_h is the opposite of the r_h–normalized Seiberg–Witten invariant. Hence the equivariant SWIC says that the periodic constants of $\mathcal{P}_h$ and Z_h are equal. Hence, it is natural to ask for the validity of an even stronger identity, namely for $\mathcal{P}(\mathbf{t}) = Z(\mathbf{t})$. If this identity holds, then it provides a topological characterisation of the multivariable Hilbert function of the divisorial filtration. For some simple singularities, e.g. for cyclic quotient singularities one can compute directly both sides, and their equality follows visibly.

Theorem 7.1.1. *The equality $\mathcal{P}(\mathbf{t}) = Z(\mathbf{t})$ is true in the following cases: (a) rational singularities Campillo, Delgado, and Gusein-Zade [2004] and Guseĭn-Zade, Delgado, and Kampil'o [2008] (for a different proof see Némethi [2008b]); (b) minimally elliptic singularities Némethi [ibid.]; (c) splice quotient singularities Némethi [2012] (this includes e.g. the weighted homogeneous case as well).*

Even the 'reduced identity' $\mathcal{P}^{\mathcal{U}} = Z^{\mathcal{U}}$, for some subset $\mathcal{U} \subset \mathcal{V}$, can be interesting, even if $\mathcal{U}$ contains only one element v. In the splice quotient case $\mathcal{P}^{\{v\}} = Z^{\{v\}}$ for certain nodes was proved and used in Okuma [2008]. In the weighted homogeneous case, when the minimal good graph is star–shaped and v is the central vertex, then $\mathcal{P}^{\{v\}}_{h=0}$ coincides also with the Poincaré series of the $\mathbb{Z}_{\geq 0}$–graded algebra of the singular point (grading induced by the $\mathbb{C}^*$–action). For this series Pinkham provided a topological expression in terms of the Seifert invariants of the Seifert 3–manifold link Pinkham [1977], which coincides with $Z^{\{v\}}_{h=0}$ (see e.g. Némethi and Nicolaescu [2004]). In the case of suspension singularities the difference $\mathcal{P}^{\{C\}}_{h=0} - Z^{\{C\}}_{h=0}$ is captured by the polynomial R, see Section 6.4.

We note also that the identity $P_h = Z_h$ is much stronger than SWIC for h: one can construct examples when $P_h \neq Z_h$ but the SWIC holds. On the other hand, in any situation when the SWIC fails, the identity $\mathcal{P} = Z$ also fails (e.g. for certain superisolated singularities, see also Némethi [2008b]).

7.2 A closer look at splice quotient singularities. Splice quotient singularities were introduced by Neumann and Wahl [2005b,a]. From any fixed graph Γ (whose plumbed manifold is a rational homology sphere and which has some additional special arithmetical properties, see below) one constructs a family of singularities with common equisingularity type, such that any member admits a distinguished resolution, whose dual graph is exactly Γ. The construction suggests that the analytic properties of the singularities constructed in this way are strongly linked with a fixed resolution and with its graph Γ. (Hence, the expectation is that certain analytic invariants might be computable from Γ.)

In present, there are three different approaches how one can introduce and study splice quotient singularities; each of them is based on a different geometric property. They are: (a) the 'original' construction of Neumann–Wahl, (b) the 'modified' version by Okuma [2008], and (c) considering singularities satisfying the 'end–curve condition'. It turns out that all these approaches are equivalent.

In the first two cases we start with a topological type (that is, with Γ), which satisfies certain restrictions, and we endow it with an analytic structure, the 'splice quotient' analytic type. In the third case we start with an analytic structure, which satisfies a certain analytic property.

The construction of Neumann and Wahl [2005a] imposes two combinatorial restriction on Γ, the *semigroup and congruence conditions*. The congruence condition is empty if $\det(,) = 1$. Using the first condition one writes the equations of a complete intersection (Y, o). The equations depend only on the splice diagram associated with the graph, in particular they are called 'splice diagram equations'. Then one defines an action of H on this complete intersection, free off o, (here the congruence condition is needed), and sets $(X, o) = (Y, o)/G$. It turns out that (X, o) has a resolution with dual graph Γ and (Y, o) is the universal abelian covering of (X, o).

Okuma replaces the semigroup and congruence conditions by the *monomial conditions*, otherwise the construction and the output is the same. Singularities constructed in this way (either Neumann–Wahl version or Okuma version) are called splice quotient singularities.

The third approach defines a family of singularities with a special analytic property, with the *end curve condition*. This requires the existence of a resolution which has the following property: For each exceptional irreducible component E_v, which corresponds to an end–vertex of Γ, there exists an analytic function whose reduced strict transform is irreducible, it intersects the exceptional curve only along E_v, and this intersection is transversal. These are called ‘end curve functions’.

Theorem 7.2.1. *(I) (Topological part) Fix a graph* Γ. *The following facts are equivalent:*

(a) There exists a splice quotient singularity with resolution graph Γ*,*

(b) Γ *satisfies the semigroup and congruence conditions;*

(c) Γ *satisfies the monomial condition.*

(II) (Analytic part) Fix a normal surface singularity (X, o). *The following facts are equivalent:*

(a) (X, o) *is splice quotient (in the sense of Neumann–Wahl or Okuma);*

(b) (X, o) *satisfies the end curve condition;*

(c) $\mathcal{P}(\mathbf{t}) = Z(\mathbf{t})$.

(I) follows from Neumann and Wahl [ibid.], the equivalence $(I)(b) \Leftrightarrow (c)$ was proved in Neumann and Wahl [ibid., §13]). Regarding (II), the fact that splice quotient singularities satisfy the ‘end curve condition’ follows basically from the construction of the singularities: some powers of the coordinate functions of (Y, o) are ‘end curve function’. The converse is the subject of the ‘End Curve Theorem’ Neumann and Wahl [2010] and Okuma [2010]. Part $(b) \Rightarrow (c)$ was proved in Némethi [2012], part $(c) \Rightarrow (b)$ follows from definitions.

Example 7.2.2. The end curve condition is satisfied in the following cases: (a) rational singularities, where π is an arbitrary resolution; (b) minimally elliptic singularities, and π is a minimal resolution; (c) weighted homogeneous singularities, where π is the minimal good resolution.

As we already said, we do not know the ‘limits’ of the SWIC, but the stronger version $\mathcal{P}(\mathbf{t}) = Z(\mathbf{t})$ occurs exactly when (X, o) is splice quotient (provided that M is a rational homology sphere). In this case the analytic $\mathcal{P}$ make the topological choice Z.

Problem 7.2.3. Find other topological candidates for $\mathcal{P}(\mathbf{t})$ — or, transformed into a question: what other topological choices might have $\mathcal{P}(\mathbf{t})$ when we vary the analytic structure of (X, o) ?

What is the ‘multivariable series lift’ of $\min_{\gamma \in \mathfrak{P}} \mathfrak{eu}(\mathbb{H}^0(\gamma, K))$? What is $\mathcal{P}_{h=0}(\mathbf{t})$ for hypersurface superisolated or Newton non–degenerate germs ? (In the last cases it can even happen that $\mathcal{P}_{h=0}(\mathbf{t})$ is not constant along the equisingular strata, then find $\mathcal{P}$ for some ‘normal form’.) Describe/characterize the universal abelian covers of hypersurface superisolated or Newton non–degenerate singularities.

7.3 The analytic semigroup of (X,o). In Section 2.1 we introduced the 'topological semigroup' $\mathcal{S}'$ determined from the lattice L'. Its analytic counterpart is defined as

$$\mathcal{S}'_{an,h} = \{r_h + \mathrm{div}_E(s), \text{ where } s \in H^0(\mathcal{O}_{\widetilde{X}}(-r_h))\}$$

for any $h \in H$, and $\mathcal{S}'_{an} = \cup_h \mathcal{S}'_{an,h}$. One shows that $\mathcal{S}'_{an} \subset \mathcal{S}'$, and $\mathcal{P}(\mathbf{t})$ is supported in $\mathcal{S}'_{an}$, while $Z(\mathbf{t})$ is supported in $\mathcal{S}'$. In both cases, usually the supports are much smaller then the corresponding semigroups. However, both semigroups conceptually guide important geometric properties of the analytic/topological type of (X,o). For rational or minimally elliptic singularities $\mathcal{S}'_{an} = \mathcal{S}'$, however the computation of $\mathcal{S}'_{an}$ usually is extremely hard.

Problem 7.3.1. Find efficient methods for the computation of $\mathcal{S}'_{an}$. Describe $\mathcal{S}'_{an}$ for certain key families of singularities.

7.4 Linear subspace arrangements, as 'lifts' of the series $\mathcal{P}(\mathbf{t})$ and $Z(\mathbf{t})$. Fix (X,o), a resolution π and the filtration $\{\mathcal{F}(l')\}_{l'\in L'}$ as in Section 2.2. For any $l' \in L'$, the linear space

$$(\mathcal{F}(l')/\mathcal{F}(l'+E))_{\theta([l'])} = H^0(\mathcal{O}_{\widetilde{X}}(-l'))/H^0(\mathcal{O}_{\widetilde{X}}(-l'-E))$$

naturally embeds into

$$T(l') := H^0(\mathcal{O}_E(-l')).$$

Let its image be denoted by $A(l')$. Furthermore, for every $v \in \mathcal{V}$, consider the linear subspace $T_v(l')$ of $T(l')$ given by

$$T_v(l') := H^0(\mathcal{O}_{E-E_v}(-l'-E_v)) = \ker\big(\, H^0(\mathcal{O}_E(-l')) \to H^0(\mathcal{O}_{E_v}(-l'))\,\big) \subset T(l').$$

Then the image $A_v(l')$ of $H^0(\mathcal{O}_{\widetilde{X}}(-l'-E_v)/H^0(\mathcal{O}_{\widetilde{X}}(-l'-E))$ in $T(l')$ satisfies $A_v(l') = A(l') \cap T_v(l')$.

The point is that one can show that the vector space $T(l')$ and the linear subspace arrangement $\{T_v(l')\}_v$ in $T(l')$ depends only on the resolution graph.

Definition 7.4.1. The (finite dimensional) arrangement of linear subspaces $\mathcal{A}_{\mathrm{top}}(l') = \{T_v(l')\}_v$ in $T(l')$ is called the 'topological arrangement' at $l' \in L'$. The arrangement of linear subspaces $\mathcal{A}_{\mathrm{an}}(l') = \{A_v(l') = T_v(l') \cap A(l')\}_v$ in $A(l')$ is called the 'analytic arrangement' at $l' \in L'$. The corresponding projectivized arrangement complements will be denoted by $\mathbb{P}(T(l') \setminus \cup_v T_v(l'))$ and $\mathbb{P}(A(l') \setminus \cup_v A_v(l'))$ respectively.

If $l' \notin \mathcal{S}'$ then there exists v such that $(E_v, l') > 0$, that is $h^0(\mathcal{O}_{E_v}(-l')) = 0$, proving that $T_v(l') = T(l')$. Hence $A_v(l') = A(l')$ too. In particular, both arrangement complements are empty. In fact, if $l' \notin \mathcal{S}'_{an}$, then by similar argument, the analytic arrangement complement is empty too.

The connection with the series $\mathcal{P}(\mathbf{t})$ and $\mathbb{Z}(\mathbf{t})$ is given by the following topological Euler characteristic formulae associated with all the linear subspace arrangements for all l'.

Theorem 7.4.2.

$$\mathcal{P}(\mathbf{t}) = \sum_{l' \in \mathcal{S}'_{an}} \chi_{\text{top}}(\,\mathbb{P}(A(l') \setminus \cup_v A_v(l'))\,) \cdot \mathbf{t}^{l'};$$

$$Z(\mathbf{t}) = \sum_{l' \in \mathcal{S}'} \chi_{\text{top}}(\,\mathbb{P}(T(l') \setminus \cup_v T_v(l'))\,) \cdot \mathbf{t}^{l'}.$$

For proof see Némethi [n.d.(a)], the analytic case (in the language of $\{\mathcal{F}(l')\}_{l'}$) already appeared in Campillo, Delgado, and Gusein-Zade [2004] and Guseĭn-Zade, Delgado, and Kampil'o [2008].

The corresponding dimensions of the linear subspaces in $\mathcal{Q}_{\text{an}}(l')$ are as follows. For any $l' \in L'$ and $I \subset \mathcal{V}$ one has $\dim A(l') = \mathfrak{h}(l' + E) - \mathfrak{h}(l')$, $\dim \cap_{v \in I} A_v(l') = \mathfrak{h}(l' + E) - \mathfrak{h}(l' + E_I)$. Thus, the analytic arrangement is rather sensitive to the modification of the analytic structure, and in general, does not coincide with the topological arrangement. The corresponding dimensions in the topological case are computed in Némethi [n.d.(a)], they are slightly more technical. Examples show that $\chi_{\text{top}}(\mathbb{P}(A(l') \setminus \cup_v A_v(l'))) = \chi_{\text{top}}(\mathbb{P}(T(l') \setminus \cup_v T_v(l')))$ can happen even if $A(l') \neq T(l')$.

7.4.3. Note that the analytic subspace arrangement $\mathcal{Q}_{an}(l')$, naturally determined by the divisorial filtration, exists even without its embedding into $T(l')$. On the other hand, if one wishes to find its topological analogue, its embedding into the topological $T(l')$ is the most natural possibility, that is, the choice of $\mathcal{Q}_{top}(l')$ is the most natural universal object, which might include all the possible analytic arrangements indexed by different analytic structures.

In this way, $(A(l'), \{A_v(l')\}_v) \subset (T(l'), \{T_v(l')\}_v)$ looks a perfect pairing. This immediately induces (by taking the Euler characteristic of the corresponding spaces) the two series $Z(\mathbf{t})$ and $\mathcal{P}(\mathbf{t})$. Though these two series looked artificially paired at the beginning, now, after Theorem 7.4.2, this fact is totally motivated and justified. Furthermore, taking the periodic constants of the series Z and P, we get that the pairing predicted by the SWIC is indeed very natural and totally justified.

In particular, these steps provide a totally conceptual explanation for the appearance of the Seiberg–Witten invariant in the theory of complex surface singularities.

7.4.4. Extensions. The above picture allows to extend the series $\mathcal{P}(\mathbf{t})$ and $Z(\mathbf{t})$ to capture some additional information from the corresponding Hodge or Grothendieck ring structures as well. In the analytic case the extension of $\mathcal{P}(\mathbf{t})$ to the series $\sum_{l' \in \mathcal{S}'} [\mathbb{P}(A(l') \setminus$

$\cup_v A_v(l'))] \cdot \mathbf{t}^{l'}$ with coefficients in the Grothendieck ring was already considered e.g. in Campillo, Delgado, and Gusein-Zade [2007]. Once we have the topological arrangement in hand, we can also introduce the following series with coefficients in the Grothendieck ring

$$Z(\mathbb{L},\mathbf{t}) = \sum_{l'\in\mathcal{S}'} [\mathbb{P}(T(l') \setminus \cup_v T_v(l'))] \cdot \mathbf{t}^{l'}. \tag{7.4.5}$$

It is remarkable that this series has a closed expression in terms of lattice too. Indeed, if $\mathcal{E}$ denotes the set of edges of Γ, then (see Némethi [n.d.(a)])

$$Z(\mathbb{L},\mathbf{t}) = \frac{\prod_{(u,v)\in\mathcal{E}} (1-\mathbf{t}^{E_u^*} - \mathbf{t}^{E_v^*} + \mathbb{L}\mathbf{t}^{E_u^*+E_v^*})}{\prod_{v\in\mathcal{V}} (1-\mathbf{t}^{E_v^*})(1-\mathbb{L}\mathbf{t}^{E_v^*})}. \tag{7.4.6}$$

$\mathscr{D}$-MODULES IN BIRATIONAL GEOMETRY

MIHNEA POPA

Abstract

It is well known that numerical quantities arising from the theory of $\mathscr{D}$-modules are related to invariants of singularities in birational geometry. This paper surveys a deeper relationship between the two areas, where the numerical connections are enhanced to sheaf theoretic constructions facilitated by the theory of mixed Hodge modules. The emphasis is placed on the recent theory of Hodge ideals.

1 Introduction

Ad hoc arguments based on differentiating rational functions or sections of line bundles abound in complex and birational geometry. To pick just a couple of examples, topics where such arguments have made a deep impact are the study of adjoint linear series on smooth projective varieties, see for instance Demailly's work on effective very ampleness Demailly [1993] and its more algebraic incarnation in Ein, Lazarsfeld, and Nakamaye [1996], and the study of hyperbolicity, see for instance Siu's survey Siu [2004] and the references therein.

A systematic approach, as well as an enlargement of the class of objects to which differentiation techniques apply, is provided by the theory of $\mathscr{D}$-modules, which has however only recently begun to have a stronger impact in birational geometry. The new developments are mainly due to a better understanding of Morihiko Saito's theory of mixed Hodge modules Saito [1988], Saito [1990], and hence to deeper connections with Hodge theory and coherent sheaf theory. Placing problems in this context automatically brings in important tools such as vanishing theorems, perverse sheaves, or the V-filtration, in a unified way.

Connections between invariants arising from log resolutions of singularities and invariants arising from the theory of $\mathscr{D}$-modules go back a while however. A well-known such

MSC2010: primary 14F10; secondary 14J17, 32S25, 14F17, 14F18, 14C30.

instance is the fact that the log canonical threshold of a function f on (say) $\mathbb{C}^n$ coincides with the negative of the largest root of the Bernstein-Sato polynomial $b_f(s)$; see e.g. Yano [1983], Kollár [1997]. Numerical data on log resolutions plays a role towards the study of other roots of the Bernstein-Sato polynomial Kashiwara [1976/77], Lichtin [1989], though our understanding of these is far less thorough. Going one step further, a direct relationship between the multiplier ideals of a hypersurface in a smooth variety X and the V-filtration it induces on $\mathscr{O}_X$ was established in Budur and Saito [2005].

After reviewing some of this material, in this paper I focus on one direction of further development, worked out jointly with Mustaţă Mustaţă and Popa [2016a], Mustaţă and Popa [2016b], Mustaţă and Popa [2018a], Mustaţă and Popa [2018b] as well as by Saito in Saito [2016], namely the theory of what we call *Hodge ideals*. This is a way of thinking about the Hodge filtration (in the sense of mixed Hodge modules) on the sheaf of functions with arbitrary poles along a hypersurface, or twists thereof, and is closely related to both the singularities of the hypersurface and the Hodge theory of its complement. There are two key approaches that have proved useful towards understanding Hodge ideals:

1. A birational study in terms of log resolutions, modeled on the algebraic theory of multiplier ideals, which Hodge ideals generalize, Mustaţă and Popa [2016a], Mustaţă and Popa [2018a].

2. A comparison with the (microlocal) V-filtration, using its interaction with the Hodge filtration in the case of mixed Hodge modules, Saito [2016], Mustaţă and Popa [2018b].

Hodge ideals are indexed by the non-negative integers; at the 0-th step, they essentially coincide with multiplier ideals. Beyond the material presented in this paper, by analogy it will be interesting to develop a theory of Hodge ideals associated to ideal sheaves (perhaps leading to asymptotic constructions as well), to attempt an alternative analytic approach, and to establish connections with constructions in positive characteristic generalizing test ideals.

There are other ways in which filtered $\mathscr{D}$-modules underlying Hodge modules have been used in recent years in complex and birational geometry, for instance in the study of generic vanishing theorems, holomorphic forms, topological invariants, families of varieties and hyperbolicity; see e.g. Dimca, Maisonobe, and Saito [2011], Schnell [2012], Popa and Schnell [2013], Wang [2016], Popa and Schnell [2014], Popa and Schnell [2017], Pareschi, Popa, and Schnell [2017], Wei [2017]. The bulk of the recent survey Popa [2016b] treats part of this body of work, so I have decided not to discuss it here again. In any event, the reader is advised to use Popa [ibid.] as a companion to this article, as introductory material on $\mathscr{D}$-modules and Hodge modules together with a guide to technical literature can be found there (especially in Ch. B, C). Much of that will not be repeated here, for space reasons.

Acknowledgments. Most of the material in this paper describes joint work with Mircea Mustaţă, and many ideas are due to him. Special thanks are due to Christian Schnell, who helped my understanding of Hodge modules through numerous discussions and collaborations. I am also indebted to Morihiko Saito, whose work and ideas bear a deep influence on the topics discussed here. Finally, I thank Yajnaseni Dutta, Mircea Mustaţă, Lei Wu and Mingyi Zhang for comments on a first draft.

2 V-filtration, Bernstein-Sato polynomial, and birational invariants

One of the main tools in the theory of mixed Hodge modules is the V-filtration along a hypersurface, and its interaction with the Hodge filtration. Important references regarding the V-filtration include Kashiwara [1983], Malgrange [1983], Sabbah [1987], Saito [1988], Saito [1994].

First, let's recall the graph construction. Let D be an effective divisor on X, given (locally, in coordinates $x_1, \ldots, x_n$) by $f = 0$ with $f \in \mathscr{O}_X$, and whose support is Z. Consider the embedding of X given by the graph of f, namely:

$$i_f = (\mathrm{id}, f)\colon X \hookrightarrow X \times \mathbb{C} = Y, \quad x \to \big(x, f(x)\big).$$

On $\mathbb{C}$ we consider the coordinate t, and a vector field ∂_t such that $[\partial_t, t] = 1$.

Let $(\mathscr{M}, F)$ be a filtered left $\mathscr{D}_X$-module. We denote

$$(\mathscr{M}_f, F) := i_{f_+}(\mathscr{M}, F) = (\mathscr{M}, F) \otimes_{\mathbb{C}} (\mathbb{C}[\partial_t], F),$$

where the last equality (which means the filtration is the convolution filtration) is the definition of push-forward for filtered $\mathscr{D}$-modules via a closed embedding. More precisely, we have

- $\mathscr{M}_f = \mathscr{M} \otimes_{\mathbb{C}} \mathbb{C}[\partial_t]$, with action of $\mathscr{D}_Y = \mathscr{D}_X[t, \partial_t]$ given by: $\mathscr{O}_X$ acts by functions on $\mathscr{M}$, and
$$\partial_{x_i} \cdot (g \otimes \partial_t^i) = \partial_{x_i} g \otimes t^i - (\partial_{x_i} f) g \otimes \partial_t^{i+1},$$
$$t \cdot (g \otimes \partial_t^i) = fg \otimes \partial_t^i - i g \otimes \partial_t^{i-1}, \quad \text{and} \quad \partial_t \cdot (g \otimes \partial_t^i) = g \otimes \partial_t^{i+1}.$$

- $F_p \mathscr{M}_f = \bigoplus_{i=0}^p F_{p-i} \mathscr{M} \otimes \partial_t^i$ for all $p \in \mathbb{Z}$.

One of the key technical tools in the study of $\mathscr{D}$-modules is the V-filtration. The $\mathbb{Z}$-indexed version always exists and is unique when $\mathscr{M}_f$ is a regular holonomic $\mathscr{D}_Y$-module, due to work of Kashiwara [1983] and Malgrange [1983]. Assuming in addition that the local monodromy along f is quasi-unipotent, a condition of Hodge-theoretic origin satisfied by all the objects appearing here, one can also consider the following $\mathbb{Q}$-indexed version; cf. Saito [1988, p. 3.1.1].

Definition 2.1 (Rational V-filtration). A *rational V-filtration* of $\mathscr{M}_f$ is a decreasing filtration $V^\alpha \mathscr{M}_f$ with $\alpha \in \mathbb{Q}$ satisfying the following properties:

- The filtration is exhaustive, i.e. $\bigcup_\alpha V^\alpha \mathscr{M}_f = \mathscr{M}_f$, and each $V^\alpha \mathscr{M}_f$ is a coherent $\mathscr{O}_Y[\partial_{x_i}, \partial_t t]$-submodule of $\mathscr{M}_f$.
- $t \cdot V^\alpha \mathscr{M}_f \subseteq V^{\alpha+1}\mathscr{M}_f$ and $\partial_t \cdot V^\alpha \mathscr{M}_f \subseteq V^{\alpha-1}\mathscr{M}_f$ for all $\alpha \in \mathbb{Q}$.
- $t \cdot V^\alpha \mathscr{M}_f = V^{\alpha+1}\mathscr{M}_f$ for $\alpha > 0$.
- The action of $\partial_t t - \alpha$ on $\mathrm{gr}_V^\alpha \mathscr{M}_f$ is nilpotent for each α. (One defines $\mathrm{gr}_\alpha^V \mathscr{M}_f$ as $V^\alpha \mathscr{M}_f / V^{>\alpha}\mathscr{M}_f$, where $V^{>\alpha}\mathscr{M}_f = \cup_{\beta>\alpha} V^\beta \mathscr{M}_f$.)

We will consider other $\mathscr{D}$-modules later on, but for the moment let's focus on the case $\mathscr{M} = \mathscr{O}_X$, with the trivial filtration $F_k\mathscr{O}_X = \mathscr{O}_X$ for $k \geq 0$, and $F_k\mathscr{O}_X = 0$ for $k < 0$. It is standard to denote $\mathscr{B}_f := (\mathscr{O}_X)_f$. Via the natural inclusion of $\mathscr{O}_X$ in $\mathscr{B}_f$, for $\alpha \in \mathbb{Q}$ one defines

$$V^\alpha \mathscr{O}_X := V^\alpha \mathscr{B}_f \cap \mathscr{O}_X,$$

a decreasing sequence of coherent ideal sheaves on X. A first instance of the connections we focus on here is the following result of Budur-Saito:

Theorem 2.2 (Budur and Saito [2005, Theorem 0.1]). *If D is an effective divisor on X, then for every $\alpha \in \mathbb{Q}$ one has*

$$V^\alpha \mathscr{O}_X = \mathscr{J}\big((\alpha - \epsilon)D\big),$$

the multiplier ideal of the $\mathbb{Q}$-divisor $(\alpha-\epsilon)D$, where $0 < \epsilon \ll 1$ is a rational number.

Multiplier ideal sheaves are ubiquitous objects in birational geometry, encoding local numerical invariants of singularities, and satisfying Kodaira-type vanishing theorems in the global setting; see Lazarsfeld [2004, Ch. 9]. If $f : Y \to X$ is a log resolution of the pair (X, D), and $c \in \mathbb{Q}$, then by definition the multiplier ideal of cD is

$$\mathscr{J}(cD) = f_*\mathscr{O}_Y\big(K_{Y/X} - [cf^*D]\big).$$

Let me take the opportunity to also introduce the following notation, to be used repeatedly. Denote $Z = D_{\mathrm{red}}$, and define integers a_i, b_i and c_i by the expressions

$$f^*Z = \tilde{Z} + a_1F_1 + \cdots + a_mF_m$$

and

$$K_{Y/X} = b_1 F_1 + \cdots + b_m F_m + c_{m+1} F_{m+1} + \cdots + c_n F_n,$$

where F_j are the components of the exceptional locus and $a_i \neq 0$. We denote

$$\gamma = \min_{1 \leq i \leq m} \frac{b_i + 1}{a_i}. \tag{2.3}$$

Recall that the *Bernstein-Sato polynomial* of f is the unique monic polynomial $b_f(s)$ of minimal degree, in the variable s, such that there exists $P \in \mathscr{D}_X[s]$ satisfying the formal identity

$$b_f(s) f^s = P f^{s+1}.$$

See for instance Kashiwara [1976/77], Sabbah [1987], Saito [1994], while a nice survey can be found in Granger [2010]. It can be shown that $b_f(s)$ is independent of the choice of f such that $D = \mathrm{div}(f)$ locally, and so one also has a function $b_D(s)$ which is globally well defined; however, to keep a unique simple notation, in the statements below all information about the pair (X, D) related to $b_f(s)$ should be understood locally in this sense.

The roots of the Bernstein-Sato polynomial are interesting invariants of the singularities of f, and a number of important facts regarding them have been established in the literature. Here are some of the most significant; a posteriori, many of these facts also follow from Theorem 2.2 and the connection between the Bernstein-Sato polynomial and the V-filtration.

1. The roots of $b_f(s)$ are negative rational numbers; see Kashiwara [1976/77].
2. More precisely, in the notation above, all the roots of $b_f(s)$ are of the form $-\frac{b_i + \ell}{a_i}$ for some $i \geq 0$ and $\ell \geq 1$; see Lichtin [1989, Theorem 5].
3. The negative α_f of the largest root of $b_f(s)$ is the log canonical threshold of (X, D); Kollár [1997, Theorem 10.6], see also Yano [1983], Lichtin [1989].
4. Moreover, all jumping numbers of the pair (X, D) (see Lazarsfeld [2004, p. 9.3.22]) in the interval $(0, 1]$ can be found among the roots of $b_f(s)$; see Ein, Lazarsfeld, Smith, and Varolin [2004].

For instance, it is well known that α_f can be characterized in terms of the V-filtration as

$$\alpha_f = \max \{\beta \in \mathbb{Q} \mid V^\beta \mathscr{O}_X = \mathscr{O}_X\},$$

see for instance Saito [2016, (1.2.5)], while the log canonical threshold has a similar characterization in terms of the triviality of $\mathcal{J}\big((\beta - \epsilon)D\big)$.

Assuming that f is not invertible, it is not hard to see that -1 is always a root of $b_f(s)$. The polynomial

$$\tilde{b}_f(s) = \frac{b_f(s)}{s+1}$$

is the *reduced Bernstein-Sato polynomial* of f. Inspired by (3) above and a connection with the microlocal V-filtration Saito [1994] (cf also Section 9), Saito introduced:

Definition 2.4. The *microlocal log canonical threshold* $\tilde{\alpha}_f$ is the negative of the largest root of the reduced Bernstein-Sato polynomial $\tilde{b}_f(s)$.

In particular, if $\tilde{\alpha}_f \leq 1$, then it coincides with the log canonical threshold. In other words, $\tilde{\alpha}_f$ provides a new interesting invariant precisely when the pair (X, D) is log canonical. It is already known to be related to standard types of singularities:

Theorem 2.5. *Assume that D is reduced. Then*

1. *Saito [1993, Theorem 0.4] D has rational singularities if and only if $\tilde{\alpha}_f > 1$.*
2. *Saito [2009, Theorem 0.5] D has Du Bois singularities if and only if $\tilde{\alpha}_f \geq 1$.*[1]

Example 2.6. If f is a weighted homogeneous polynomial such that x_i has weight w_i, the convention being that if f is a sum of monomials $x_1^{m_1} \cdots x_n^{m_n}$ then $\sum m_i w_i = 1$, we have $\tilde{\alpha}_f = \sum_{i=1}^n w_i$; see e.g. Saito [ibid., p. 4.1.5].

It is well known that the log canonical threshold of the pair (X, D) can be computed in terms of discrepancies; in fact, using the notation in (2.3), given any log resolution one has

$$\alpha_f = \min\{1, \gamma\}.$$

Similar precise formulas are not known for other roots of the Bernstein-Sato polynomial. Lichtin asked the following regarding the microlocal log canonical threshold.

Question 2.7. Lichtin [1989, Remark 2, p.303] Is it true that $\gamma = \tilde{\alpha}_f$?

When $\tilde{\alpha}_f \leq 1$, this is indeed the case by the discussion above. As noted by Kollár Kollár [1997, Remark 10.8], the question otherwise has a negative answer, simply due to the fact that in general the quantity on the right hand side depends on the choice of log resolution. One of the outcomes of the results surveyed in this paper will be however the inequality $\gamma \leq \tilde{\alpha}_f$; see Theorem 9.10. It would be interesting to find similar results for other roots of $\tilde{b}_f(s)$.

[1] An equivalent statement can be found in Kovács and Schwede [2011, Corollary 6.6], where it is shown that D is Du Bois if and only if the pair (X, D) is log canonical.

3 Hodge filtration on localizations

I will now start focusing on the Hodge filtration. Saito's theory of mixed Hodge modules produces useful filtered $\mathscr{D}$-modules of geometric and Hodge theoretic origin on complex varieties, which extend the notion of a variation of Hodge structure when singularities (of fibers of morphisms, of hypersurfaces, of ambient varieties, etc.) are involved; see for instance the examples in Popa [2016b, §2]. Usually the $\mathscr{D}$-module itself is quite complicated, but here we deal with one of the simplest ones.

Namely, if X is smooth complex variety of dimension n, and D is a reduced effective divisor on X, we consider the left $\mathscr{D}_X$-module

$$\mathscr{O}_X(*D) = \bigcup_{k\geq 0} \mathscr{O}_X(kD)$$

of functions with arbitrary poles along D. Locally, if $D = \mathrm{div}(f)$, then $\mathscr{O}_X(*D)$ is simply the localization $\mathscr{O}_X[f^{-1}]$, on which differential operators act by the quotient rule. This $\mathscr{D}_X$-module underlies the extension of the trivial Hodge module across D, i.e. the mixed Hodge module $j_*\mathbb{Q}_U^H[n]$, where $U = X \smallsetminus D$ and $j : U \hookrightarrow X$ is the inclusion map. A main feature of $\mathscr{D}$-modules underlying mixed Hodge modules is that they come endowed with a (Hodge) filtration, in this case $F_k\mathscr{O}_X(*D)$ with $k \geq 0$, better behaved than those on arbitrary filtered $\mathscr{D}$-modules; besides the fundamental Saito [1988], Saito [1990], see also Schnell [2014] for an introductory survey, and Sabbah and Schnell [2016] for details.

While the $\mathscr{D}$-module $\mathscr{O}_X(*D)$ is easy to understand, the Hodge filtration can be extremely complicated to describe. This is intimately linked to understanding the singularities of D and the Deligne Hodge filtration on the singular cohomology $H^\bullet(U,\mathbb{C})$. Saito [1993], Saito [2009] studied $F_k\mathscr{O}_X(*D)$ with the help of the V-filtration, and established the following results:

Theorem 3.1. *The following hold:*

1. *Saito [1993, Proposition 0.9 and Theorem 0.11] The Hodge filtration is contained in the pole order filtration, namely*

$$F_k\mathscr{O}_X(*D) \subseteq \mathscr{O}_X\big((k+1)D\big) \quad \text{for all} \quad k \geq 0,$$

and equality holds if $k \leq \tilde{\alpha}_f - 1$.

2. *Saito [2009, Theorem 0.4]* $F_0\mathscr{O}_X(*D) = \mathscr{O}_X(D) \otimes_{\mathscr{O}_X} V^1\mathscr{O}_X$.[2]

[2] This is in fact proved in *loc. cit.* with $\widetilde{V}^1\mathscr{O}_X$, the microlocal V-filtration on $\mathscr{O}_X$ (see Section 9), instead of $V^1\mathscr{O}_X$, but it can be shown that the two coincide for V^1.

Item (1) in the theorem leads to defining for each $k \geq 0$ a coherent sheaf of ideals $I_k(D)$ by the formula

$$F_k \mathscr{O}_X(*D) = \mathscr{O}_X\big((k+1)D\big) \otimes I_k(D).$$

We call these the *Hodge ideals* of the divisor D; they, and especially their extensions to $\mathbb{Q}$-divisors, play the leading role in this note.

4 Review of Hodge ideals for reduced divisors

The papers Mustaţă and Popa [2016a] and Mustaţă and Popa [2016b] are devoted to the study of Hodge ideals of reduced divisors, using both properties coming from the theory of mixed Hodge modules, and an alternative approach based on log resolutions and methods from birational geometry.

The theory is essentially complete in this case, and I will only briefly review it in this section (see also Popa [2016b, Ch. F] for a more extensive survey) and in Section 9, where the relationship with the microlocal V-filtration Saito [2016] is explained. The rest of the paper discusses the more general case of $\mathbb{Q}$-divisors, where a complete treatment is only beginning to take shape.

One may loosely summarize the main properties and results as follows:

Theorem 4.1 (Mustaţă and Popa [2016a], Mustaţă and Popa [2016b]). *Given a reduced effective divisor D on a smooth complex variety X, the sequence of Hodge ideals $I_k(D)$, with $k \geq 0$, satisfies:*
(i) $I_0(D)$ is the multiplier ideal $\mathcal{J}\big((1-\epsilon)D\big)$,[3] so in particular $I_0(D) = \mathscr{O}_X$ if and only if the pair (X, D) is log canonical. Moreover, there are inclusions

$$\cdots I_k(D) \subseteq \cdots \subseteq I_1(D) \subseteq I_0(D).$$

(ii) When D has simple normal crossings, in a neighborhood where it is given by $x_1 \cdots x_r = 0$, $I_k(D)$ is generated by $\{x_1^{a_1} \cdots x_r^{a_r} \mid 0 \leq a_i \leq k,\ \sum_i a_i = k(r-1)\}$.
(iii) D is smooth if and only if $I_k(D) = \mathscr{O}_X$ for all k; cf. also Corollary 6.5 below.
(iv) If $I_k(D) = \mathscr{O}_X$ for some $k \geq 1$ ($\Longleftrightarrow I_1(D) = \mathscr{O}_X$), then D is normal with rational singularities. More precisely, $I_1(D) \subseteq \mathrm{Adj}(D)$, the adjoint ideal of D.[4]
(v) There are non-triviality criteria for $I_k(D)$ at a point $x \in D$ in terms of the multiplicity of D at x; cf. e.g. Theorem 6.4 below.
(vi) On smooth projective varieties, $I_k(D)$ satisfy a vanishing theorem extending Nadel Vanishing for multiplier ideals (a special case of Theorem 7.1 below).

[3]Note that this follows already by combining Theorem 3.1(2) and Theorem 2.2 above.
[4]Recall that D is normal with rational singularities if and only if $\mathrm{Adj}(D) = \mathscr{O}_X$, see Lazarsfeld [2004, Proposition 9.3.48].

(vii) If H is a smooth divisor in X such that $D|_H$ is reduced, then $I_k(D)$ satisfy

$$I_k(D|_H) \subseteq I_k(D) \cdot \mathscr{O}_H,$$

with equality when H is general.
(viii) If D_1 and D_2 are reduced divisors such that $D_1 + D_2$ is also reduced, I_k satisfy the subadditivity property

$$I_k(D_1 + D_2) \subseteq I_k(D_1) \cdot I_k(D_2).$$

(ix) If $X \to T$ is a smooth family with a section $s: T \to X$, and D is a relative divisor on X such that the restriction $D_t = D|_{X_t}$ to each fiber is reduced, then

$$\{t \in T \mid I_k(D_t) \subseteq \mathfrak{m}^q_{s(t)}\}$$

is an open subset of T, for each $q \geq 1$.
(x) $I_k(D)$ determine Deligne's Hodge filtration on the singular cohomology $H^\bullet(U, \mathbb{C})$, where $U = X \smallsetminus D$, via a Hodge-to-de Rham type spectral sequence.

Note that, in view of item (i), a number of these properties are inspired by well-known properties of multiplier ideals (see Lazarsfeld [2004, Ch. 9]), though often the proofs become substantially more involved. However (ii) and (x) simply follow from standard results, via general properties of the Hodge filtration.

Another line of results proved in Mustaţă and Popa [2016a] and Mustaţă, Olano, and Popa [2017] regards the complexity of the Hodge filtration. According to Saito [2009], one says that the filtration on a $\mathscr{D}$-module $(\mathscr{M}, F_\bullet)$ is *generated at level k* if

$$F_\ell \mathscr{D}_X \cdot F_k \mathscr{M} = F_{k+\ell} \mathscr{M} \quad \text{for all} \quad \ell \geq 0.$$

The smallest integer k with this property is called the *generating level*. In the case of $\mathscr{M} = \mathscr{O}_X(*D)$ with the Hodge filtration, this can be reinterpreted as saying that

$$\mathscr{O}_X\big((k+\ell+1)D\big) \otimes I_{k+\ell}(D) = F_\ell \mathscr{D}_X \cdot \Big(\mathscr{O}_X\big((k+1)D\big) \otimes I_k(D)\Big), \tag{4.2}$$

so all higher Hodge ideals are determined by $I_k(D)$. Thus this invariant is important for concrete calculations; see e.g. Remark 9.8 below.

Theorem 4.3. *Assume that X has dimension n. Then:*

1. *Mustaţă and Popa [2016a, Theorem B] The Hodge filtration on $\mathscr{O}_X(*D)$ is generated at level $n-2$, and this bound is optimal in general.*

2. *Mustaţă, Olano, and Popa [2017, Theorem E] If D has only isolated rational singularities and $n \geq 3$, then the Hodge filtration on $\mathscr{O}_X(*D)$ is generated at level $n-3$.*

We conjecture in Mustaţă, Olano, and Popa [2017] that (2) should hold for arbitrary divisors with rational singularities. Its converse is known not to hold in general. When D has an isolated quasihomogeneous singularity, a stronger bound was given by Saito in Saito [2009, Theorem 0.7]: the generating level of $F_\bullet \mathscr{O}_X(*D)$ is $[n - \tilde{\alpha}_f - 1]$, where $\tilde{\alpha}_f$ is the microlocal log canonical threshold defined in Section 2; cf. also Theorem 2.5(1).

Example 4.4. (1) If D is a reduced divisor on a surface, then the Hodge filtration is generated at level 0, so the multiplier ideal $I_0(D)$ determines all other $I_k(D)$ via formula (4.2) for $k = 0$. See Popa [2016b, Example 13.1] for concrete calculations.

(2) If $D = (f = 0) \subset X = \mathbb{C}^3$ is a du Val surface singularity, then $I_0(D) = \mathscr{O}_X$, and since D has rational singularities, the Hodge filtration is again generated at level 0. Thus for all $k \geq 1$ we have $I_k(D) = f^{k+1} \cdot \big(F_k \mathscr{D}_X \cdot \frac{1}{f}\big)$. If however D is an elliptic singularity, then the Hodge filtration is typically not generated at level 0 any more, but only at level 1. See for instance the elliptic cone calculation in Remark 9.8.

Some first applications. The use of Hodge ideals in geometric applications is still in its early days. There are however a number of basic consequences that can already be deduced using the results above:

- Effective bounds for the degrees of hypersurfaces on which isolated singular points on a reduced hypersurface D in $\mathbb{P}^n$ of fixed degree d impose independent conditions, in the style of a classical a result of Severi for nodal surfaces in $\mathbb{P}^3$; see Mustaţă and Popa [2016a, §27]. As an example, the isolated singular points on D of multiplicity $m \geq 2$ impose independent conditions on hypersurfaces of degree $([\frac{n}{m}] + 1)d - n - 1$.
- Solution to a conjecture on the multiplicities of points on theta divisors with isolated singularities on principally polarized abelian varieties, improving in this case well-known results of Kollár and others; see Mustaţă and Popa [ibid., §29]. For instance, one shows that every point on such a theta divisor has multiplicity at most $\frac{g+1}{2}$, where g is the dimension of the abelian variety.
- Effective bound for how far the Hodge filtration coincides with the pole order filtration on the cohomology $H^\bullet(U, \mathbb{C})$ of the complement $U = X \smallsetminus D$, in the style of results of Deligne, Dimca, Saito and others. For instance, if D is a divisor with only ordinary singularities of multiplicity $m \geq 2$ in an n-dimensional X, then

$$F_p H^\bullet(U, \mathbb{C}) = P_p H^\bullet(U, \mathbb{C}) \quad \text{for all} \quad p \leq \left[\frac{n}{m}\right] - n - 1.$$

(The two filtrations on $H^\bullet(U, \mathbb{C})$ start in degree $-n$.) See Mustaţă and Popa [ibid., Theorem D].

Space constraints do not allow me to explain all of this carefully. I will however focus in detail on the second item, and in fact on an extension to pluri-theta divisors in Section 8, in order to see the machinery in action.

5 Hodge ideals for arbitrary $\mathbb{Q}$-divisors

The case of arbitrary $\mathbb{Q}$-divisors is treated in Mustaţă and Popa [2018a]. It requires a somewhat more technical setting, where the $\mathscr{D}$-modules we consider are only direct summands of $\mathscr{D}$-modules underlying mixed Hodge modules. The initial setup can be seen as a $\mathscr{D}$-module analogue of eigensheaf decompositions in the theory of cyclic covering constructions, see e.g. Esnault and Viehweg [1992, §3].

Let D be an effective $\mathbb{Q}$-divisor on X, with support Z. We denote $U = X \smallsetminus Z$ and let $j : U \hookrightarrow X$ be the inclusion map. Locally we can assume that $D = \alpha \cdot \mathrm{div}(h)$ for some nonzero $h \in \mathscr{O}_X(X)$ and $\alpha \in \mathbb{Q}_{>0}$. We denote $\beta = 1 - \alpha$.

To this data one associates by a well-known construction the left $\mathscr{D}_X$-module $\mathscr{M}(h^\beta) := \mathscr{O}_X(*Z)h^\beta$, a rank 1 free $\mathscr{O}_X(*Z)$-module with generator the symbol h^β, on which a derivation D of $\mathscr{O}_X$ acts via the rule

$$D(wh^\beta) := \left(D(w) + w\frac{\beta \cdot D(h)}{h}\right)h^\beta.$$

The case $\beta = 0$ is the localization $\mathscr{O}_X(*Z)$ considered in Section 3.

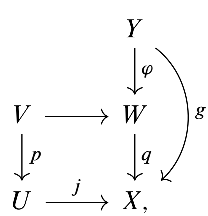
This $\mathscr{D}_X$-module does not necessarily itself underlie a Hodge module. It is however a filtered direct summand of one such, via the following construction. Let ℓ be an integer such that $\ell\beta \in \mathbb{Z}$, and consider the finite étale map

$$p\colon V = \mathbf{Spec}\, \mathscr{O}_U[y]/(y^\ell - h^{\ell\beta}) \longrightarrow U.$$

Consider also the cover

$$q\colon W = \mathbf{Spec}\, \mathscr{O}_X[z]/(z^\ell - h^{\ell\beta}) \longrightarrow X,$$

and a log-resolution $\varphi\colon Y \to W$ of the pair (W, q^*Z) that is an isomorphism over V and is equivariant with respect to the natural $\mathbb{Z}/\ell\mathbb{Z}$ action. This all fits in a commutative diagram



where the bottom square is Cartesian. Denote by E the support of $g^{-1}(Z)$.

Lemma 5.1. *Mustaţă and Popa [2018a] There is an isomorphism of filtered left $\mathscr{D}_X$-modules*

$$g_+\big(\mathscr{O}_Y(*E), F_\bullet\big) \simeq j_+ p_+(\mathscr{O}_V, F_\bullet) \simeq \bigoplus_{i=0}^{\ell-1} \big(\mathscr{M}(h^{i\beta}), F_\bullet\big),$$

where the filtration on the left hand side is given by the pushforward of the Hodge filtration in Section 3 (cf. also Theorem 4.1(iii)), while on each summand on the right hand side we consider the induced filtration.

For the notation in the lemma, recall that for any proper morphism of smooth varieties $f : X \to Y$ there is a filtered direct image functor

$$f_+ : \mathbf{D}^b\big(\mathrm{FM}(\mathscr{D}_X)\big) \longrightarrow \mathbf{D}^b\big(\mathrm{FM}(\mathscr{D}_Y)\big)$$

between the bounded derived categories of filtered $\mathscr{D}$-modules; see Saito [1990, §2.3].

Thus in this theory, the basic (local) object associated to an effective $\mathbb{Q}$-divisor D as above is the filtered $\mathscr{D}_X$-module

$$\big(\mathscr{M}(h^\beta), F_\bullet\big), \quad \text{with} \quad F_k\mathscr{M}(h^\beta) \neq 0 \Longleftrightarrow k \geq 0,$$

and for most practical purposes this has the same properties as a filtered $\mathscr{D}$-module underlying a mixed Hodge module.

One can show by a direct calculation that when the support Z is *smooth*, itself given by the equation h, then

$$F_k\mathscr{M}(h^\beta) = \mathscr{O}_X\big((k+1-[\beta])Z\big)h^\beta \subseteq \mathscr{O}_X\big((k+1)Z\big)h^\beta, \quad \text{for all} \quad k \geq 0.$$

Using this and standard reduction arguments, it follows that in general (even when Z is not necessarily defined by h), if $H = \mathrm{div}(h)$ so that $D = \alpha H$, we have

$$F_k\mathscr{M}(h^\beta) \subseteq \mathscr{O}_X\big(kZ + H\big)h^\beta, \quad \text{for all} \quad k \geq 0.$$

This allows us to formulate the following:

Definition 5.2. For each $k \geq 0$, the *k-th Hodge ideal* associated to the $\mathbb{Q}$-divisor D is defined by

$$F_k\mathscr{M}(h^\beta) = I_k(D) \otimes_{\mathscr{O}_X} \mathscr{O}_X\big(kZ + H\big)h^\beta.$$

It is standard to check that the definition of these ideals is independent of the choice of α and h, and therefore makes sense globally on X. The reduced case described in Section 3 and Section 4 corresponds to the value $\beta = 0$.

Assumption. From now on, for simplicity we assume that $\lceil D \rceil = Z$ (for instance, $D = \alpha Z$ with $0 < \alpha \leq 1$). This makes the statements more compact, while the general situation can be reduced to this case by noting that we always have

$$I_k(D) \simeq I_k(B) \otimes_{\mathscr{O}_X} \mathscr{O}_X(Z - \lceil D \rceil),$$

with $B = Z + D - \lceil D \rceil$.

In the rest of this section I will briefly explain the approach to the study of Hodge ideals based on log resolutions, originating in Mustaţă and Popa [2016a] in the reduced case, and completed in Mustaţă and Popa [2018a] in the general case. In Section 9 I will discuss the connection with the microlocal V-filtration discovered by Saito [2016], and its extension to the twisted case in Mustaţă and Popa [2018b].

Let $f : Y \to X$ be a log resolution of the pair (X, D) that is an isomorphism over $U = X \smallsetminus Z$, and denote $g = h \circ f \in \mathscr{O}_Y(Y)$. One has a filtered isomorphism

$$\big(\mathscr{M}(h^\beta), F_\bullet\big) \simeq f_+\big(\mathscr{M}(g^\beta), F_\bullet\big).$$

We use the notation $G = f^*D$ and $E = \mathrm{Supp}(G)$, the latter being a simple normal crossing divisor. It turns out that there exists a complex on Y:

$$C^\bullet_{(g^\beta, \lceil G \rceil)} : \ 0 \to \mathscr{O}_Y(-\lceil G \rceil) \otimes_{\mathscr{O}_Y} \mathscr{D}_Y \to \mathscr{O}_Y(-\lceil G \rceil) \otimes_{\mathscr{O}_Y} \Omega^1_Y(\log E) \otimes_{\mathscr{O}_Y} \mathscr{D}_Y$$

$$\to \ldots \to \mathscr{O}_Y(-\lceil G \rceil) \otimes_{\mathscr{O}_Y} \omega_Y(E) \otimes_{\mathscr{O}_Y} \mathscr{D}_Y \to 0,$$

which is placed in degrees $-n, \ldots, 0$, and such that if $x_1, \ldots, x_n$ are local coordinates, its differential is given by

$$\eta \otimes Q \to d\eta \otimes Q + \sum_{i=1}^n (dx_i \wedge \eta) \otimes \partial_i Q + (1-\beta)\big(\mathrm{dlog}(g) \wedge \eta\big) \otimes Q.$$

Moreover, this complex has a natural filtration given, for $k \geq 0$, by subcomplexes

$$F_{k-n} C^\bullet_{(g^\beta, \lceil G \rceil)} := 0 \to \mathscr{O}_Y(-\lceil G \rceil) \otimes F_{k-n}\mathscr{D}_Y \to$$

$$\to \mathscr{O}_Y(-\lceil G \rceil) \otimes \Omega^1_Y(\log E) \otimes F_{k-n+1}\mathscr{D}_Y \to \cdots \to \mathscr{O}_Y(-\lceil G \rceil) \otimes \omega_Y(E) \otimes F_k\mathscr{D}_Y \to 0.$$

The key point shown in *loc. cit.* is that the that there is a filtered quasi-isomorphism

$$(5.3) \qquad \big(C^\bullet_{g^\beta, \lceil G \rceil)}, F_\bullet\big) \simeq \big(\mathscr{M}_r(g^\beta), F_\bullet\big),$$

where

$$\mathscr{M}_r(g^\beta) := \mathscr{M}(g^\beta) \otimes_{\mathscr{O}_Y} \omega_Y \simeq h^\beta \omega_Y(*E)$$

is the filtered right $\mathscr{D}_Y$-module associated to $\mathscr{M}(g^\beta)$. In other words, the filtered complex on the left computes the Hodge filtration on $\mathscr{M}_r(g^\beta)$, hence the Hodge ideals for the simple normal crossings divisor E.

Given this fact, one can use $(C^\bullet_{(g^\beta,\lceil G\rceil)}, F_\bullet)$ as a concrete representative for computing the filtered $\mathscr{D}$-module pushforward of $\big(\mathscr{M}_r(g^\beta), F_\bullet\big)$, hence for computing the ideals $I_k(D)$. If we denote as customary by

$$\mathscr{D}_{Y\to X} = \mathscr{O}_Y \otimes_{f^{-1}\mathscr{O}_X} f^{-1}\mathscr{D}_X$$

the transfer $\mathscr{D}$-module (isomorphic to $f^*\mathscr{D}_X$ as an $\mathscr{O}_Y$-module), the result is:

Theorem 5.4. *Mustaţă and Popa [2018a] With the above notation, the following hold:*

1. *For every $p \neq 0$ and every $k \in \mathbb{Z}$, we have*

$$R^p f_*\big(C^\bullet_{(g^\beta,\lceil G\rceil)} \otimes_{\mathscr{D}_Y} \mathscr{D}_{Y\to X}\big) = 0 \quad \text{and} \quad R^p f_* F_k\big(C^\bullet_{(g^\beta,\lceil G\rceil)} \otimes_{\mathscr{D}_Y} \mathscr{D}_{Y\to X}\big) = 0.$$

2. *For every $k \in \mathbb{Z}$, the natural inclusion induces an injective map*

$$R^0 f_* F_k\big(C^\bullet_{(g^\beta,\lceil G\rceil)} \otimes_{\mathscr{D}_Y} \mathscr{D}_{Y\to X}\big) \hookrightarrow R^0 f_*\big(C^\bullet_{(g^\beta,\lceil G\rceil)} \otimes_{\mathscr{D}_Y} \mathscr{D}_{Y\to X}\big).$$

3. *We have a canonical isomorphism*

$$R^0 f_*\big(C^\bullet_{(g^\beta,\lceil G\rceil)} \otimes_{\mathscr{D}_Y} \mathscr{D}_{Y\to X}\big) \simeq \mathscr{M}_r(h^\beta)$$

that, using (2), induces for every $k \in \mathbb{Z}$ an isomorphism

$$R^0 f_* F_{k-n}\big(C^\bullet_{(g^\beta,\lceil G\rceil)} \otimes_{\mathscr{D}_Y} \mathscr{D}_{Y\to X}\big) \simeq h^\beta \omega_X\big(kZ + H\big) \otimes_{\mathscr{O}_X} I_k(D).$$

Example 5.5 ($I_0(D)$ is a multiplier ideal)**.** The lowest term in the filtration on the complex above reduces to the sheaf

$$F_{-n} C^\bullet_{(g^\beta,\lceil G\rceil)} = \omega_Y(E - \lceil f^*D\rceil)$$

in degree 0. Thus

$$I_0(D) = f_*\mathscr{O}_Y\big(K_{Y/X} + E - \lceil f^*D\rceil\big) = f_*\mathscr{O}_Y\big(K_{Y/X} - [(1-\epsilon)f^*D]\big).$$

This is by definition the multiplier ideal associated to the $\mathbb{Q}$-divisor $(1-\epsilon)D$ with $0 < \epsilon \ll 1$. Consequently (see Lazarsfeld [2004, p. 9.3.9]):

$$I_0(D) = \mathscr{O}_X \iff (X, D) \text{ is log canonical.}$$

Remark 5.6 (Local vanishing)**.** In view of Theorem 5.4(3) and Example 5.5, the statement in Theorem 5.4(1) can be seen as a generalization of Local Vanishing for multiplier ideals Lazarsfeld [ibid., Theorem 9.4.1].

Given the equivalence between the triviality of $I_0(D)$ and log canonicity, it is natural to introduce the following:

Definition 5.7. We say that the pair (X, D) is k-log canonical if

$$I_0(D) = \cdots = I_k(D) = \mathscr{O}_X.$$

Under our running assumption on D, Corollary 9.5 below implies that this is in fact equivalent to simply asking that $I_k(D) = \mathscr{O}_X$.

Example 5.8. Let Z have an ordinary singularity of multiplicity m, i.e. an isolated singular point whose projectivized tangent cone is smooth (for example the cone over a smooth hypersurface of degree m in $\mathbb{P}^{n-1}$). If $D = \alpha Z$ with $0 < \alpha \leq 1$, then (X, D) is k-log canonical if and only if $k \leq [\frac{n}{m} - \alpha]$. See Corollary 9.9, noting that $\tilde{\alpha}_f = \frac{n}{m}$ according to Saito [2009]; cf. also Mustaţă and Popa [2016a, Theorem D and Example 20.13].

Example 5.9. Irreducible theta divisors on principally polarized abelian varieties are 0-log canonical, but may sometimes not be 1-log canonical; see Mustaţă and Popa [ibid., Remark 29.3(2)]. Generic determinantal hypersurfaces are 1-log canonical, but they are not 2-log canonical; see Mustaţă and Popa [ibid., Example 20.14]. Both have rational singularities; compare with Theorem 4.1(iv).

The generation level of the Hodge filtration on $\mathscr{M}(h^\beta)$ is not well understood at the moment; for instance, depending on the value of α, examples in Mustaţă and Popa [2018a] show that on surfaces it can be either 0 or 1. It is natural to ask what is the analogue of Theorem 4.3, but also, concretely, whether the analogue of Saito's result discussed immediately after it holds:

Question 5.10. If $D = \alpha Z$, with Z reduced and having an isolated quasi-homogeneous singularity, is the generation level of the Hodge filtration on $\mathscr{M}(h^\beta)$ equal to $[n - \tilde{\alpha}_f - \alpha]$?

6 (Non)triviality criteria

The applications of the theory of multiplier ideals rely crucially on effective criteria for understanding whether they are trivial or not at a given point. The most basic are as follows; if D is an effective $\mathbb{Q}$-divisor, then:

1. If $\mathrm{mult}_x(D) \geq n = \dim X$, then $\mathcal{J}(D)_x \neq \mathscr{O}_{X,x}$; see Lazarsfeld [2004, Proposition 9.3.2].

2. If $\mathrm{mult}_x(D) < 1$, then $\mathcal{J}(D)_x = \mathcal{O}_{X,x}$; see Lazarsfeld [2004, Proposition 9.5.13].

The first is quite standard, while the second is a slightly more delicate application of inversion of adjunction.

Multiplier ideals also satisfy a birational transformation formula. If $f : Y \to X$ is any proper birational map, then

$$\mathcal{J}(D) \simeq f_*\big(\mathcal{O}_Y(K_{Y/X}) \otimes_{\mathcal{O}_Y} \mathcal{J}(f^*D)\big).$$

See Lazarsfeld [ibid., Theorem 9.2.33]. Such a compact statement is not available for higher Hodge ideals; however, using Theorem 5.4, one can show a partial analogue.

Theorem 6.1. *Mustaţă and Popa [2016a, Theorem 18.1], Mustaţă and Popa [2018a] Let $f : Y \to X$ be a projective morphism, with Y smooth. Let $Z = D_{\mathrm{red}}$, $E = (f^*D)_{\mathrm{red}}$, and denote $T_{Y/X} = \mathrm{Coker}(T_Y \to f^*T_X)$. Then:*

1. There is an inclusion

$$f_*\big(I_k(f^*D) \otimes_{\mathcal{O}_Y} \mathcal{O}_Y(K_{Y/X} + k(E - f^*Z))\big) \subseteq I_k(D).$$

2. If J is a coherent ideal on X such that $J \cdot T_{Y/X} = 0$, then

$$J^k \cdot I_k(D) \subseteq f_*\big(I_k(f^*D) \otimes_{\mathcal{O}_Y} \mathcal{O}_Y(K_{Y/X} + k(E - f^*Z))\big).$$

The first statement leads quite quickly to the following triviality criterion, in terms of the coefficients of exceptional divisors on a fixed log resolution.

Corollary 6.2. *Assume that $D = \alpha Z$ (with $0 < \alpha \le 1$) and for $f : Y \to X$ a log resolution of the pair (X, D), define γ as in (2.3). If*

$$\gamma \ge k + \alpha,$$

then $I_k(D) = \mathcal{O}_X$.

This is a key ingredient in bounding the microlocal log canonical threshold of D in terms discrepancies; see Theorem 9.10 below.

On the other hand, the second statement in Theorem 6.1 leads to nontriviality criteria that, just as in the case of multiplier ideals, are useful when combined with global statements like the vanishing theorem explained in the next section.

Corollary 6.3. *If $x \in X$ is such that $\mathrm{mult}_x Z = a$ and $\mathrm{mult}_x D = b$, and if q is a nonnegative integer such that*

$$b + ka > q + r + 2k - 1,$$

then $I_k(D) \subseteq \mathfrak{m}_x^q$. In particular, this happens if $\mathrm{mult}_W D > \frac{q+r+2k-1}{k+1}$.

At least for the moment, one can obtain somewhat stronger statements in the reduced case; the following collects some of the results in Mustaţă and Popa [2016a]. The proofs are more involved, (1) relying for instance on a deformation to ordinary singularities argument using Theorem 4.1(ix), combined with explicit calculations in that case.

Theorem 6.4. *If $x \in D$ is a point on a reduced divisor, with $m = \operatorname{mult}_x(D)$, then:*

1. *$I_k(D) \subseteq \mathfrak{m}_x^q$ if $q = \min\{m-1, (k+1)m - n\}$; see Mustaţă and Popa [ibid., Theorem E].*
2. *$I_k(D) \subseteq \mathfrak{m}_x^q$ if $m \geq 2 + \frac{q+n-2}{k+1}$; see Mustaţă and Popa [ibid., Corollary 19.4].*

As an example, for $k = 1$ the criterion in (1) can be rephrased as

$$m \geq \max\left\{q+1, \frac{n+q}{2}\right\} \implies I_1(D) \subseteq \mathfrak{m}_x^q.$$

It also implies that if $x \in D$ is a *singular* point, then

$$I_k(D) \subseteq \mathfrak{m}_x, \quad \text{for all } \ k \geq \frac{n-1}{2}.$$

In particular one obtains a smoothness criterion in terms of the Hodge filtration:

Corollary 6.5. *Mustaţă and Popa [ibid., Theorem A] The divisor D is smooth $\iff$ $I_k(D) = \mathscr{O}_X$ for all k $\iff$ $I_k(D) = \mathscr{O}_X$ for some $k \geq \frac{n-1}{2}$.*

7 Global setting and vanishing theorem

While the locally defined ideals in Definition 5.2 glue together into a global object, this is not usually the case with the $\mathscr{D}$-modules $\mathscr{M}(h^\beta)$. There is however a setting in which this can be done.

Namely, assume that $D = \frac{1}{\ell}H$, where H is an integral divisor and ℓ is a positive integer, and that there is a line bundle M such that $\mathscr{O}_X(H) \simeq M^{\otimes \ell}$. (This of course always holds when D is integral.) Let $s \in \Gamma(X, M^{\otimes \ell})$ be a section whose zero-locus is H. Recall that $U = X \smallsetminus Z$, and $j : U \hookrightarrow X$ is the inclusion. Since s does not vanish on U, we may consider the section $s^{-1} \in \Gamma(U, (M^{-1})^{\otimes \ell})$. Let

$$p \colon V = \mathbf{Spec}\big(\mathscr{O}_X \oplus M \oplus \ldots \oplus M^{\otimes(\ell-1)}\big) \longrightarrow U$$

be the étale cyclic cover corresponding to s^{-1}. The filtered $\mathscr{D}_X$-module

$$(\mathscr{M}, F_\bullet) = j_+ p_+(\mathscr{O}_V, F_\bullet)$$

underlies a mixed Hodge module, and the obvious μ_ℓ-action on $\mathscr{M}$ induces an eigenspace decomposition

$$(\mathscr{M}, F_\bullet) = \bigoplus_{i=0}^{\ell-1} (\mathscr{M}_i, F_\bullet),$$

where $\mathscr{M}_i$ is the eigenspace corresponding to the map $\lambda \to \lambda^i$, and on each $\mathscr{M}_i$ we consider the induced filtration.

On open subsets W on which M is trivialized we have isomorphisms of filtered $\mathscr{D}_W$-modules

$$\mathscr{M}_i \simeq \mathscr{M}(s_{|W}^{-i/\ell}) \quad \text{for} \quad 0 \le i \le \ell - 1,$$

which glue to a global isomorphism

$$\mathscr{M}_i \simeq M^{\otimes i} \otimes_{\mathscr{O}_X} \mathscr{O}_X(*Z) = j_* j^* M^{\otimes i}.$$

Twisting in order to globalize the $\mathscr{M}(h^\beta)$ picture, with $\beta = 1 - \frac{1}{\ell}$, we obtain global coherent ideals given by

$$F_k \mathscr{M}_i \simeq M^{\otimes i}(-H) \otimes_{\mathscr{O}_X} I_k(i/\ell \cdot H) \otimes_{\mathscr{O}_X} \mathscr{O}_X\big(kZ + H\big),$$

and the Hodge ideals $I_k(D)$ are defined by the case $i = 1$.

In this global setting, there is a vanishing theorem for Hodge ideals that in the case $k = 0$ is nothing else but the celebrated Nadel vanishing theorem for multiplier ideals. This was shown in Mustaţă and Popa [2016a, Theorem F] in the reduced case, and in Mustaţă and Popa [2018a] in general. Recall that here we are assuming $\lceil D \rceil = Z$, the support of D, for simplicity.

Theorem 7.1. *Assume that X is a smooth projective variety of dimension n, and D is a $\mathbb{Q}$-divisor as at the beginning of this section. Let L a line bundle on X such that $L + Z - D$ is ample. For some $k \ge 0$, assume that the pair (X, D) is $(k-1)$-log-canonical, i.e. $I_0(D) = \cdots = I_{k-1}(D) = \mathscr{O}_X$. Then we have:*

1. *If $k \le n$, and $L(pZ)$ is ample for all $1 \le p \le k$, then*

$$H^i\big(X, \omega_X \otimes L((k+1)Z) \otimes I_k(D)\big) = 0$$

for all $i \ge 2$. Moreover,

$$H^1\big(X, \omega_X \otimes L((k+1)Z) \otimes I_k(D)\big) = 0$$

holds if $H^j\big(X, \Omega_X^{n-j} \otimes L((k-j+1)Z)\big) = 0$ for all $1 \le j \le k$.

2. *If $k \geq n+1$ and $L((k+1)Z)$ is ample, then*

$$H^i\big(X, \omega_X \otimes L((k+1)Z) \otimes I_k(D)\big) = 0 \quad \text{for all} \quad i > 0.$$

3. *If $D + pZ$ is ample for $0 \leq p \leq k-1$, then (1) and (2) also hold with $L = M(-Z)$.*

The main ingredient in the proof is Saito's Kodaira-type vanishing theorem Saito [1990, §2.g] for mixed Hodge modules, stating that if $(\mathscr{M}, F_\bullet)$ is the filtered $\mathscr{D}$-module underlying a mixed Hodge module on a projective variety X, then

$$\mathbf{H}^i\big(X, \mathrm{gr}_k^F \mathrm{DR}(\mathscr{M}, F_\bullet) \otimes L\big) = 0 \quad \text{for all} \quad i > 0,$$

where L is any ample line bundle, and $\mathrm{gr}_k^F \mathrm{DR}(\mathscr{M}, F_\bullet)$ denotes for each k the associated graded of the induced filtration on the de Rham complex of $\mathscr{M}$. See Schnell [2016], Popa [2016a] for more on this theorem, and also Popa [2016b, §3] for a guide to interesting generalizations. In (3), this is replaced by Artin vanishing (on affine varieties) for the perverse sheaf associated to $\mathscr{M}$ via the Riemann-Hilbert correspondence.

Remark 7.2. When X has cotangent bundle with special properties, for instance when it is an abelian variety or $\mathbb{P}^n$ (or more generally a homogeneous space), the hypotheses on $(k-1)$-log canonicity and borderline Nakano-type vanishing are not needed, so vanishing holds in a completely arbitrary setting; see for instance Mustaţă and Popa [2016a, §25, §28]. Similarly, stronger vanishing holds on toric varieties Dutta [2018].

It will be important to address the following natural problem for non-reduced divisors:

Question 7.3. Does vanishing for $\mathbb{Q}$-divisors hold without the global assumption on the existence of ℓ-th roots of $\mathscr{O}_X(H)$ at the beginning of the section?

8 Example of application: pluri-theta divisors on abelian varieties

The goal here is to see explicitly how the combination of local nontriviality criteria and global vanishing for Hodge ideals can be put to use towards concrete applications. I will focus on one example: divisors in pluri-theta linear series on principally polarized abelian varieties. The result below is new, extending (and also marginally improving) part of Mustaţă and Popa [2016a, Theorem I], though the general idea is quite similar.

Let (A, Θ) be a principally polarized abelian variety of dimension g. Let $D \in |n\Theta|$ for some $n \geq 1$, whose support Z has only isolated singularities.

Theorem 8.1. *Under the hypotheses above, if $\epsilon(\Theta)$ denotes the Seshadri constant of Θ, and $x \in D$, we have:*

1. $\operatorname{mult}_x D \le n^2 g!\epsilon(\Theta) + ng!$.

2. *If A is general in the sense that $\rho(A) = 1$, or if $n = 1$, then* $\operatorname{mult}_x D \le n^2\epsilon(\Theta) + n$.

Recall that the definition of the Seshadri constant easily implies that $\epsilon(\Theta) \le \sqrt[g]{g!}$; see Lazarsfeld [2004, Proposition 5.1.9]. Before proving the theorem, let's introduce the notation $s(\ell, x)$ for the largest integer s such that the linear system $|\ell\Theta|$ separates s-jets at x, i.e. such that the restriction map

$$H^0\big(A, \mathscr{O}_A(\ell\Theta)\big) \longrightarrow H^0\big(A, \mathscr{O}_A(\ell\Theta) \otimes \mathscr{O}_A/\mathfrak{m}_x^{s+1}\big)$$

is surjective. A basic fact is that

$$\frac{s(\ell, x)}{\ell} \le \epsilon(\Theta, x), \tag{8.2}$$

the Seshadri constant of Θ at x, and that $\epsilon(\Theta, x)$ is the limit of these quotients as $\ell \to \infty$; see Lazarsfeld [ibid., Theorem 5.1.17] and its proof. Since A is homogeneous, $\epsilon(\Theta, x)$ does not actually depend on x, so it is denoted $\epsilon(\Theta)$.

Proof of Theorem 8.1. We prove (1), and at the end indicate the necessary modification needed to deduce (2). Write $D = \sum a_i Z_i$, with Z_i prime divisors, so that $Z = \sum Z_i$. Since effective divisors on abelian varieties are nef, for each i we have

$$a_i Z_i \cdot \Theta^{g-1} \le H \cdot \Theta^{g-1} = n \cdot g! \tag{8.3}$$

and since Θ is ample it follows that $a_i \le n \cdot g!$. Thus $D \le ng!Z$, so if $m = \operatorname{mult}_x(D)$, then

$$\operatorname{mult}_x(Z) \ge \lceil \frac{m}{ng!} \rceil.$$

Since x is fixed, for simplicity we denote $s_\ell = s(\ell, x)$. I claim that

$$\frac{m}{ng!} \le \lceil \frac{m}{ng!} \rceil \le \frac{(s_{n(k+1)} + g + k + 1)}{k+1}, \quad \text{for all} \quad k \ge 1. \tag{8.4}$$

Assuming the opposite inequality for some k, by Theorem 6.4(2) we have

$$I_k(Z) \subseteq \mathfrak{m}_x^{s_{n(k+1)}+2}.$$

Now according to the vanishing in Mustaţă and Popa [2016a, Theorem 28.2], a refinement on abelian varieties of the statement of Theorem 7.1 (cf. Remark 7.2), we have:

$$H^1\big(A, \mathscr{O}_A((k+1)Z) \otimes \alpha \otimes I_k(Z)\big) = 0$$

for every $\alpha \in \mathrm{Pic}^0(A)$.[5] Again using the fact that effective divisors on an abelian varieties are nef, we can write

$$(k+1)D = (k+1)Z + N,$$

where N is a nef divisor on A. On the other hand, nef line bundles on abelian varieties are special examples of what are called GV-sheaves (a condition involving the Fourier-Mukai transform, see e.g. Pareschi and Popa [2011, §2]), as they are topologically trivial twists of pullbacks of ample line bundles, so we conclude using Pareschi and Popa [ibid., Proposition 3.1][6] that we have

$$H^1\big(A, \mathscr{O}_A(n(k+1)\Theta) \otimes \alpha \otimes I_k(Z)\big) = 0 \quad \text{for all} \quad \alpha \in \mathrm{Pic}^0(A).$$

Going back to the inclusion $I_k(Z) \subseteq \mathfrak{m}_x^{s_{n(k+1)}+2}$, since Z has only isolated singularities, the quotient $\mathfrak{m}_x^{s_{n(k+1)}+2}/I_k(Z)$ is supported in dimension 0. We obtain

$$H^1\big(A, \mathscr{O}_A(n(k+1)\Theta) \otimes \alpha \otimes \mathfrak{m}_x^{s_{n(k+1)+2}}\big) = 0$$

for every $\alpha \in \mathrm{Pic}^0(A)$. But the collection of line bundles $\mathscr{O}_A(n(k+1)\Theta) \otimes \alpha$ is, as α varies in $\mathrm{Pic}^0(X)$, the same as the collection of line bundles $t_a^*\mathscr{O}_A(n(k+1)\Theta)$ as a varies in X, where t_a denotes translation by a. Therefore the vanishing above is equivalent to the statement that $|n(k+1)\Theta|$ separates $(s_{n(k+1)}+1)$-jets, which gives a contradiction and proves (8.4).

Finally, since $s_{n(k+1)} \le n(k+1)\epsilon(\Theta)$ by (8.2), we deduce that

$$m \le \frac{ng!(n(k+1)\epsilon(\Theta) + g + k + 1)}{k+1}, \quad \text{for all} \quad k \ge 1.$$

Letting $k \to \infty$, we obtain the inequality in the statement.

For the statement in (2), note that under the extra assumptions, each component Z_i satisfies $Z_i \cdot \Theta^{g-1} \ge g!$. Thus (8.3) implies the stronger bound $a_i \le n$, hence $\mathrm{mult}_x(Z) \ge \frac{m}{n}$. We can therefore eliminate the term $g!$ from all the formulas, while the rest of the argument is completely identical. □

9 V-filtration and microlocal log-canonical threshold

In this final section I turn to the connection between Hodge ideals and the V-filtration, first noted in Saito [2016]. For a $\mathbb{Q}$-divisor D on X, defined locally as $D = \alpha \cdot \mathrm{div}(f)$,

[5] Even though Z itself might not be ample, its complement $A \smallsetminus Z$ is affine, so the proof in *loc. cit.* works unchanged.

[6] The local freeness condition in the statement in *loc. cit.* is not needed in its proof.

just as in Section 5 we assume for simplicity that $Z = \mathrm{div}(f)$ is the reduced structure on D, and that $0 < \alpha \leq 1$. The corresponding statements for arbitrary D can be found in Mustaţă and Popa [2018b].

We return to the notation introduced in Section 2. Recall that for a $\mathscr{D}_X$-module $\mathscr{M}$, we denote by $\mathscr{M}_f$ its pushforward via the graph of f. In line with Saito [1993] and Saito [2016], I will use the notation

$$\mathcal{B}_f := (\mathscr{O}_X)_f, \quad \mathcal{B}_f(*Z) := (\mathscr{O}_X(*Z))_f, \quad \text{and} \quad \mathcal{B}_f^{\beta}(*Z) := (\mathscr{O}_X(*Z)f^{\beta})_f.$$

One can use the V-filtration on $\mathcal{B}_f$ in order to define some interesting ideals on X associated to D.

Definition 9.1. For each $k \geq 0$, we define

$$\tilde{I}_k(D) := \{v \in \mathscr{O}_X \mid \exists\, v_0, v_1, \ldots, v_k = v \in \mathscr{O}_X \text{ such that } \sum_{i=0}^{k} v_i \otimes \partial_t^i \in V^{\alpha}\mathcal{B}_f\} \subseteq \mathscr{O}_X.$$

Since $0 < \alpha \leq 1$, this is just another way of writing the filtration $\widetilde{V}^{\bullet}\mathscr{O}_X$ induced on $\mathscr{O}_X$ by Saito's *microlocal V-filtration* Saito [1994], Saito [2016]. In the notation of *loc. cit.*, we have

$$\tilde{I}_k(D) = \widetilde{V}^{k+\alpha}\mathscr{O}_X. \tag{9.2}$$

When $D = Z$ is a reduced divisor (i.e. $\alpha = 1$), a comparison theorem between Hodge ideals and these "microlocal" ideals was established recently by Saito.

Theorem 9.3. *Saito [ibid., Theorem 1] If D is reduced, then for every $k \geq 0$ we have*

$$I_k(D) = \tilde{I}_k(D) \mod f.$$

The statement means that the equality happens only in the quotient $\mathscr{O}_D$. For $k = 0$ it holds without modding out by f, by Theorem 2.2. However, for higher k it does not necessarily hold in $\mathscr{O}_X$; see Remark 9.8.

Its extension to arbitrary $\mathbb{Q}$-divisors is established in Mustaţă and Popa [2018b], as a consequence of a statement which is more explicit, in the sense of completely computing Hodge ideals in terms of the V-filtration, even in the reduced case. For $i \geq 0$, we denote

$$Q_i(X) = \prod_{j=0}^{i-1}(X + j) \in \mathbb{Z}[X].$$

Theorem 9.4. *Mustaţă and Popa [ibid.] If D is a $\mathbb{Q}$-divisor as above, then for every $k \geq 0$ we have*

$$I_k(D) = \left\{ \sum_{j=0}^{p} Q_j(\alpha) f^{p-j} v_j \mid \sum_{j=0}^{p} v_j \otimes \partial_t^j \delta \in V^\alpha \mathcal{B}_f \right\}.$$

In particular, we have

$$I_k(D) = \tilde{I}_k(D) \mod f.$$

One of the key technical points in Mustaţă and Popa [ibid.] is a description of the V-filtration on $\mathcal{B}_f^\beta(*Z)$ in terms of that on $\mathcal{B}_f(*Z)$, based on Sabbah's computation of the V-filtration in terms of the Bernstein-Sato polynomials of individual elements in the $\mathscr{D}$-module Sabbah [1987].

Theorem 9.4 has consequences regarding the basic behavior of Hodge ideals that, surprisingly, at the moment are not known by other means. Recall for instance the chain of inclusions in Theorem 4.1(i); this seems unlikely to hold in the general $\mathbb{Q}$-divisor case, but the following is nevertheless true, given (9.2).

Corollary 9.5. *For each $k \geq 1$ we have*

$$I_k(D) + (f) \subseteq I_{k-1}(D) + (f).$$

Stronger statements hold for the first nontrivial ideal, as it is not hard to see that the k-log-canonicity of a divisor D (see Definition 5.7) implies that $(f) \subseteq I_{k+1}(D)$.

Corollary 9.6. *If (X, D) is $(p-1)$-log canonical, then*

$$\tilde{I}_p(D) \subseteq I_p(D) = \tilde{I}_p(D) + (f)$$

and also

$$I_{p+1}(D) \subseteq I_p(D).$$

In particular, we always have $I_1(D) \subseteq I_0(D)$.

Another important consequence regards the behavior of the Hodge ideals $I_k(\alpha Z)$ when α varies. In the case of I_0, it is well known that they get smaller as α increases, and that there is a discrete set of values of α (called jumping coefficients) where there the ideal actually changes; see Lazarsfeld [2004, Lemma 9.3.21]. This is not the case for higher k; for the cusp $Z = (x^2 + y^3 = 0)$ and $5/6 < \alpha \leq 1$, one can see that

$$I_2(\alpha Z) = (x^3, x^2y^2, xy^3, y^4 - (2\alpha + 1)x^2 y),$$

and thus we obtain incomparable ideals. However, Theorem 9.4 implies that the picture does becomes similar to that for multiplier ideals if one considers the images in $\mathscr{O}_D$.

Corollary 9.7. *Given any k, there exists a finite set of rational numbers $0 = c_0 < c_1 < \cdots < c_s < c_{s+1} = 1$ such that for each $0 \le i \le s$ and each $\alpha \in (c_i, c_{i+1}]$ we have*

$$I_k(\alpha Z) \bmod f = I_k(c_{i+1}Z) \bmod f = \text{constant}$$

and such that

$$I_k(c_{i+1}Z) \bmod f \subseteq I_k(c_i Z) \bmod f.$$

In fact, for a fixed k, the set of c_i is contained in the set of jumping coefficients for the V-filtration on $\mathcal{B}_f$ in the interval $(k, k+1]$.

Remark 9.8 (Calculations)**.** There are also significant computational consequences; indeed, in Saito [2016, §2.2-2.4], Saito fully computes the microlocal V-filtration for weighted-homogeneous isolated singularities. For example, in the case of diagonal hypersurfaces $f = x_1^{a_1} + \cdots + x_n^{a_n}$ (which was previously obtained in Maxim, Saito, and Schuermann [2016, Example 2.6] using a Thom-Sebastiani type theorem), $\widetilde{V}^\alpha$ is generated by monomials of the form $x_1^{\nu_1} \cdots x_n^{\nu_n}$ satisfying

$$\sum_{i=1}^{n} \frac{1}{a_i}\left(\nu_i + 1 + \left[\frac{\nu_i}{a_i - 1}\right]\right) \ge \alpha.$$

Saito also shows in *loc. cit.* that $I_1(D) = \tilde{I}_1(D)$ in the reduced homogeneous case, though this typically fails for $k \ge 2$. Consider as an example the elliptic cone $D = (x^3 + y^3 + z^3 = 0) \subseteq \mathbf{A}^3$. The pair is log canonical, hence $I_0(D) = \mathcal{O}_X$. Moreover, it follows from the above that

$$I_1(D) = \tilde{I}_1(D) = (x^2, y^2, z^2, xyz).$$

Theorem 4.3(1) implies that from this one can compute all other $I_k(D)$. The calculations in Saito [2016] show however that the element $-2x^4 + xy^3 + xz^3$ belongs to $I_2(D)$, but not to $\tilde{I}_2(D)$. Many concrete calculations of Hodge ideals can also be performed based on the results in Saito [2009]; see also the upcoming Zhang [2018] for generalizations to $\mathbb{Q}$-divisors.

Microlocal log canonical threshold. Part of the usefulness of the results above stems from the connection between the (microlocal) V-filtration and the Bernstein-Sato polynomial of f and its roots; cf. Section 9. Most importantly for us here, and by analogy with the description of the log canonical threshold in terms of $V^\bullet \mathcal{O}_X$, one has

$$\tilde{\alpha}_f = \max\{\gamma \in \mathbb{Q} \mid \widetilde{V}^\gamma \mathcal{O}_X = \mathcal{O}_X\},$$

see for instance Saito [2016, (1.3.8)]. Therefore Theorem 9.4 immediately implies the following formula for the log canonicity index of D, obtained first in Saito [ibid.] when $\alpha = 1$; recall that we are assuming $D = \alpha Z$ with $0 < \alpha \le 1$.

Corollary 9.9. *Let*

$$p_0 := \min\{p \mid I_p(D) \neq \mathscr{O}_X\} = \max\{p \mid (X, D) \text{ is } (p-1)\text{–log canonical}\}.$$

Then $p_0 = [\tilde{\alpha}_f - \alpha + 1]$.

Corollary 9.9 can be combined with the information in Corollary 6.2, coming from the birational description of Hodge ideals, in order to obtain the inequality

$$\gamma < [\tilde{\alpha}_f - \alpha] + \alpha + 1, \quad \text{for all } \ 0 < \alpha \leq 1.$$

Going back to Question 2.7 and the subsequent comments, optimizing as α varies we obtain the following partial positive answer to Lichtin's question:

Theorem 9.10. *Mustaţă and Popa [2018b] We have* $\gamma \leq \tilde{\alpha}_f$.

One can also use the methods explained here in order to give bounds on $\tilde{\alpha}_f$, the first of which is a result of Saito [1994]:

Corollary 9.11. *Let* $n = \dim X$. *Then:*

1. $\tilde{\alpha}_f \leq [n/2]$.
2. *If* Z *has only singular points of multiplicity at most* m, *whose projectivized tangent cone satisfies* $\dim \operatorname{Sing}\big(\mathbb{P}(C_x D)\big) \leq r$, *then* $[\tilde{\alpha}_f] \geq \frac{n-r-1}{m}$.

Indeed, if this weren't the case in (1), then by Corollary 9.9 for $\alpha = 1$ we would have $I_k(Z) = \mathscr{O}_X$ for some $k \geq \frac{n-1}{2}$. But then Corollary 6.5 implies that Z is smooth, a contradiction. For (2) one uses the bound for $I_k(Z) = \mathscr{O}_X$ in Mustaţă and Popa [2016b, Corollary D], based on Theorem 4.1(vii).

This bound in (1) is optimal, since by Example 2.6 for a quadric $f = x_1^2 + \cdots + x_n^2$ one has $\tilde{\alpha}_f = n/2$. Saito shows in fact in Saito [1994, Theorem 0.4] that all the negatives of the roots of $\tilde{b}_f(s)$ are contained in the interval $[\tilde{\alpha}_f, n - \tilde{\alpha}_f]$. Alternatively, one can see this result, together with Theorem 9.3, as recovering Corollary 6.5.

INTERACTION BETWEEN SINGULARITY THEORY AND THE MINIMAL MODEL PROGRAM

Chenyang Xu (许晨阳)

Abstract

We survey some recent topics on singularities, with a focus on their connection to the minimal model program. This includes the construction and properties of dual complexes, the proof of the ACC conjecture for log canonical thresholds and the recent progress on the 'local stability theory' of an arbitrary Kawamata log terminal singularity.

1 Introduction

Through out this paper, we will consider algebraic singularities in characteristic 0. It is well known that even if we are mostly interested in smooth varieties, for many different reasons, we have to deal with singular varieties. For the minimal model program (MMP) (also known as Mori's program), the reason is straightforward, mildly singular varieties are built into the MMP process, and there is no good way to avoid them (see e.g. Kollár and Mori [1998]). In fact, the development of the MMP has been intertwined with the progress of our understanding of the corresponding singularity theory, in particular for the classes of singularities preserved by an MMP sequence. This is one of the main reasons why when the theory was started around four decades ago, people spent a lot of time to classify these singularities. However, once we move beyond dimension three, an explicit characterisation of these singularities is often too complicated, and we have to search for a more intrinsic and qualitative method. It turns out that MMP theory itself provides many new tools for the study of singularities. In this note, we will survey some recent progress along these lines. More precisely, we will discuss the construction and properties of dual complexes, the proof of the ACC conjecture for log canonical thresholds, and the recently developed concept of 'local stability theory' of an arbitrary Kawamata log

terminal singularity. We hope these different aspects will give the reader an insight to the modern philosophy of studying singularities from the MMP viewpoint.

In the rest of the introduction, we will give a very short account on some of the main ideas. Given a singularity $x \in X$ in characteristic 0, the first birational model that one probably thinks of is a smooth one given by Hironaka's theorem on resolution of singularities. However, started from dimension three, there are often too many possible resolutions and examples clearly suggest that in a general case, an 'optimal resolution' does not exist. By the philosophy of MMP, we should run a sequence of relative MMP, which allows us to start from a general birational model over $x \in X$, e.g., an arbitrary resolution, and produce a sequence of relative birational models. The output of this MMP is a birational model, which usually is mildly singular but still equipped with many desirable properties. Furthermore, since during the MMP process, each step is a simple surgery like a divisorial contraction or a flip, we can keep track of many properties of the models and use this information to answer questions. As an example, in Section 2, we will consider the construction of a CW-complex as a topological invariant for an isolated singularity $x \in X$ with K_X being $\mathbb{Q}$-Cartier, namely the dual complex of a minimal resolution denoted by $\mathfrak{DMR}(x \in X)$.

A possibly more profound principle is that there is a local-to-global analogue between different types of singularities and the building blocks of varieties. More precisely, the MMP can be considered as a process to transform and decompose an arbitrary projective variety into three types, which respectively have positive (Fano), zero (Calabi-Yau) or negative (KSBA) first Chern class. These three classes are naturally viewed as building blocks for higher dimensional varieties. As a local counterpart, we consider normal singularities whose canonical class is $\mathbb{Q}$-Cartier. There is a closely related trichotomy: the minimal log discrepancy is larger, equal or smaller than 0. In fact, guided by the local to global principle, we are able to discover striking new results on singularities. In Section 3, we will focus on the proof of Shokurov's ACC conjecture on log canonical thresholds, which is achieved via an intensive interplay between local and global geometry. In Section 4, we will investigate in a new perspective on Kawamata log terminal (klt) singularities which are precisely the singularities with positive log discrepancies and form the local analog of Fano varieties. We will explain some deep insights on klt singularities inspired by advances in the study of Fano varieties. More precisely, for Fano varieties, we have the notion of K-(semi,poly)stability which has a differential geometry origin, as it is expected to characterise the existence of a Kähler-Einstein metric. For klt singularities, the local to global principle leads us to discover a (conjectural) stability theory, packaged in the *Stable Degeneration Conjecture* 4.4, which can be considered as a local analogue to the K-stability for Fano varieties.

Reference: Giving a comprehensive account of the relation between the singularity theory and the MMP is far beyond the scope of this note. The singularity theory in the MMP is extensively discussed in the book Kollár [2013b]. Ever since Kollár's book was published, many different aspects of singularity theory have significantly evolved, and important new results have been established.

Acknowledgments. I want to thank my coauthors, especially Christopher Hacon, János Kollár, Chi Li and James McKernan for many discussions and joint works on the mathematical materials surveyed in this note. I am grateful to Christopher Hacon and János Kollár for long lists of valuable comments.

2 Dual complex

There are many standard references in the subject of MMP, see e.g. Kollár and Mori [1998]. Here we recall some basic definitions. Given a normal variety X and a $\mathbb{Q}$-divisor Δ whose coefficients along prime components are contained in $\mathbb{Q}\cap[0,1]$, we call (X,Δ) a *$\mathbb{Q}$-Cartier log pair* if $K_X+\Delta$ is $\mathbb{Q}$-Cartier, e.g. there is some positive integer N such that $N(K_X+\Delta)$ is Cartier. For a divisorial valuation E whose centre on X is non-empty, we can assume there is a birational model $f: Y\to X$, such that E is a divisor on Y. Then we can define the *discrepancy* $a(E,X,\Delta)$ for a $\mathbb{Q}$-Cartier log pair (X,Δ) to be the multiplicity of

$$K_{Y/X}+f^*\Delta=K_Y-f^*(K_X+\Delta)$$

along E. This is a rational number of the form $\frac{p}{N}$ for some integer p. For many questions, it is more natural to look at the *log discrepancy* $A(E,X,\Delta)=a(E,X,\Delta)+1$, which is also denoted by $A_{X,\Delta}(E)$ in the literature. We say that (X,Δ) is *log canonical* (resp. *Kawamata log terminal* (*klt*)) if $A(E,X,\Delta)\geq 0$ (resp. $A(E,X,\Delta)>0$) for all divisorial valuations E whose centre $\mathrm{Center}_X(E)$ on X is non-empty. There is another important class called *divisorial log terminal* (*dlt*) sitting in between: a log pair (X,Δ) is dlt if there is a smooth open locus $U\subset X$, such that $\Delta_U=_{\mathrm{defn}}\Delta|_U$ is a reduced divisor satisfying (U,Δ_U) is simple normal crossing, and any divisor E with the centre $\mathrm{Center}_X(E)\subset X\setminus U$ satisfies $A(E,X,\Delta)>0$. The main property for the discrepancy function is that $a(E,X,\Delta)$ monotonically increases under a MMP sequence, which implies that the MMP will preserve the classes of singularities defined above (cf. Kollár and Mori [ibid., pp. 3.42–3.44]).

We call a projective variety X to be *a $\mathbb{Q}$-Fano variety* if X only has klt singularities and $-K_X$ is ample. Similarly, a projective pair (X,Δ) is called *a log Fano pair* if (X,Δ) is klt and $-K_X-\Delta$ is ample.

2.1 Dual complex as PL-homeomorphism invariant. For a simple normal crossing variety E, it is natural to consider how the components intersect with each other. This combinatorial data is captured by the dual complex $\mathcal{D}(E)$ (see Definition 2.1). A typical example one can keep in mind is the dual graph $\mathcal{D}(E)$ for a resolution $(Y, E) \to X$ of a normal surface singularity, where the exceptional curve E is assumed to be of simple normal crossings. This invariant is indispensable for the study of surface singularities (see e.g. Mumford [1961]). Nevertheless, the concept of dual complex can be defined in a more general context.

Definition 2.1 (Dual Complex)**.** Let $E = \bigcup_{i \in I} E_i$ be a pure dimensional scheme with irreducible components E_i. Assume that

1. each E_i is normal and

2. for every $J \subset I$, if $\cap_{i \in J} E_i$ is nonempty, then every connected component of $\cap_{i \in J} E_i$ is irreducible and has codimension $|J| - 1$ in E.

Note that assumption (2) implies the following.

3. For every $j \in J$, every irreducible component of $\cap_{i \in J} E_i$ is contained in a unique irreducible component of $\cap_{i \in J \setminus \{j\}} E_i$.

The *dual complex* $\mathcal{D}(E)$ of E is the regular cell complex obtained as follows. The vertices are the irreducible components of E and to each irreducible component of $W \subset \cap_{i \in J} E_i$ we associate a cell of dimension $|J| - 1$. This cell is usually denoted by v_W. The attaching map is given by condition (3). Note that $\mathcal{D}(E)$ is a simplicial complex iff $\cap_{i \in J} E_i$ is irreducible (or empty) for every $J \subset I$.

Fixed a dlt pair (X, Δ), the reduced part $E =_{\text{defn}} \Delta^{=1}$ of Δ satisfies the assumptions in Definition 2.1 (see e.g. Kollár [2013b, Section 4.2]), thus we can define $\mathcal{D}(X, \Delta) =_{\text{defn}} \mathcal{D}(E)$. Clearly, by the definition of U in the definition of dlt singularity (X, Δ), we can pick any such U, then $\mathcal{D}(X, \Delta) = \mathcal{D}(\Delta|_U)$. Furthermore, if two dlt pairs (X, Δ) and (X', Δ') are crepant birationally equivalent, i.e., the pull backs of $K_X + \Delta$ and $K_{X'} + \Delta'$ to a common model are the same, then applying the weak factorisation theorem to log resolutions of (X, Δ) and (X', Δ') and carefully tracking the dual complex given by divisors with log discrepancy 0 on each birational model, we can show that $\mathcal{D}(X, \Delta)$ and $\mathcal{D}(X', \Delta')$ are PL-homeomorphic (see de Fernex, Kollár, and Xu [2017, p. 11]).

Given a sequence of MMP

$$(X_1, \Delta_1) \dashrightarrow (X_2, \Delta_2) \dashrightarrow \cdots \dashrightarrow (X_k, \Delta_k),$$

as the log discrepancies of (X_i, Δ_i) monotonically increase, we have

$$\mathcal{D}(X_1, \Delta_1) \supset \mathcal{D}(X_2, \Delta_2) \supset \cdots \supset \mathcal{D}(X_k, \Delta_k).$$

Remark 2.2. Although part of the MMP, including the abundance conjecture, remains to be conjectural, all the MMP results we need in this note are already proved in Birkar, Cascini, Hacon, and McKernan [2010] and its extensions, e.g. Hacon and Xu [2013].

We know the following technical but useful criterion.

Lemma 2.3 (de Fernex, Kollár, and Xu [2017, p. 19]). *If for a step $(X_i, \Delta_i) \dashrightarrow (X_{i+1}, \Delta_{i+1})$ of an MMP sequence, the extremal ray R_i satisfies that $R_i \cdot D_i > 0$ for a component D_i of $\Delta_i^{=1}$, then $\mathfrak{D}(X_i, \Delta_i) \supset \mathfrak{D}(X_{i+1}, \Delta_{i+1})$ is a homotopy equivalence.*

Now we can apply this to various geometric situations. We first consider the application to the study of a singularity $x \in X \subset \mathbb{C}^N$. It has been known for long time (see Milnor [1968]) that all local topological information of $x \in X$ is encoded in the link defined as

$$\text{Link}(x \in X) =_{\text{defn}} X \cap B_\epsilon(x)$$

for a sufficiently small radius ϵ. Following the strategy of studying surfaces (as in e.g. Mumford [1961]), we pick a log resolution $Y \to (x \in X)$ and let $E =_{\text{defn}} f^{-1}(x))$ (in particular, E is simple normal crossing). Then $\text{Link}(x \in X)$ is a tubular neighbourhood of E and $\mathfrak{D}(E)$ contains some key information of this tubular structure.

Example 2.4. Consider the well known classification of rational double points (or Du Val singularities) on surface:

1. Type A_n: $x^2 + y^2 + z^{n+1} = 0$.
2. Type D_n: $x^2 + zy^2 + z^{n-1} = 0$ $(n \geq 4)$.
3. Type E_6: $x^2 + y^3 + z^4 = 0$.
4. Type E_7: $x^2 + y(y^2 + z^3) = 0$
5. Type E_8: $x^2 + y^3 + z^5 = 0$.

Then the minimal resolution Y with the exceptional locus E forms a log resolution, and $\mathfrak{D}(E)$ is the graph underlying the corresponding Dynkin diagram.

Using the weak factorisation theorem Abramovich, Karu, Matsuki, and Włodarczyk [2002], one shows that the homotopy class of $\mathfrak{D}(E)$ is a well-defined homotopy invariant $\mathfrak{DR}(x \in X)$ which does not depend on the choice of the log resolution (Y, E) (see e.g. Payne [2013]). The strategy in our previous discussion then can be used to show the following result.

Theorem 2.5. *For an isolated normal singularity $x \in X$ with K_X being $\mathbb{Q}$-Cartier, we can define a canonical PL-homeomorphism invariant $\mathfrak{DMR}(x \in X)$ which has the homotopy class of $\mathfrak{DR}(x \in X)$.*

Proof. First we take a log resolution $(Y, E) \to X$ which is isomorphic outside $X \setminus \{x\}$, then run a relative MMP of (Y, E) over X. The output $(X^{\rm dlt}, \Delta^{\rm dlt})$ is called *a dlt modification* of $x \in X$. Then we define a regular complex

$$\mathfrak{DMR}(x \in X) =_{\rm defn} \mathfrak{D}(\Delta^{\rm dlt}).$$

Since different dlt modifications are crepant birationally equivalent to each other, we know $\mathfrak{DMR}(x \in X)$ gives a well defined PL-homeomorphism class by the discussion before. Furthermore, we can deduce from Lemma 2.3 that for all the birational models appearing in steps of the relative MMP, including the last one $(X^{\rm dlt}, \Delta^{\rm dlt})$, the dual complexes have the same homotopy type. Then it implies $\mathfrak{DMR}(x \in X)$ is homotopy equivalent to $\mathfrak{DR}(x \in X)$. □

The regular complex $\mathfrak{DMR}(x \in X)$ can be considered as a geometric realisation of the weight 0 part of the Hodge theoretic invariant attached to $x \in X$. An interesting corollary to Theorem 2.5 is that if we consider a klt singularity $x \in X$, then $\mathfrak{DR}(x \in X)$ is contractible, as in the special case of Example 2.4.

Another natural context in which the dual complex appears is for the motivic zeta function using the log resolution formula (cf. Denef and Loeser [2001, Section 3]). The techniques developed here can be used to show that the only possible maximal order pole of the motivic zeta function is the negative of the log canonical threshold, which was a conjecture by Veys (see Nicaise and Xu [2016a]).

2.2 Dual complex of log Calabi-Yau pairs. Similar ideas can be applied when we consider the setting of a proper degeneration $Y \to C$ of projective varieties over a smooth pointed curve $(C, 0)$. Here we consider the dual complex $\mathfrak{D}(Y_0^{\rm red})$ where $Y_0^{\rm red}$ is the reduced fiber over 0 and assume $(Y, Y_0^{\rm red})$ is a dlt pair.

For subjects like mirror symmetry, the degeneration of Calabi-Yau varieties is of particular interests. From a birational geometry view, if we consider a family $\pi : Y \to C$, and assume a general fiber has $K_{Y_t} \sim_{\mathbb{Q}} 0$, then after running an MMP over C (cf. Fujino [2011]), we end up with a model Y which satisfies $K_Y + Y_0^{\rm red} \sim_{\mathbb{Q}} 0$. Then for such models with this extra condition, any two of them are crepant birationally equivalent which implies $\mathfrak{D}(Y_0^{\rm red})$ is well defined up to PL-homeomorphism.

Indeed in this case, the topological invariant $\mathfrak{D}(Y_0^{\rm red})$ is first defined by Kontsevich-Soibelman as the 'essential skeleton' of the Berkovich theoretic non-archimedean analytification $Y^{\rm an}$ (see Kontsevich and Soibelman [2001], Mustaţă and Nicaise [2015], and Nicaise and Xu [2016b]), and it plays an important role in the study of the algebro-geometric version of the SYZ conjecture (cf. Strominger, Yau, and Zaslow [1996], Kontsevich and Soibelman [2001], and Gross and Siebert [2011] etc.). The same argument for proving Theorem 2.5 can be used to show the essential skeleton $\mathcal{D}(Y_0^{\mathrm{red}})$ is homotopy equivalent to Y^{an} (see Nicaise and Xu [2016b]).

To understand $\mathcal{D}(Y_0^{\mathrm{red}})$, we first need to describe its local structure, i.e., for a prime component $X \subset Y_0$, to understand the link of the corresponding vertex v_X in $\mathcal{D}(Y_0^{\mathrm{red}})$. It is given by $\mathcal{D}(\Delta^{=1})$ where Δ is defined by formula

$$(K_Y + Y_0^{\mathrm{red}})|_X = K_X + \Delta \sim_{\mathbb{Q}} 0.$$

Our goal is to show under suitable conditions, the dual complex coming from a (log) Calabi-Yau variety is close to simple objects like a sphere or a disc. In fact, we can show the following.

Theorem 2.6 (Kollár and Xu [2016])**.** *Let* (X, Δ) *be a projective dlt pair which satisfies* $K_X + \Delta \sim_{\mathbb{Q}} 0$. *Assume* $\dim(\mathcal{D}(\Delta^{=1})) > 1$, *then the following holds.*

1. $H^i(\mathcal{D}(\Delta^{=1}), \mathbb{Q}) = 0$ *for* $1 \le i \le \dim(\mathcal{D}(\Delta^{=1}, \mathbb{Q}))$.
2. $\mathcal{D}(\Delta^{=1})$ *is a pseudo-manifold with boundary (Kollár and Kovács [2010]).*
3. *There is a natural surjection* $\pi_1(X^{\mathrm{sm}}) \twoheadrightarrow \pi_1(\mathcal{D}(\Delta^{=1}))$.
4. *The profinite completion* $\hat{\pi}_1(\mathcal{D}(\Delta^{=1}))$ *is finite.*

Proof. We sketch the proof under the extra assumption that $\dim(\mathcal{D}(\Delta^{=1}))$ is maximal, i.e. equal to $n-1$. Then (1) is easily obtained using Hodge theory. We need to apply MMP theory to show (2) and (3). Here we explain the argument for (3). A carefully chosen MMP process (see Kollár and Xu [2016, Section 6]) allows us to change the model from X to a birational model X', with the property that if we define the effective $\mathbb{Q}$-divisor Δ' on X' to be the one such that (X, Δ) and (X', Δ') are crepant birationally equivalent, then the support of Δ' contains an ample divisor. From this we conclude that

$$\pi_1(X'^{\mathrm{sm}}) \twoheadrightarrow \pi_1(\Delta'^{=1}) \twoheadrightarrow \pi_1(\mathcal{D}(\Delta^{=1})),$$

where the first surjection follows from the (singular version of) Lefschetz Hyperplane Theorem. We also have $\pi_1(X^{\mathrm{sm}}) \to \pi_1(X'^{\mathrm{sm}})$ by tracking the MMP process, which concludes (3). Finally, (4) follows from Xu [2014]. (We note here that we indeed expect $\pi_1(\mathcal{D}(\Delta^{=1}))$ is finite, but to apply the above argument, we need $\pi_1(X^{\mathrm{sm}})$ for the underlying variety X of a log Fano pair. For now, we only know its pro-finite completion is finite.) □

A remaining challenging question is to understand the torsion cohomological group $H^i(\mathcal{D}(\Delta^{=1}), \mathbb{Z})$ for a dlt log Calabi-Yau pair (X, Δ).

3 ACC of log canonical thresholds

Given a holomorphic function f with $f(0)=0$, the complex singular index

$$c(f)=\sup\{c \mid \frac{1}{|f|^c} \text{ is locally } L^2\text{-integrable at } 0\}$$

introduced by Arnold is a fundamental invariant, which appears in many contexts (see Arnol'd, Guseĭn-Zade, and Varchenko [1985, II. Chap. 13]). In a more general setting, in birational geometry, this invariant is interpreted as the *log canonical threshold* of an effective $\mathbb{Q}$-divisor D with respect to a log pair (X,Δ)

$$\mathrm{lct}(X,\Delta;D)=\max\{t \mid (X,\Delta+tD) \text{ is log canonical}\}.$$

Using a log resolution, it is not hard to show that when X is the local germ $0\in\mathbb{C}^n$, $\Delta=0$ and $D=(f)$, $\mathrm{lct}(X;D)=c(f)$.

Example 3.1. Let $X=\mathbb{C}^n$, $f=x_1^{m_1}+\cdots+x_n^{m_n}$, then by Kollár [1997, p. 8.15]

$$\mathrm{lct}(\mathbb{C}^n,f)=\min\{1,\sum_{i=1}^{n}\frac{1}{m_i}\}.$$

For a fixed n, all such numbers form an infinite set which satisfies the ascending chain condition.

See Kollár [ibid., Section 8-10] for a wonderful survey, including relations with other branches of mathematics.

We define the following set.

Definition 3.2. Fix the dimension n and two sets of positive numbers I and J, we denote by $\mathrm{LCT}_n(I,J)$ the set consisting of all numbers $\mathrm{lct}(X,\Delta;D)$ such that $\dim(X)=n$, the coefficients of Δ are in I and the coefficients of D are in J.

Our main contribution to the study of log canonical thresholds is showing the following theorem.

Theorem 3.3 (Hacon, McKernan, and Xu [2014, Theorem 1.1], ACC Conjecture for log canonical thresholds)**.** *If I and J satisfy the descending chain condition (DCC), then* $\mathrm{LCT}_n(I,J)$ *satisfies the ascending chain condition (ACC).*

In such a generality, this was conjectured in Shokurov [1992], although in a lot of earlier works, questions of a similar flavour already appeared. For $X=\mathbb{C}^n$ (or even more generally for bounded singularities) and $D=(f)$, this was solved by de Fernex, Ein, and Mustaţă [2010] using a different approach. In fact, while our proof is via global geometry, the argument in de Fernex, Ein, and Mustaţă [ibid.] uses a more local method.

To understand our strategy, we start with a well-known construction: Given a log canonical pair (X, Δ) with a prime divisor E over X with the log discrepancy $A(E, X, \Delta) = 0$, if X admits a boundary Δ' such that (X, Δ') is klt, then applying the MMP we can construct a model $f : Y \to X$ such that $\mathrm{Ex}(f)$ is equal to the divisor E (see Birkar, Cascini, Hacon, and McKernan [2010, p. 1.4.3]). Denote by $\Delta_Y = E + f_*^{-1}\Delta$ and restrict $K_Y + \Delta_Y$ to a general fiber F of $f : E \to f(E)$. Since E has coefficient one in Δ_Y, the adjunction formula says there is a boundary Δ_F such that

$$K_F + \Delta_F = (K_Y + \Delta_Y)|_F = f^*(K_X + \Delta) \sim_{\mathbb{Q}} 0.$$

In other words, using the model Y constructed by an MMP technique, from a lc pair (X, Δ) which is not klt along a subvariety $f(E)$, we obtain a log Calabi-Yau pair (F, Δ_F) of smaller dimensional.

We note that even in the case $\Delta_Y = E$, since Y could be singular along codimension 2 points on E, it is not always the case that $\Delta_E = 0$. Nevertheless, if the coefficients of Δ are in a set $I \subset [0, 1]$, then the coefficients of Δ_F are always in the set

$$D(I) =_{\mathrm{defn}} \{\frac{n-1+a}{n} \mid n \in \mathbb{N}, a = \sum_{i=1}^{j} a_i \text{ where } a_i \in I\} \cap [0, 1]$$

(see e.g. Kollár [2013b, p. 3.45]). In particular, if I satisfies the DCC, then $D(I)$ satisfies the DCC. This is why we work with such a general setting of coefficients as it works better with the induction.

Moreover, if there is a sequence of pairs (X_i, Δ_i) and strictly increasing log canonical thresholds t_i with respect to the divisors D_i, then the above construction will produce a sequence of log Calabi-Yau varieties (F_i, Δ_{F_i}) corresponding to $(X_i, \Delta_i + t_i D_i)$ with the property that the restriction of $f_*^{-1}(\Delta_i + t_i D_i)$ on F_i yields components of Δ_{F_i} with strictly increasing coefficients as $i \to \infty$. Therefore, to get a contradiction, it suffices to prove the following global version of the ACC conjecture.

Theorem 3.4 (Hacon, McKernan, and Xu [2014, Theorem 1.5])**.** *Fix n and a DCC set I, then there exists a finite set $I_0 \subset I$ such that for any projective n-dimensional log canonical Calabi-Yau pair (X, Δ), i.e. $K_X + \Delta \sim_{\mathbb{Q}} 0$, with the coefficients of Δ contained in I, it indeeds holds that the coefficients of Δ are in I_0.*

We note that Theorem 3.4 in dimension $n-1$ implies Theorem 3.3 in dimension n. More crucially, Theorem 3.4 changes the problem from a local setting to a global one and we have many new tools to study it. In particular, as we will explain below, Theorem 3.4

relates to the boundedness results on log general type pairs. This is a central topic in the study of such pairs, especially for the construction of the compact moduli space of KSBA stable pairs, which is the higher dimensional analogue of the moduli space of marked stable curves $\overline{\mathfrak{M}}_{g,n}$ (see e.g. Kollár [2013a] and Hacon, McKernan, and Xu [2016]).

Since I satisfies the DCC, if such a finite set I_0 does not exist, we can construct an infinite sequences (X_i, Δ_i) of log canonical Calabi-Yau pairs of dimension at most n, such that after reordering, if we write $\Delta_i = \sum_{j=1}^{k} a_i^j \Delta_i^j$, $\{a_i^j\}_{i=1}^{\infty}$ monotonically increases for any fixed $1 \le j \le k$ and strictly increases for at least one. Furthermore, after running an MMP, we can reduce to the case that the underlying variety X_i is a Fano variety with the Picard number $\rho(X_i) = 1$. Then if we push up the coefficients of Δ_i to get a new boundary

$$\Delta_i' =_{\text{defn}} \sum_{j=1}^{k} a_\infty^j \Delta_i^j \qquad \text{where } a_\infty^j = \lim_i a_i^j,$$

$K_{X_i} + \Delta_i'$ is ample. By enlarging I, we can start with the assumption that all accumulation points of I are also contained I. In particular, the coefficients $a_\infty^j \in I$. Moreover, recall that by induction on the dimension, we can assume Theorem 3.4 holds for dimension $n-1$, which implies Theorem 3.3 in dimension n. Thus for i sufficiently large, (X_i, Δ_i') is also log canonical. Then we immediately get a contradiction to the second part of (2) in the following theorem.

Theorem 3.5 (Hacon, McKernan, and Xu [2014, Theorem 1.3])**.** *Fix dimension n and a DCC set $I \subset [0,1]$. Let $\mathfrak{D}_n(I)$ be the set of all pairs*

$$\{(X, \Delta) \mid \dim(X) = n, (X, \Delta) \textit{ is lc and the coefficients of } \Delta \textit{ are in } I\},$$

and $\mathfrak{D}_n^\circ(I) \subset \mathfrak{D}_n(I)$ the subset of pairs with $K_X + \Delta$ being big. Then the following holds.

1. *The set* $\mathrm{Vol}_n(I) = \{\mathrm{vol}(K_X + \Delta) \mid (X, \Delta) \in \mathfrak{D}_n(I)\}$ *satisfies DCC.*
2. *There exists a positive integer $N = N(n, I)$ depending on n and I such that the linear system $|N(K_X + \Delta)|$ induces a birational map for any $(X, \Delta) \in \mathfrak{D}_n^\circ(I)$. Moreover, there exists $\delta > 0$ depending only on n and I, such that if $(X, \Delta) \in \mathfrak{D}_n^\circ(I)$, then $K_X + (1-\delta)\Delta$ is big.*

The part (1) was a conjecture of Alexeev-Kollár (cf. Kollár [1994] and Alexeev [1994]). As already mentioned, it is the key in the proof of the boundedness of the moduli space of KSBA stable pairs with fixed numerical invariants. See Hacon, McKernan, and Xu [2016] for a survey on this topic and related literature.

During the proof of Theorem 3.5, we have to treat (1) and (2) simultaneously. Such a strategy was first initiated in Tsuji [2007], and carried out by Hacon and McKernan [2006] and Takayama [2006] for X with canonical singularities and $\Delta = 0$. It started with the simple observation that for smooth varieties of general type, birationally boundedness implies boundedness (after the MMP is settled). In Hacon, McKernan, and Xu [2013], we prove a log version of this, which says that log birational boundedness essentially implies Theorem 3.5. This is significantly harder, and we use ideas from Alexeev [1994] which established the two dimensional case of Theorem 3.5. After this, it remains to show that all pairs in $\mathfrak{D}^{\circ}_n(I)$ with the volume bounded from above by an arbitrarily fixed constant is always log birationally bounded, which is done in Hacon, McKernan, and Xu [2014]. One key ingredient is to produce appropriate boundaries on the log canonical centres such that the classical techniques of inductively cutting log canonical centres initiated in Angehrn and Siu [1995] can be followed here.

Addressing the proof for the ACC of the log canonical thresholds in this circle of global questions is a crucial idea in our solution to it. In fact, in the pioneering work McKernan and Prokhorov [2004], an attempt was already made to establish a connection between the ACC of log canonical thresholds and a global question on boundedness but for the set of K_X-negative varieties, i.e. Fano varieties. More precisely, it has been shown in McKernan and Prokhorov [ibid.] that the ACC conjecture of log canonical thresholds is implied by Borisov-Alexeev-Borisov (BAB) conjecture which is about the bounededness of Fano varieties with a uniform positive lower bound on log discrepancies. More recently, the BAB conjecture is proved in Birkar [2016].

In Hacon, McKernan, and Xu [2014], under a suitable condition on I and assuming that $J = \{\mathbb{N}\}$, we show that the accumulation points of $\mathrm{LCT}_n(I) =_{\mathrm{defn}} \mathrm{LCT}_n(I, \mathbb{N})$ are contained in $\mathrm{LCT}_{n-1}(I)$, confirming the Accumulation Conjecture due to Kollár.

It attracts considerable interests to find out the effective bound for the constants appearing in Theorem 3.3 and Theorem 3.5. So far it is only successful for low dimension. For instance when $I = 0$, Theorem 3.3 implies that there exists an optimal $\delta_n < 1$ such that $\mathrm{LCT}_n =_{\mathrm{defn}} \mathrm{LCT}(\{0\}) \subset [0, \delta_n] \cup \{1\}$, and $(\delta_n, 1)$ is called *the n-dimensional gap*. It is known $\delta_2 = \frac{5}{6}$, but δ_3 is unknown. In Kollár [1997, p. 8.16], it is asked whether

$$\delta_n = 1 - \frac{1}{a_n} \qquad \text{where } a_1 = 2, a_i = a_1 \cdots a_{i-1} + 1.$$

Our approach in general only gives the existence of δ_n.

Remark 3.6 (ACC Conjecture on minimal log discrepancy)**.** There is another deep conjecture about ACC properties of singularities due to Shokurov, which seems to be still far open.

ACC Conjecture of mld: Given a log canonical singularity $x \in (X, \Delta)$, we can define

$$\mathrm{mld}_{X,\Delta}(x) = \min\{A_{X,\Delta}(E) \mid \mathrm{Center}_E(X) = \{x\}\}.$$

If we fix a finite set I, and it is conjectured that the set

$$\mathrm{MLD}_n(I) = \{\mathrm{mld}_{X,\Delta}(x) | \ \dim(X) = n, \text{ coefficients of } \Delta \text{ are in I}\}$$

satisfies the ACC.

However, compared to the log canonical thresholds, what kind of global questions connect to this conjecture still remains to be in a myth. For instance, it is not clear which special geometric structure is carried by a divisor attaining the minimal log discrepancy.

4 Klt singularities and K-stability

In this section, our discussion will focus on klt singularities. When klt singularities were first introduced, they appeared to be just a technical tool to prove results in the MMP. However, it has become more and more clear that the klt singularities form a very interesting class of singularities, which naturally appears in many context besides the MMP such as constructing Kähler-Einstein metrics of Fano varieties etc..

In particular, philosophically, it has been clear that there is an analogy between klt singularities and Fano varieties. Traditionally, people often prove some properties for an arbitrary Fano variety, then figure out what they imply for the cone singularity over a Fano variety, and finally generalise the statements to any klt singularity. Only after the corresponding MMP results are established (e.g. Birkar, Cascini, Hacon, and McKernan [2010]), such analogy can be carried out in a more concrete manner by really attaching suitable global objects, e.g. Fano varieties, to the singularities. The first construction was the plt blow up (cf. e.g. Xu [2014]) which for a given klt singularity $x \in (X, \Delta)$, one constructs a birational model $f : Y \to X$ such that f is isomorphic outside x, $f^{-1}(x)$ is an irreducible divisor S, and $(Y, S + f_*^{-1}\Delta)$ is plt. We can also assume $-S$ is ample over X, and then (S, Δ_S) is a log Fano pair, where

$$K_S + \Delta_S =_{\mathrm{defn}} (K_Y + S + f_*^{-1}\Delta)|_S.$$

The divisor S in this construction is called *a Kollár component*. It was used to show some local topological properties of $x \in X$ including $\mathfrak{DR}(x \in X)$ is contractible (de Fernex, Kollár, and Xu [2017]), and the pro-finite completion $\hat{\pi}_1^{\mathrm{loc}}(x \in X)$ of the local fundamental group

$$\pi_1^{\mathrm{loc}}(x \in X) =_{\mathrm{defn}} \pi_1(\mathrm{Link}(x \in X))$$

is finite (Xu [2014] and Z. Tian and Xu [2016]). However, given a klt singularity, usually there could be many Kollár components over it. Only until the circle of ideas of local stability were introduced in Li [2015b], a more canonical picture, though some parts still remain conjectural, becomes clear. In what follows we give a survey on this topic.

Definition 4.1 (Valuations)**.** Let R be an n-dimensional regular local domain essentially of finite type over a ground field k of characteristic zero. Then a (real) valuation v of $K = \mathrm{Frac}(R)$ is any map $v\colon K^* \to \mathbb{R}$ which satisfies the following properties for all a, b in K^*:

1. $v(ab) = v(a) + v(b)$,

2. $v(a+b) \geq \min(v(a), v(b))$, with equality if $v(a) \neq v(b)$.

Let $(X, x) = (\mathrm{Spec}(R), \mathfrak{m})$, we denote the space of valuations

$$\mathrm{Val}_{X,x} = \{\text{real valuations } v \text{ of } K \text{ with } v(f) > 0 \text{ for any } f \in \mathfrak{m}\}.$$

It has a natural topology (see Jonsson and Mustaţă [2012, Section 4.1]).

If (X, Δ) is klt, following Jonsson and Mustaţă [ibid., Section 5], we can define the function of log discrepancy $A_{X,\Delta}(v)$ on $\mathrm{Val}_{X,x}$ extending the log discrepancy of divisorial valuations defined in Section 2, and we denote by $\mathrm{Val}^{=1}_{X,x} \subset \mathrm{Val}_{X,x}$ the subset consisting of all valuations with log discrepancy equal to 1. Similar to the global definition of volumes, we can also define a local volume of a valuation for $v \in \mathrm{Val}_{X,x}$ (see Ein, Lazarsfeld, and Smith [2003])

$$\mathrm{vol}(v) = \lim \frac{\mathrm{length}(R/\mathfrak{a}_k)}{k^n/n!},$$

where $\mathfrak{a}_k = \{f \in R \mid v(f) \geq k\}$.

Definition 4.2 (Li [2015b])**.** For any valuation $v \in \mathrm{Val}_{X,x}$, we define the *normalised volume* $\widehat{\mathrm{vol}}_{X,\Delta}(v) = (A_{X,\Delta}(v))^n \cdot \mathrm{vol}(v)$, and the volume of the klt singularity $x \in (X, \Delta)$ to be $\mathrm{vol}(x, X, \Delta) = \inf_{v \in \mathrm{Val}_{X,x}} \widehat{\mathrm{vol}}(v)$. By abuse of notation, we will often denote $\mathrm{vol}(x, X, \Delta)$ by $\mathrm{vol}(x, X)$ if the context is clear.

It is easy to see that $\widehat{\mathrm{vol}}(v) = \widehat{\mathrm{vol}}(\lambda v)$ for any $\lambda > 0$, so that we can only consider the function $\widehat{\mathrm{vol}}$ on $\mathrm{Val}^{=1}_{X,x}$. In Li [ibid.], it was shown that $\mathrm{vol}(x, X) > 0$. In Liu [2016], a different characterisation is given:

$$\mathrm{vol}(x, X) = \inf_{\mathfrak{m}-\text{primary } \mathfrak{a}} \mathrm{mult}(\mathfrak{a}) \cdot \mathrm{lct}(X, \Delta; \mathfrak{a})^n. \tag{1}$$

See Lazarsfeld [2004, p. 9.3.14] for the definition of the log canonical threshold of a klt pair (X, Δ) with respect to an ideal $\mathfrak{a}$. Then in Blum [2016], using an argument combining estimates on asymptotic invariants and the generic limiting construction, it is show that there always exists a valuation v such that $\mathrm{vol}(x, X) = \widehat{\mathrm{vol}}(v)$, i.e., the infimum is indeed a minimum, confirming a conjecture in Li [2015b]. Therefore the main questions left are two-fold.

Question 4.3. For a klt singularity $x \in (X, \Delta)$,

I. Characterise the geometric properties of the minimiser v.

II. Compute the volume $\mathrm{vol}(x, X)$.

In what follows below, we will discuss these two questions in different sections.

4.1 Geometry of the minimiser. In the recent birational geometry study of Fano varieties, it has become clear that the interplay between the ideas from higher dimensional geometry and the ideas from the complex geometry, centred around the study of Kähler-Einstein metrics, will lead to deep results. The common ground is the notion of K-(semi, poly)stability and their cousin definitions (see e.g. Odaka [2013], Li and Xu [2014], and Fujita [2015] etc.). An example is the construction of a proper moduli scheme parametrising the smoothable K-polystable Fano varieties (see e.g. Li, Wang, and Xu [2014]). Although to establish a moduli space of Fano varieties is certainly a natural question to algebraic geometers, without a condition like K-stability with a differential geometry origin, such a functor does not behave well (e.g. the functor of smooth family Fano manifolds is not seperated.). Moreover the arguments used in the current construction of moduli spaces of K-polystable Fano varieties heavily depend on the results proved using analytic tools as in Chen, Donaldson, and Sun [2015] and G. Tian [2015].

Our main motivation to consider v is to establish a 'local K-stability' theory for klt singularities, guided by the local-to-global philosophy mentioned in the introduction. In particular, we propose the following conjecture for all klt singularities.

Conjecture 4.4 (Stable Degeneration Conjecture, Li [2015b] and Li and Xu [2017]). *Given any arbitrary klt singularity $x \in (X = \mathrm{Spec}(R), \Delta)$. There is a unique minimiser v up to rescaling. Furthermore, v is quasi-monomial, with a finitely generated associated graded ring $R_0 =_{\mathrm{defn}} \mathrm{gr}_v(R)$, and the induced degeneration*

$$(X_0 = \mathrm{Spec}(R_0), \Delta_0, \xi_v)$$

is a K-semistable Fano cone singularity. (See below for the definitions.)

For the definition of quasi-monomial valuations, see Jonsson and Mustaţă [2012, Section 3]. It is shown that they are the same as Abhyankar valuations (Ein, Lazarsfeld, and Smith [2003, p. 2.8]). From an arbitrary quasi-monomial valuation $v \in \mathrm{Val}_{X,x}$, there is a standard process to degenerate $\mathrm{Spec}(R)$ to the associated graded ring $\mathrm{Spec}(R_0)$ over a complicated (e.g. non-Noetherian) base (see Teissier [2003]). However, when R_0 is finitely generated, the degeneration can be understood in a much simpler way: we can embed $\mathrm{Spec}(R)$ into an affine space $\mathbb{C}^N$ of sufficiently large dimension, such that there exists a $\mathbb{C}^*$-action on $\mathbb{C}^N$ with a suitable weight $(\lambda_1, ..., \lambda_N)$ satisfying that $\mathrm{Spec}(R_0)$ is the degeneration of $\mathrm{Spec}(R)$ under this one-parameter $\mathbb{C}^*$-action (see e.g. Li and Xu [2017]).

The following example which predates our study is a prototype from the context of constructing Sasaki-Einstein metrics in Sasaki geometry.

Example 4.5 (Fano cone singularity)**.** Assume that $X = \mathrm{Spec}_{\mathbb{C}}(R)$ is a normal affine variety. Denote by T a complex torus $(\mathbb{C}^*)^r$ which acts on X faithfully. Let $N = \mathrm{Hom}(\mathbb{C}^*, T) \cong \mathbb{Z}^{\oplus r}$ be the co-weight lattice and $M = N^*$ the weight lattice. We have a weight space decomposition

$$R = \bigoplus_{\alpha \in \Gamma} R_\alpha \text{ where } \Gamma = \{\alpha \in M |\ R_\alpha \neq 0\}.$$

We assume $R_{(0)} = \mathbb{C}$ which means there is a unique fixed point o contained in the closure of each orbit. Denote by $\sigma^\vee \subset M_{\mathbb{R}}$ the convex cone generated by Γ, which is called the *weight cone* (or the *moment cone*). We define the *Reeb cone*

$$\mathfrak{t}^+_{\mathbb{R}} := \{\ \xi \in N_{\mathbb{R}}\ \ |\ \langle \alpha, \xi \rangle > 0 \text{ for any } \alpha \in \Gamma\}.$$

Then for any vector $\xi \in \mathfrak{t}^+_{\mathbb{R}}$ on X we can associate a natural valuation v_ξ, which is given by

$$v_\xi(f) = \min\{\langle \alpha, \xi \rangle \mid f_\alpha \neq 0 \text{ if we write } f = \sum f_\alpha\}.$$

If X have klt singularities, we call (X, ξ) a *Fano cone singularity* for the following reason: for any $\xi \in N_{\mathbb{Q}} \cap \mathfrak{t}^+_{\mathbb{R}}$, then it generates a $\mathbb{C}^*$-action on X, and the quotient will be a log Fano pair as we assume X is klt.

For isolated Fano cone singularities, minimising the normalised volume $\widehat{\mathrm{vol}}$ among all valuations of the form v_ξ ($\xi \in \mathfrak{t}^+_{\mathbb{R}}$) was initiated in the work Martelli, Sparks, and Yau [2008], where $\widehat{\mathrm{vol}}$ is defined analytically. It is shown there that the existence of a Sasaki-Einstein metric along ξ_0 implies v_{ξ_0} is a minimiser among all $\xi \in \mathfrak{t}^+_{\mathbb{R}}$. Moreover, it is proved that $\widehat{\mathrm{vol}}$ is strictly convex on $\mathfrak{t}^+_{\mathbb{R}}$, which is an evidence for the claim of the uniqueness in Conjecture 4.4.

Later, in Collins and Székelyhidi [2015], following G. Tian [1997] and Donaldson [2001], the K-(semi)polystability was formulated for Fano cone singularities. It was a straightforward calculation from the definition to show that if (X, ξ_0) is K-semistable, then v_{ξ_0} is a minimiser among all valuations of the form v_ξ for $\xi \in \mathfrak{t}^+_{\mathbb{R}}$. However, it takes significant more work in Li and Xu [2017] to show that if (X, ξ_0) is K-semistable, then v_{ξ_0} is a minimiser in the much larger space $\mathrm{Val}_{X,x}$ and unique among all quasi-monomial valuations up to rescaling (see Step 3 and 6 in the sketch of the proofs of Theorem 4.6 and Theorem 4.7 below).

For a normal singularity $x \in (X = \mathrm{Spec}(R), \Delta)$ with a quasi-monomial valuation $v \in \mathrm{Val}_{X,x}$ of rational rank r, we assume that its associated graded ring R_0 is finitely generated. By the grading, $\mathrm{Spec}(R_0)$ admits a torus $T \cong (\mathbb{C}^*)^r$-action, thus we can put it in (a log generalisation of) the setting of Example 4.5 as follows. Let Φ be the valuative semigroup of v, then it generates a group $\Phi^g \cong \mathbb{Z}^r$ which is isomorphic to the weight lattice $M = N^*$. Under this isomorphism the weight cone is generated by $\alpha \in \Phi$. Since the embedding $\iota_v \colon \Phi^g \to \mathbb{R}$ restricts to $\iota_v^+ \colon \Phi \to \mathbb{R}_+$, it yields a vector in the Reeb cone $\mathfrak{t}^+_{\mathbb{R}} \subset N_{\mathbb{R}}$, denoted by ξ_v. Let Δ_0 be the natural divisorial degeneration of Δ on $X_0 = \mathrm{Spec}(R_0)$. We call such a valuation $v \in \mathrm{Val}_{x,X}$ to be *K-semistable*, if (X_0, Δ_0, ξ_v) is a K-semistable Fano cone. In particular, we require (X_0, Δ_0) to be klt. Since a K-semistable valuation is always a minimiser (see Theorem 4.7), Conjecture 4.4 predicts that for any klt singularity $x \in (X, \Delta)$, the minimiser of $\widehat{\mathrm{vol}}$ is precisely the same as the notion of a K-semistable valuation.

We have established various parts of Conjecture 4.4. First we consider the case that the minimiser is a divisorial valuation.

Theorem 4.6 (Li and Xu [2016, Theorem 1.2])**.** *Let $x \in (X, \Delta)$ be a klt singularity. If a divisorial valuation $\mathrm{ord}_S \in \mathrm{Val}_{X,x}$ minimises the function $\widehat{\mathrm{vol}}_{X,\Delta}$, then S is a Kollár component over x, and the induced log Fano pair (S, Δ_S) is K-semistable. Furthermore, $\widehat{\mathrm{vol}}(\mathrm{ord}_S) < \widehat{\mathrm{vol}}(\mathrm{ord}_E)$ for any divisor $E \neq S$ centred on x.*

Conversely, if S is a Kollár component centred on x such that the induced log Fano pair (S, Δ_S) is K-semistable, then ord_S minimises $\widehat{\mathrm{vol}}_{X,\Delta}$.

An immediate consequence is that, if instead of searching general Kollár components, we only look for the semi-stable ones, then if one exists, it is unique. In general, Conjecture 4.4 predicts that if we choose a sequence of rational vectors $v_i \in \mathfrak{t}^+_{\mathbb{Q}}$ that converge to v, then the quotient of X_0 by the $\mathbb{C}^*$-action along v_i induces a Kollár component S_i centred on $x \in (X, \Delta)$ which satisfies $c_i \cdot \mathrm{ord}_{S_i} \to \xi_v$ after a suitable rescaling (cf. Li [2015a] and Li and Xu [2017]). In Li and Xu [2016], we confirm that any minimiser is always a limit of a sequence of Kollár components with a suitable rescaling.

In general, a quasi-monomial valuation with higher rational rank could appear as the minimiser (cf. Blum [2016]). In this case, we can also prove the following result.

Theorem 4.7 (Li and Xu [2017, Theorem 1.1])**.** *Let $x \in (X, \Delta)$ be a klt singularity. Let v be a quasi-monomial valuation in $\mathrm{Val}_{X,x}$ that minimises $\widehat{\mathrm{vol}}_{(X,\Delta)}$ and has a finitely generated associated graded ring $\mathrm{gr}_v(R)$. Then the following properties hold:*

(a) The degeneration $\big(X_0 =_{\mathrm{defn}} \mathrm{Spec}\big(\mathrm{gr}_v(R)\big), \Delta_0, \xi_v\big)$ is a K-semistable Fano cone, i.e. v is a K-semistable valuation;

(b) Let v' be another quasi-monomial valuation in $\mathrm{Val}_{X,x}$ that minimises $\widehat{\mathrm{vol}}_{(X,\Delta)}$. Then v' is a rescaling of v.

Conversely, any quasi-monomial valuation that satisfies (a) above is a minimiser.

Sketch of ideas in the Proofs of Theorem 4.6 and Theorem 4.7. The proof consists of a few steps, involving different techniques.

Step 1: In this step, we illustrate how Kollár components come into the picture. From each ideal $\mathfrak{a}$, we can take a dlt modification of

$$f : (Y, \Delta_Y) \to (X, \Delta + \mathrm{lct}(X, \Delta; \mathfrak{a}) \cdot \mathfrak{a}),$$

where $\Delta_Y = f_*^{-1}\Delta + \mathrm{Ex}(f)$ and for any component $E_i \subset \mathrm{Ex}(f)$ we have

$$A_{X,\Delta}(E) = \mathrm{lct}(X, \Delta; \mathfrak{a}) \cdot \mathrm{mult}_E\, f^*\mathfrak{a}.$$

There is a natural inclusion $\mathfrak{D}(\Delta_Y) \subset \mathrm{Val}^{=1}_{X,x}$, and using a similar argument as in Li and Xu [2014], we can show that there exists a Kollár component S whose rescaling in $\mathrm{Val}^{=1}_{X,x}$ contained in $\mathfrak{D}(\Delta_Y)$ satisfies that

$$\widehat{\mathrm{vol}}(\mathrm{ord}_S) = \mathrm{vol}^{\mathrm{loc}}(-A_{X,\Delta}(S) \cdot S) \le \mathrm{vol}^{\mathrm{loc}}(-K_Y - \Delta_Y) \le \mathrm{mult}(\mathfrak{a}) \cdot \mathrm{lct}^n(X, \Delta; \mathfrak{a}).$$

Then (1) implies that

$$\mathrm{vol}(x, X) = \inf\{\widehat{\mathrm{vol}}(\mathrm{ord}_S) |\ S \text{ is a Kollár component}\}.$$

We can also show that if a minimiser is a divisor then it is indeed a Kollár component (this is proved independently in Blum [2016]).

Moreover, if $x \in (X, \Delta)$ admits a torus group T-action, then by degenerating to the initial ideals, as the colengths are preserved and the log canonical thresholds may only decrease, the right hand side of (1) can be replaced by all T-equivariant ideals. Moreover, equivariant MMP allows us to make all the above data Y and S T-equivariant.

Step 2: In this step, we show that if a minimiser v is quasi-monomial such that $R_0 = \mathrm{gr}_v(R)$ is finitely generated, then the degeneration pair $(X_0 =_{\mathrm{defn}} \mathrm{Spec}(R_0), D_0)$ is klt. After Step 1, this is easy in the case of Theorem 4.6, as the Kollár component is klt. To treat the higher rank case in Theorem 4.7, we verify two ingredients: first we show that a rescaling of ord_{S_i} for the approximating sequence of S_i in Step 1 can be all chosen in the dual complex of a fixed model considered as a subspace of $\mathrm{Val}^{=1}_{X,x}$; then we show as $\mathrm{gr}_v(R)$ is finitely generated, for any i sufficiently large, $\mathrm{gr}_v(R) \cong \mathrm{gr}_{\mathrm{ord}_{S_i}}(R)$. This immediately implies that (X_0, D_0) is the same as the corresponding cone $C(S_0, \Delta_{S_0})$ over the Kollár component S_0, and then we conclude it is klt as before.

Step 3: To proceed we need to establish properties of a general log Fano cone (X_0, Δ_0, ξ_v) and show that the corresponding valuation v is a minimiser if and only if (X_0, Δ_0, ξ_v) is K-semistable. First assume (X_0, Δ_0, ξ_v) is K-semistable, then by Step 1, it suffices to show that for any T-equivariant Kollár component S, $\widehat{\mathrm{vol}}(\mathrm{ord}_S) \geq \widehat{\mathrm{vol}}(v)$. In fact, for any such S, it induces a special degeneration of (X_0, Δ_0, ξ_v) to (Y, Δ_Y, ξ_Y) admitting a $((\mathbb{C}^*)^r \times \mathbb{C}^*)$-action and a new rational vector $\eta_S \in N \oplus \mathbb{Z}$ corresponding to the $\mathbb{C}^*$-action on the special fiber induced by the degeneration. Then an observation going back to Martelli, Sparks, and Yau [2008] says that

$$\frac{d\, \widehat{\mathrm{vol}}(\xi_Y + t \cdot \xi_S)}{dt} = \mathrm{Fut}(Y, \Delta_Y, \xi_Y; \xi_S) \geq 0.$$

Here the generalised Futaki invariant $\mathrm{Fut}(Y, \Delta_Y, \xi_Y; \xi_S)$ is defined in Collins and Székelyhidi [2015, p. 2.2], and then the last inequality comes from the K-semistability assumption. It is also first observed in Martelli, Sparks, and Yau [2008] that the normalised volume function $\widehat{\mathrm{vol}}$ is convex on the space of valuations $\{\xi_v \mid v \in \mathfrak{t}^+_{\mathbb{R}}\}$. Thus by restricting the function on the ray $\xi_Y + t \cdot \xi_S$ $(t \geq 0)$ and applying the convexity, we conclude that

$$\widehat{\mathrm{vol}}_{X_0}(\mathrm{ord}_S) = \lim_{t\to\infty} \widehat{\mathrm{vol}}_Y(\xi_Y + t \cdot \xi_S) \geq \widehat{\mathrm{vol}}_Y(\xi_Y) = \widehat{\mathrm{vol}}_{X_0}(\xi_v).$$

Reversing the argument, one can show that if v is a minimiser of $\widehat{\mathrm{vol}}$ for a log Fano cone singularity (X_0, Δ_0, ξ_v), then for any special degeneration with the same notation as above, we have $\mathrm{Fut}(Y, \Delta_Y, \xi_Y; \xi_S) \geq 0$.

Step 4: An consequence of Step 3 is that for a valuation v on X such that the degeneration (X_0, Δ_0, ξ_v) is K-semistable, since the degeneration to the initial ideal argument implies that $\mathrm{vol}(x, X) \geq \mathrm{vol}(o, X_0)$, then

$$\widehat{\mathrm{vol}}_X(v) = \widehat{\mathrm{vol}}_{X_0}(\xi_v) = \mathrm{vol}(o, X_0)$$

is equal to $\mathrm{vol}(x, X)$.

Step 5: Then we proceed to show that if a log Fano cone (X_0, Δ_0, ξ_v) comes from a degeneration of a minimiser as in Step 2, then it is K-semistable. If not, by Step 3, we can find a degeneration (Y, Δ_Y, ξ_Y) induced by an equivariant Kollár component S with $\widehat{\mathrm{vol}}_Y(\mathrm{ord}_S) < \widehat{\mathrm{vol}}_Y(\xi_Y) = \widehat{\mathrm{vol}}_{X_0}(\xi_v)$. Then arguments similar to Anderson [2013, Section 5] show we can construct a degeneration of (X, Δ) to (Y, Δ_Y) and a family of valuations $v_t \in \mathrm{Val}_{X,x}$ for $t \in [0, \epsilon]$ (for some $0 < \epsilon \ll 1$), with the property that

$$\widehat{\mathrm{vol}}_X(v_t) = \widehat{\mathrm{vol}}_Y(\xi_Y + t \cdot \xi_S) < \widehat{\mathrm{vol}}_Y(\xi_Y) = \widehat{\mathrm{vol}}_{X_0}(\xi_v) = \widehat{\mathrm{vol}}_X(v),$$

where for the second inequality, we use again the fact that $\widehat{\mathrm{vol}}_Y(\xi_Y + t \cdot \xi_S)$ is a convex function. But this is a contradiction.

Step 6: Now we turn to the uniqueness. In this step, we show this for a K-semistable Fano cone singularity (X_0, Δ_0, ξ_v). In fact, for any T-equivariant valuation μ, we can connect ξ_v and μ by a path μ_t such that $\mu_0 = \xi_v$ and $\mu_1 = \mu$. A Newton-Okounkov body type construction (similar to Kaveh and Khovanskii [2014]) can interpret the volumes $\widehat{\mathrm{vol}}(\mu_t)$ to be the volumes of the regions $\mathfrak{A}_t$ contained in the convex cone $\mathfrak{C}$ cut out by a hyperplane H_t passing through a given vector inside $\mathfrak{C}$. Then we conclude by the fact in the convex geometry which says that such a function $f(t) = \mathrm{vol}(\mathfrak{A}_t)$ is strictly convex. Thus it has a unique minimiser, which is ξ_v by Step 3.

Step 7: The last step is to prove the uniqueness in general, under the assumption that it admits a degeneration (X_0, Δ_0, ξ_v) given by a K-semistable minimiser v. For another quasi-monomial minimiser v' of rank r', by a combination of the Diophantine approximation and an MMP construction including the application of ACC of log canonical thresholds (see Section 3), we can obtain a model $f : Z \to X$ which extracts r' divisors E_i $(i = 1, \dots, r')$ such that $(Z, \Delta_Z =_{\mathrm{defn}} \sum E_i + f_*^{-1}\Delta)$ is log canonical. Moreover, the quasi-monomial valuation v' can be computed at the generic point of a component of the intersection of E_i, along which (Z, Δ_Z) is toroidal. Then with the help of the MMP, a careful analysis can show $Z \to X$ degenerates to a birational morphism $Z_0 \to X_0$. Moreover, there exists a quasi-monomial valuation w computed on Y_0 which can be considered as a degeneration of v' with

$$\widehat{\mathrm{vol}}_{X_0}(w) = \widehat{\mathrm{vol}}_X(v') = \widehat{\mathrm{vol}}_X(v) = \widehat{\mathrm{vol}}_{X_0}(\xi_v).$$

Thus $w = \xi_v$ by Step 5 after a rescaling. Since $w(\mathbf{in}(f)) \geq v'(f)$ and $\mathrm{vol}(w) = \mathrm{vol}(v')$, we may argue this implies $\xi_v(\mathbf{in}(f)) = v'(f)$. Therefore, v' is uniquely determined by ξ_v. □

Weaker than Theorem 4.6, in Theorem 4.7 we can not show the finite generation of $\mathrm{gr}_v(R)$, thus we have to post it as an assumption. This is due to the fact that unlike in the divisorial case where the construction of Kollár component provides a satisfying birational model to understand ord_S, for a quasi-monomial valuation of higher rank, the auxiliary models (see Step 1 and 6 in the above proof) we construct are less canonical. Moreover, compared to the statement in Conjecture 4.4, it remains wide open to verify that the minimiser is always quasi-monomial.

One of the main applications of Theorem 4.6 and Theorem 4.7 is to address Donaldson–Sun's conjecture in Donaldson and Sun [2017] on the algebraicity of the construction of the metric tangent cone, which can be considered as a local analogue of Donaldson and Sun [2014], G. Tian [2013], and Li, Wang, and Xu [2014]. More precisely, it was proved that the Gromov-Hausdorff limit of a sequence of Kähler-Einstein metric Fano varieties is a Fano variety X_∞ with klt singularities (see Donaldson and Sun [2014] and G. Tian [2013]). And to understand the metric structure near a singularity $x \in X_\infty$, we need to understand its metric tangent cone C (cf. Cheeger, Colding, and G. Tian [2002]). In the work Donaldson and Sun [2017], a description of C was given by a two-step degeneration process: first there is a valuation v on $\mathrm{Val}_{X_\infty,x}$ whose associated graded ring induces a degeneration of $x \in X_\infty$ to $o \in M$; then there is a degeneration of Fano cone from $o \in M$ to $o' \in C$. In Donaldson-Sun's definitions of M and C, they used the local metric structure around $x \in X_\infty$. However, they conjectured that both M and C only depend on the underlying algebraic structure of the germ $x \in X_\infty$. Built on the previous works of Li [2015a], Li and Liu [2016], and Li and Xu [2016], we answer the first part of their conjecture affirmatively, which says M is determined by the algebraic structure of the germ $x \in X_\infty$. We achieve this by showing that v is a K-semistable valuation in $\mathrm{Val}_{X,x}$ and such a K-semistable valuation is unique up to rescaling.

Theorem 4.8 (Li and Xu [2017]). *The valuation v is the unique minimiser (up to scaling) of $\widehat{\mathrm{vol}}$ in all quasi-monomial valuations in $\mathrm{Val}_{X_\infty,x}$.*

Proof. From the results proved in Donaldson and Sun [2017], we can verify that $o \in (W, \xi_v)$ is a K-semistable Fano cone singularity, which exactly means v is a K-semistable valuation. Thus v is a minimiser of $\widehat{\mathrm{vol}}$ by the last statement of Theorem 4.7. Then up to rescaling, v is the unique quasi-monomial minimiser again by Theorem 4.7. □

We expect that the tools we developed, especially those on equivariant K-stability, are enough to solve the second part of Donaldson-Sun's conjecture, i.e. to confirm the metric tangent cone C only depends on the algebraic structure of $x \in X_\infty$.

4.2 The volume of a klt singularity.

As $\mathrm{vol}(x, X)$ carries deep information on the singularity $x \in X$, calculating this number consists an important part of the theory. It also has applications to global questions. We discuss some related results and questions in this section.

In general, it could be difficult to compute $\mathrm{vol}(x, X)$. Even for the smooth point $x \in \mathbb{C}^n$, knowing $\mathrm{vol}(x, \mathbb{C}^n)$ (which is, not surprisingly, equal to n^n) involves highly nontrivial arguments. An illuminating example is the following.

Example 4.9 (Li [2015a], Li and Liu [2016], and Li and Xu [2016])**.** A $\mathbb{Q}$-Fano variety is K-semistable if and only if for the cone $C = C(X, -rK_X)$, the canonical valuation v obtained by blowing up the vertex o is a minimiser.

On one hand, this means that finding out the minimiser is in general at least as hard as testing the K-semistablity of (one dimensional lower) Fano varieties, which has been known to be a challenging question; on the other hand, this sheds new light on the question of testing K-stability. For example, using properties of degenerating ideals to their initials, we can prove that for a klt Fano variety X with a torus group T-action, to test the K-semistability of X it suffices to test on T-equivariant special test configurations (see Li and Xu [2016]).

The Stable Degeneration Conjecture 4.4 implies many properties of $\mathrm{vol}(x, X)$. The first one we want to discuss is a finite degree multiplication formula.

Conjecture 4.10. *If $\pi : x_1 \in (X_1, \Delta_1) \to x_2 \in (X_2, \Delta_2)$ is a finite dominant morphism between klt singularities such that $\pi^*(K_{X_2} + \Delta_2) = K_{X_1} + \Delta_1$, then*

$$\deg(\pi) \cdot \mathrm{vol}(x_2, X_2) = \mathrm{vol}(x_1, X_1).$$

This can be easily reduced to the case that the finite covering $X_1 \to X_2$ is Galois, and we denote the Galois group by G. Then it suffices to show that the minimiser of X_1 is G-equivariant, which is implied by the uniqueness claim in Conjecture 4.4. Conjecture 4.10 is verified in Li and Xu [2017] for $x \in X_\infty$ where X_∞ is a Gromov-Hausdorff limit of Kähler-Einstein Fano manifolds. Since any point will have its volume less or equal to n^n (see Liu and Xu [2017, Appendix]), Conjecture 4.10 implies that for a klt singularity $x \in (X, \Delta)$,

$$\mathrm{vol}(x, X) \leq n^n / |\hat{\pi}_1^{\mathrm{loc}}(x, X)|, \tag{2}$$

where the finiteness of $\hat{\pi}_1^{\mathrm{loc}}(x, X)$ is proved in Xu [2014].

Combining Conjecture 4.4 with the well known speculation that K-semistable is a Zariski open condition, we also have the following conjecture.

Conjecture 4.11. *Given a klt pair (X, Δ), then the function $\mathrm{vol}(x, X)$ is a constructible function, i.e. we can stratify X into constructible sets $X = \sqcup_i S_i$, such that for any i, $\mathrm{vol}(x, X)$ takes a constant value for all $x \in S_i$.*

A degeneration argument in Liu [2017] implies that the volume function should be lower semi-continuous. A special case we know is that the volume of any n-dimensional klt non-smooth point is always less than n^n (see Liu and Xu [2017, Appendix]).

Finally, we discuss some applications of the volume of singularities to K-stability of Fano varieties. A useful formula connecting local and global geometries is the following.

Theorem 4.12 (Fujita [2015] and Liu [2016])**.** *If X is a K-semistable $\mathbb{Q}$-Fano variety, then for any point $x \in X$, we have*

$$\operatorname{vol}(x, X) \geq \left(\frac{n+1}{n}\right)^n (-K_X)^n. \tag{3}$$

So if we can bound the type of klt singularities from the lower bound of their volumes, then we can restrict the type of singularities appearing on a K-semistable $\mathbb{Q}$-Fano variety with a given volume. In particular, this applies to the Gromov-Hausdorff limit X_∞ of a sequence of Kähler-Einstein Fano manifolds X_i (with a large volume of $-K_{X_i}$). If the restriction is sufficiently effective, then X_∞ would appear in an explicit simple ambient space on which we can carry out the orbital geometry calculation to identify X_∞ by showing all other possible limits are K-unstable.

For instance, by revisiting the classification results of three dimensional singularities, we show that $\operatorname{vol}(x, X) \leq 16$ if $x \in X$ is singular and the equality holds if and only if $x \in X$ is a rational double point (see Liu and Xu [2017]). As a consequence, we could solve the question on the existence of Kähler-Einstein metrics for cubic threefolds.

Corollary 4.13 (Liu and Xu [ibid.])**.** *GIT polystable (resp. semistable) cubic threefolds are K-polystable (resp. K-semistable). In particular, all GIT polystable cubic threefolds, including every smooth one, admit Kähler-Einstein metrics.*

HODGE THEORY AND CYCLE THEORY OF LOCALLY SYMMETRIC SPACES

NICOLAS BERGERON

Abstract

We discuss several results pertaining to the Hodge and cycle theories of locally symmetric spaces. The unity behind these results is motivated by a vague but fruitful analogy between locally symmetric spaces and projective varieties.

1 Introduction

Locally symmetric spaces are complete Riemannian manifolds locally modeled on certain homogeneous spaces. Their holonomy groups are typically smaller than SO_n – the holonomy group of a generic Riemannian manifold – and there are invariant tensors on the tangent space that are preserved by parallel transport. It was first observed by Chern [1957] that Hodge theory can be used to promote these local algebraic structures to structures that exist on the cohomology groups of locally symmetric spaces. This is very similar to what happens for compact Kähler manifolds. In fact the analogy between locally symmetric spaces and Kähler manifolds – or rather complex projective varieties – is a fruitful one in many aspects. In this report we shall discuss several instances of this analogy. We don't give proofs, we only state recent results that illustrate various items of the following dictionary.

	Projective varieties $V \subset \mathbb{P}^n$	**Locally symmetric spaces $\Gamma \backslash S$**
Complexity	degree	volume
Hodge theory	Hodge-Lefschetz decomposition	Matsushima's fomula and $(\mathfrak{g}, K)$-cohomology
Cycles	Algebraic cycles (Intersections of) Hyperplane sections	Modular cycles Sums of Hecke translates of modular cycles
Cohomology	Kodaira vanishing Theorem Lefschetz hyperplane Theorem Hodge Conjecture	Vanishing theorems using spinors Automorphic Lefschetz' properties Hodge type theorems

MSC2010: primary 11F75; secondary 14C30, 14G35, 57T25, 11F70, 22E40.

The following result (see Theorem 8 below), jointly obtained with Millson and Moeglin, shows that the right side of the above dictionary may eventually shed some light on the left (more classical) side.

Theorem. *On a projective unitary Shimura variety uniformized by the complex n-ball, any Hodge* (r,r)*-class with* $r \in [0,n] \backslash]\frac{n}{3}, \frac{2n}{3}[$ *is algebraic.*

Context. There has been a great deal of work on the cohomology of locally symmetric spaces. This involves methods from geometry, analysis and number theory. We note in particular that related topics have been discussed Harris [2014], Venkataramana [2010], and Speh [2006] in the last three ICMs. Indeed, Harris [2014] contains an overview of the program for analyzing cohomology of Shimura varieties developed by Langlands and Kottwitz. It aims at attaching Galois representations to the corresponding cohomology classes. Our point of view is closer to Venkataramana [2010] and Speh [2006] that discuss conjectures that naturally fit into the above dictionnary. The latter has been very much influenced by former works of Oda, Venkataramana, Harris-Li discussed in Venkataramana [2010]. We also have borrowed some expository ideas from §3 of Venkatesh Takagi lectures Venkatesh [2017].

2 Locally symmetric spaces

2.1 Symmetric spaces. A *symmetric space* is a Riemannian manifold whose group of symmetries contains an inversion symmetry about every point. We will be mainly concerned with symmetric spaces of non-compact type. Such a space S is associated to a connected center-free semi-simple Lie group G without compact factor. As a manifold S is the quotient G/K of G by a maximal compact subgroup $K \subset G$; it is known that all such K are conjugate inside G. One may easily verify that G preserves a Riemannian metric on S. Unless otherwise specified our symmetric spaces S will always be assumed to be of non-compact types.

For example, if $G = \mathrm{PSL}_2(\mathbb{R})$, we can take $K = \mathrm{PSO}_2$, and the associated symmetric space $S = G/K$ can be identified with the Poincaré upper-half plane $\mathbb{H}^2 = \{z \in \mathbb{C} : \mathrm{Im}(z) > 0\}$ and the action of G is by fractional linear transformations; it preserves the standard hyperbolic metric $|dz|^2/\mathrm{Im}(z)^2$.

If $G = \mathrm{PSL}_2(\mathbb{C})$, we can take $K = \mathrm{PSU}_2$, and the associated symmetric space S can be identified with the three-dimensional hyperbolic space $\mathbb{H}^3$.

We shall be particularly concerned with cases where G is either a unitary group $\mathrm{PU}(p,q)$ or an orthogonal group $\mathrm{SO}_0(p,q)$. Thanks to special isomorphisms between low dimensional Lie groups the symmetric spaces associated to $\mathrm{PU}(1,1)$ and $\mathrm{SO}_0(2,1)$ are both isometric to the Poincaré upper-half plane $\mathbb{H}^2$ and the symmetric space associated to $SO_0(3,1)$ is isometric to the three-dimensional hyperbolic space $\mathbb{H}^3$.

Another important case to consider is that of $G = PSL_n(\mathbb{R})$. Then we can take $K = PSO_n$, and the symmetric space S can be identified with the space of positive definite, symmetric, real valued $n \times n$ matrices A with $\det(A) = 1$, with metric given by $\mathrm{trace}(A^{-1}dA)^2$.

2.2 Locally symmetric spaces. Locally symmetric spaces are complete Riemannian manifolds locally modeled on some symmetric space S with changes of charts given by restrictions of elements of G. It is known that all such manifolds are isometric to quotients $\Gamma\backslash S$ of S by some discrete torsion-free subgroup $\Gamma \subset G$. One may measure the complexity of a locally symmetric space by considering its volume, or equivalently the volume of a fundamental domain for the action of Γ on S. We shall be only concerned with locally symmetric spaces of finite volume; the group Γ is then a lattice in G – in many cases we shall even restrict to compact locally symmetric spaces.

By a general theorem of Borel, any symmetric space S admits a compact manifold quotient (S-manifold) $\Gamma\backslash S$. In Borel's construction Γ is a *congruence arithmetic group*. For our purpose let us define these groups as those obtained by taking a semi-simple algebraic $\mathbb{Q}$-group $\mathbf{H} \subset SL_N$, and taking

$$\{h \in \mathbf{H}(\mathbb{Q}) \ : \ h \text{ has integral entries}\}. \tag{2-1}$$

Each such group is contained in an ambient Lie group, namely the real points of $\mathbf{H}$. If $\mathbf{H}(\mathbb{R})$ is isogeneous to $G \times$ (compact) the projection on the first factor maps the discrete subgroup (2-1) onto a lattice Γ in G. If the compact factor in $\mathbf{H}(\mathbb{R})$ is non-trivial then Γ is necessarily co-compact in G. Finally, replacing the discrete group (2-1) by its intersection with the kernel of a reduction mod ℓ map $SL_N(\mathbb{Z}) \to SL_N(\mathbb{Z}/\ell\mathbb{Z})$, one can obtain a torsion-free lattice Γ. We refer to the corresponding locally symmetric spaces $\Gamma\backslash S$ as *congruence arithmetic*.

2.3 Examples. Locally symmetric spaces play a central role in geometry. Here are some important examples:

Shimura varieties. These appear in algebraic geometry as moduli spaces of certain types of Hodge structures. E.g. for all g the moduli space $\mathcal{K}_g$ of genus g quasi-polarized K3 surfaces identifies with a locally symmetric space associated to $G = SO_0(2,19)$. Shimura varieties themselves are quasi-projective varieties. They play an important role in number theory through Langlands' program.

Complex ball quotients. By Yau's solution to the Calabi conjecture, complex algebraic surfaces whose Chern numbers satisfy $c_1^2 = 3c_2$ are quotients of the unit ball in $\mathbb{C}^2$ by a torsion-free co-compact lattice in $\mathrm{PU}(2,1)$. Most famously, this includes the classification of fake projective planes by Klingler [2003], Prasad and Yeung [2009] and Cartwright and Steger [2010]. Picard [1881], Deligne and Mostow [1986] and Thurston [1998] give many examples of ball quotients coming from natural moduli problems. Congruence arithmetic ball quotients are particular Shimura varieties.

Hyperbolic manifolds. In dimension 3, according to Thurston's geometrization conjecture, proved by Perelman, a 'generic' manifold is hyperbolic. More generally, Gromov theory of δ-hyperbolic groups suggest that negative curvature is 'quite generic.' However, at least in dimension ≥ 5, all known (to the author) constructions of closed manifolds that can carry a negatively curved metric are essentially obtained by rather simple surgeries on locally symmetric manifolds. These spaces therefore form a fundamental family of examples in geometry and more generally play a crucial role in geometric group theory.

Teichmüller spaces of flat unimodular metrics on tori $\mathbb{R}^n/\mathbb{Z}^n$. These are locally symmetric spaces associated to $\mathrm{PSL}_n(\mathbb{R})$. Their cohomology groups are very tightly bound to algebraic K-theory. In particular this viewpoint quite naturally leads to the famous regulator of Borel.

2.4 Notation. We have already defined $K \subset G$ and the associated Riemannian symmetric space $S = G/K$. Let $\mathfrak{g}$ be the complexified Lie algebra of G and let G^c be a compact form of G. Let $S^c = G^c/K$ be the compact dual of S. Let θ be the Cartan involution of G fixing K and let $\mathfrak{g} = \mathfrak{p} \oplus \mathfrak{k}$ be the associated Cartan decomposition. We normalize the Riemannian metric on S^c such that multiplication by i in $\mathfrak{p}$ becomes an isometry $T_{eK}S \to T_{eK}S^c$.

From now on $\Gamma\backslash S$ will denote a finite volume locally symmetric S-manifold. In general we try to reserve n for its real dimension, or complex dimension if S is Hermitian.

We denote by $b_k(M)$ the Betti numbers of a manifold M.

3 Hodge theory

For simplicity, in this section, we will assume that all the locally symmetric spaces $\Gamma\backslash S$ we consider are compact. This excludes some of the important examples mentioned above. However modified versions of the discussion below still apply and we will abusively ignore this issue in the rest of this document.

Being a compact manifold, the quotient $\Gamma\backslash S$ satisfies Poincaré duality. But, as mentioned in the Introduction, the Riemannian manifold $\Gamma\backslash S$ in general has a much smaller holonomy group than SO_n, and one can show that this forces $\Gamma\backslash S$ to satisfy many more constraints, see (3-5) and (3-6). These constraints can be understood in terms of *cohomological representations*, i.e. unitary representations π of G such that the relative Lie algebra cohomology $H^*(\mathfrak{g}, K; \pi)$ is non-zero (see Section 3.2 below).

Since the general setup of $(\mathfrak{g}, K)$-cohomology is rather forbidding we will discuss in more detail two special examples. But first, let us emphasize the analogy with projective manifolds, or rather here with Kähler manifolds.

3.1 Comparison with Kähler manifolds. Hodge theory gives a way to study the cohomology of a closed Riemannian manifold M. Indeed, each class in $H^*(M, \mathbb{C})$ has a *canonical* 'harmonic' representative: a differential form ω that represents this class and is of minimal L^2 norm. Equivalently the form ω is annihilated by the Hodge-Laplace operator Δ. One gets

$$\underbrace{\text{harmonic } k\text{-forms on } M}_{:=\mathcal{H}^k(M)} \xrightarrow{\simeq} H^k(M, \mathbb{C}). \tag{3-1}$$

Suppose furthermore that M is an n-dimensional complex Kähler manifold. Then, its holonomy group is contained in the unitary group $\mathrm{U}_n \subset \mathrm{SO}_{2n}$ and there is an action of $\mathbb{C}^*$ on each tangent space that is preserved by parallel transport. This yields an action of $\mathbb{C}^*$ on differential forms with complex coefficients. A crucial aspect of the theory of Kähler manifolds is that this action preserves harmonic forms. It then follows from Hodge theory that $\mathbb{C}^*$ acts on the cohomology groups and this gives rise to the Hodge decomposition.

3.2 Matsushima's formula. Let us now come back to the case of a compact locally symmetric manifold $\Gamma\backslash S$.

Because the cotangent bundle $T^*(\Gamma\backslash S)$ is isomorphic to the bundle $\Gamma\backslash G \times_K \mathfrak{p}^* \to \Gamma\backslash G/K$, which is associated to the principal K-bundle $K \to \Gamma\backslash G \to \Gamma\backslash S$ and the adjoint representation of K in $\mathfrak{p}^*$, the space of differential k-forms on $\Gamma\backslash S$ can be identified with $\mathrm{Hom}_K(\wedge^k \mathfrak{p}, C^\infty(\Gamma\backslash G))$. The corresponding complex computes the $(\mathfrak{g}, K)$-cohomology of $C^\infty(\Gamma\backslash G)$ – the subspace of smooth vectors in the right (quasi-)regular representation of G in $L^2(\Gamma\backslash G)$. One similarly defines the $(\mathfrak{g}, K)$-cohomology groups $H^\bullet(\mathfrak{g}, K; \pi)$ of any unitarizable $(\mathfrak{g}, K)$-module (π, V_π). By a theorem of Harish-Chandra, the set of equivalence classes of irreducible unitarizable $(\mathfrak{g}, K)$-modules is naturally identified with the set of equivalence classes of irreducible unitary representations of G. In the following, we will abusively use the same notation to denote an irreducible unitary representation and its associated $(\mathfrak{g}, K)$-module of smooth vectors.

The decomposition of $\wedge^\bullet \mathfrak{p}^*$ into irreducible K-modules induces a decomposition of the exterior algebra $\wedge^\bullet T^*(\Gamma\backslash S) = \Gamma\backslash G \times_K \wedge^\bullet(\mathfrak{p}^*)$. This decomposition commutes with the action of the Hodge-Laplace operator, giving birth to a decomposition of the cohomology $H^\bullet(\Gamma\backslash S, \mathbb{C})$ which refines the Hodge decomposition if S is Hermitian symmetric and gives an analogous decomposition of the cohomology in the case S is not Hermitian. In both cases we will call this decomposition of $H^\bullet(\Gamma\backslash S, \mathbb{C})$ the *generalized Hodge decomposition*; it is better understood in terms of cohomological representations through Matsushima's formula:

$$H^\bullet(\Gamma\backslash S, \mathbb{C}) = \bigoplus_\pi m(\pi, \Gamma) H^\bullet(\mathfrak{g}, K; \pi). \tag{3-2}$$

Here the (finite) sum is over (classes of) irreducible unitary representations of G such that $H^\bullet(\mathfrak{g}, K; \pi) \neq 0$ and $m(\pi, \Gamma)$ is the (finite) multiplicity with which π occurs in the quasi-regular representation $L^2(\Gamma\backslash G)$.

Cohomological representations of G are classified in terms of the θ-stable parabolic subalgebras $\mathfrak{q} \subset \mathfrak{g}$. Let $\mathfrak{q} = \mathfrak{l} \oplus \mathfrak{u}$ be the θ-stable Levi decomposition of $\mathfrak{q}$. We have $\mathfrak{u} = \mathfrak{u} \cap \mathfrak{k} \oplus \mathfrak{u} \cap \mathfrak{p}$. Put $R = \dim(\mathfrak{u} \cap \mathfrak{p})$. The line $\wedge^R(\mathfrak{u} \cap \mathfrak{p})$ generates an irreducible representation $V(\mathfrak{q})$ of K in $\wedge^R \mathfrak{p}$.

The classification of unitary irreducible cohomological representations of G associates to each θ-stable parabolic subalgebras $\mathfrak{q} \subset \mathfrak{g}$ a cohomological representation $A_\mathfrak{q}$ characterized by the property that the only irreducible K-representation common to $\wedge^\bullet \mathfrak{p}$ and $A_\mathfrak{q}$ is the representation $V(\mathfrak{q})$. Moreover, every cohomological representation is an $A_\mathfrak{q}$, see Vogan and Zuckerman [1984].

Each $H^\bullet(\mathfrak{g}, K; A_\mathfrak{q})$ identifies with the cohomology – with degree shifted by R – of the *compact* symmetric space associated to a subgroup $L \subset G^c$ with complexified Lie algebra $\mathfrak{l}$. In particular, the component corresponding to the trivial representation of G in (3-2) is isomorphic to $H^\bullet(S^c, \mathbb{C})$. In the Hermitian case we recover Hirzebruch proportionality principle.

If ω belongs to $H^R(\Gamma\backslash S, \mathbb{C})$ and, under the Matsushima decomposition (3-2), lies in the component corresponding to some $A_\mathfrak{q}$ with $R = \dim(\mathfrak{u} \cap \mathfrak{p})$, by analogy with the notion of primitive class in the Hodge-Lefschetz decomposition, we refer to ω as a *strongly primitive* class of type $A_\mathfrak{q}$.

3.3 Two families of examples.

3.3.1 Compact quotients of the symmetric space associated to $\mathrm{PU}(p, q)$**.** Then the holonomy group is contained in $\mathrm{U}_p \times \mathrm{U}_q$ and S^c is the complex Grassmannian $\mathrm{Gr}_p(\mathbb{C}^{p+q})$

of p-planes in $\mathbb{C}^{p+q}$. We first consider the decomposition of $\wedge^\bullet \mathfrak{p}^*$ into irreducible K-modules. The symmetric space S being of Hermitian type, the exterior algebra $\wedge^\bullet \mathfrak{p}$ decomposes as:

$$\wedge^\bullet \mathfrak{p} = \wedge^\bullet \mathfrak{p}' \otimes \wedge^\bullet \mathfrak{p}'' \tag{3-3}$$

where $\mathfrak{p}'$ and $\mathfrak{p}''$ respectively denote the holomorphic and anti-holomorphic tangent spaces. In the case $q = 1$ – then S is the complex ball of dimension p – it is an exercise to check that the decomposition of (3-3) into irreducible modules recovers the usual Lefschetz decomposition. But, in general, the decomposition is much finer, and it is hard to write down the full decomposition of (3-3) into irreducible modules. Indeed: as a representation of $\mathrm{GL}_p(\mathbb{C}) \times \mathrm{GL}_q(\mathbb{C})$ the space $\mathfrak{p}'$ is isomorphic to $V_+ \otimes V_-^*$ where $V_+ = \mathbb{C}^p$ (resp. $V_- = \mathbb{C}^q$) is the standard representation of $\mathrm{GL}_p(\mathbb{C})$ (resp. $\mathrm{GL}_q(\mathbb{C})$) and the decomposition of $\wedge^\bullet \mathfrak{p}'$ is already quite complicated (see Fulton [1997, Equation (19), p. 121]):

$$\wedge^R (V_+ \otimes V_-^*) \cong \bigoplus_{\lambda \vdash R} S_\lambda(V_+) \otimes S_{\lambda^*}(V_-)^*. \tag{3-4}$$

Here we sum over all partitions of R (equivalently Young diagrams of size $|\lambda| = R$) and λ^* is the conjugate partition (or transposed Young diagram).

However, the classification of cohomological representations we just alluded to implies that very few of the irreducible submodules of $\wedge^\bullet \mathfrak{p}^*$ can occur as refined Hodge types of non-trivial cohomology classes. This is very analogous to the Kodaira vanishing theorem. The proof indeed makes a crucial use of a 'Dirac inequality' due to Parthasarathy, see Borel and Wallach [2000, Lemma II.6.11 and §II.7]. The vanishing theorem thus obtained generalizes a celebrated result of Matsushima [1962].

The K-types $V(\mathfrak{q})$ that can occur are determined by *admissible* pairs of partitions (λ, μ) i.e. partitions λ and μ as in (3-4) and such that if λ (resp. μ) is on the top left (resp. bottom right) corner of the rectangle $p \times q$ as pictured below (with $p = 4$, $q = 7$, $\lambda = (6, 6, 2, 0)$ and $\mu = (5, 2, 1, 0)$), the complementary boxes form a disjoint union of rectangles $p_1 \times q_1 \cup \ldots \cup p_r \times q_r$ (in the example below $1 \times 2 \cup 1 \times 3 \cup 1 \times 1$), see Bergeron [2009, Lemme 6].

•	•	•	•	•	•	
•	•	•	•	•	•	*
•	•				*	*
		*	*	*	*	*

We denote by $V(\lambda, \mu)$ the corresponding K-type. In particular the K-module $V(\lambda) := V(\lambda, 0)$ is isomorphic to $S_\lambda(V_+) \otimes S_{\lambda^*}(V_-)^*$. In general $V(\lambda, \mu)$ is isomorphic to the Cartan product of $V(\lambda)$ and $V(\mu)^*$. The first degree where such a K-type can occur in the cohomology is $R = |\lambda| + |\mu|$. More precisely, it contributes to the cohomology of bi-degree $(|\lambda|, |\mu|)$ in the Hodge-Lefschetz decomposition and we have:

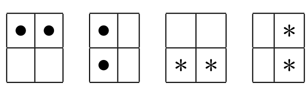
$$H^\bullet(\mathfrak{g}, K; A_\mathfrak{q}) \cong H^{\bullet - R}(\mathrm{Gr}_{p_1}(\mathbb{C}^{p_1+q_1}) \times \ldots \times \mathrm{Gr}_{p_r}(\mathbb{C}^{p_r+q_r}), \mathbb{C}).$$

Matsushima's formula (3-2) then strongly refines the Hodge-Lefschetz decomposition of compact quotients $\Gamma \backslash S$.

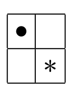
Example. Take $p = 2$ and $q = 2$. Compact quotients $\Gamma \backslash S$ are 4-dimensional complex manifolds. Their Betti numbers satisfy the relation $b_k = b_{8-k}$ because of Poincaré duality. They moreover decompose as sums $b_k = \sum_{p+q=k} h^{p,q}$ of Hodge numbers that satisfy $h^{p,q} = h^{q,p}$. But more is true: the vector $(b_0, \ldots, b_8)$ of Betti numbers of a compact quotient $\Gamma \backslash S$ is actually of the form

$$\begin{pmatrix}1\\0\\1\\0\\2\\0\\1\\0\\1\end{pmatrix} + 2h^{2,0}\begin{pmatrix}0\\0\\1\\0\\1\\0\\1\\0\\0\end{pmatrix} + (h^{1,1}-1)\begin{pmatrix}0\\0\\1\\0\\2\\0\\1\\0\\0\end{pmatrix} + 2(h^{3,0}+h^{2,1})\begin{pmatrix}0\\0\\0\\1\\0\\1\\0\\0\\0\end{pmatrix} + k\begin{pmatrix}0\\0\\0\\0\\1\\0\\0\\0\\0\end{pmatrix} \tag{3-5}$$

for some integer $k \geq 0$. The first vector indeed corresponds to the component of the trivial representation in Matsushima's formula. The second term corresponds to the components of the cohomological representations $A_\mathfrak{q}$ with $R = 2$ that contribute either to the holomorphic or anti-holomorphic cohomology. Their associated pairs of partitions (λ, μ) are



The third term corresponds to the components of the (unique) cohomological representation $A_\mathfrak{q}$ with $R = 2$ that contributes to the cohomology of bi-degree $(1, 1)$. Its associated pair of partitions (λ, μ) is



And so on...

3.3.2 Compact quotients of the symmetric space associated to $\mathrm{SO}_0(p, q)$**.** Even though these are not Hermitian in general, Matshushima's formula still makes sense. Considerations, similar to those in the unitary case, show that cohomological representations of G are essentially[1] parametrized by partitions $\lambda = (\lambda_1, \dots, \lambda_p)$, with $q \geq \lambda_1 \geq \dots \geq \lambda_p \geq 0$, such that the pair (λ, λ) is admissible.

Example. Take $p = 5$ and $q = 4$. Compact quotients $\Gamma \backslash S$ are 20-dimensional real manifolds. Their Betti numbers satisfy the relation $b_k = b_{20-k}$ because of Poincaré duality. But more is true: the Betti numbers of a compact quotient $\Gamma \backslash S$ actually verify the relations

$$b_1 = b_2 = b_3 = 0, \quad b_8 \geq 2b_6 \quad \text{and} \quad b_{10} \geq 3b_6. \tag{3-6}$$

Hyperbolic manifolds of dimension n correspond to $p = n$ and $q = 1$. Then Matsushima's formula essentially gives no restrictions on the Betti numbers.[2]

Among the family of symmetric spaces associated to $\mathrm{SO}_0(p, q)$, the ones where $q = 2$ are – up to exchanging the roles of p and q – the only Hermitian spaces; these are of complex dimension $n = p$. In these cases, $K \subset \mathrm{O}_n \times \mathrm{O}_2$ acts on $\mathfrak{p} = \mathbb{C}^n \otimes (\mathbb{C}^2)^*$ through the standard representation of O_n on $\mathbb{C}^n$ and the standard representation of O_2 on $\mathbb{C}^2$. Denote by $\mathbb{C}^+$ and $\mathbb{C}^-$ the $\mathbb{C}$-span of the vectors $e_1 + ie_2$ and $e_1 - ie_2$ in $\mathbb{C}^2$. The two lines $\mathbb{C}^+$ and $\mathbb{C}^-$ are left stable by O_2. This yields a decomposition $\mathfrak{p} = \mathfrak{p}^+ \oplus \mathfrak{p}^-$ which corresponds to the decomposition given by the natural complex structure on $\mathfrak{p}_0$. For each non-negative integer k the K-representation $\wedge^k \mathfrak{p} = \wedge^k(\mathfrak{p}^+ \oplus \mathfrak{p}^-)$ decomposes as the sum:

$$\wedge^k \mathfrak{p} = \bigoplus_{r+s=k} \wedge^r \mathfrak{p}^+ \otimes \wedge^s \mathfrak{p}^-.$$

The K-representations $\wedge^r \mathfrak{p}^+ \otimes \wedge^s \mathfrak{p}^-$ are not irreducible in general: there is at least a further splitting given by the Lefschetz decomposition:

$$\wedge^r \mathfrak{p}^+ \otimes \wedge^s \mathfrak{p}^- = \bigoplus_{\ell=0}^{\min(r,s)} \tau_{r-\ell, s-\ell}.$$

One can check that for $2(r+s) < n$ each K-representation $\tau_{r,s}$ is irreducible. Moreover in the range $2(r+s) < n$ only those with $r = s$ can occur as a K-type $V(\mathfrak{q})$ associated to a cohomological representation. One can moreover check that each $\tau_{r,r}$ is irreducible as long as $r < n$; it is isomorphic to some $V(\mathfrak{q})$ and corresponds to the partition $\lambda = (2_r, 0_{n-r})$.[3] Let us denote by $A_{r,r}$ the corresponding cohomological representation. We have:

$$H^{i,j}(\mathfrak{g}, K; A_{r,r}) = \begin{cases} \mathbb{C} & \text{if } r \leq i = j \leq n - r,\ 2i \neq n \\ \mathbb{C} + \mathbb{C} & \text{if } 2i = 2j = n \\ 0 & \text{otherwise.} \end{cases}$$

[1] This is completely true only if both p and q are odd.

[2] To be precise it gives no restriction at all if n is odd and one recovers that $b_{n/2}$ is even if n is even.

[3] When $2(r+s) \geq n$ the partitions $(2_r, 1_s, 0_{n-r-s})$ also correspond to cohomological representations.

In the particular case where n is even and $(r,r) = (0,0)$ – so that $A_{0,0}$ is the trivial representation – we have $H^\bullet(\mathfrak{g}, K; A_{0,0}) = H^\bullet(S^c, \mathbb{C})$, where $S^c = \mathrm{SO}(n+2)/\mathrm{SO}(n)\times \mathrm{SO}(2)$ is the complex quadric. The space $H^\bullet(S^c, \mathbb{C})$ has a basis $\{1, c_1, c_1^2, \dots, c_1^{n-1}, e\}$, where c_1 is the Chern class of the complexification of the line bundle arising from the standard representation of $\mathrm{SO}(2)$, i.e. the Kähler form on S^c, and where e is the Euler class of the vector bundle arising from the standard representation of $\mathrm{SO}(n)$.

4 Betti numbers of locally symmetric manifolds

One may wonder:

> what are the Betti numbers of a random locally symmetric space ?

A classical theorem of Gromov (see Ballmann, Gromov, and Schroeder [1985]) bounds from above the Betti numbers of a locally symmetric space by a constant (depending only of the dimension) times its volume. It is therefore natural to investigate the growth of the Betti numbers as the volume tends to infinity. The analogous question for complex hypersurfaces in $\mathbb{P}^{n+1}$ is classical.

4.1 Comparison with projective hypersurfaces. The fundamental projective invariant of an n-dimensional algebraic variety $V \subset \mathbb{P}^N$ is its degree d which is also equal to the volume – with respect to the standard Kähler form on $\mathbb{P}^N$ – divided by $n!$.

In case $V \subset \mathbb{P}^{n+1}$ is an hypersurface, by standard arguments involving Lefschetz Hyperplane Theorem and Poincaré duality (see e.g. Gayet and Welschinger [2014, Lemma 3]), we have $b_k(V) = b_k(\mathbb{P}^n)$ for $k \neq n$. On the other hand, the Euler-Poincaré characteristic of V is equal to

$$\chi(V) = \langle c_n(T_V), [V]\rangle = \frac{1}{d}\left[(1-d)^{n+2} - 1\right] + n + 2.$$

It follows that the growth of the Betti numbers of V with respect to the degree d is given by

$$b_k(V) = \begin{cases} O(1) & \text{if } k \neq n \\ (-1)^n \chi(V) + O(1) = d^{n+1} + O(d^n) & \text{if } k = n. \end{cases} \tag{4-1}$$

4.2 Asymptotics of Betti numbers of locally symmetric manifolds. It is not obvious at all that large volume locally symmetric S-manifolds should have related topological behavior. However, one consequence of Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2017] and Abert, Bergeron, Biringer, and Gelander [n.d.] is the following theorem that is analogous to (4-1).

Theorem 1. *Suppose that G has property (T) and rank at least two. The growth of the Betti numbers of locally symmetric* S-manifolds *is given by*

$$b_k(\Gamma\backslash S) = \begin{cases} o\left(\mathrm{vol}(\Gamma\backslash S)\right) & \text{if } k \neq \frac{1}{2}\dim S \\ \frac{\chi(S^c)}{\mathrm{vol}(S^c)}\mathrm{vol}(\Gamma\backslash S) + o\left(\mathrm{vol}(\Gamma\backslash S)\right) & \text{if } k = \frac{1}{2}\dim S. \end{cases}$$

Example. Let $n \geq 3$ and let (Γ_m) be a sequence of distinct torsion-free lattices in $\mathrm{SL}_n(\mathbb{R})$. Then for all k, we have $b_k(\Gamma_m) = o(\mathrm{vol}(\Gamma_m\backslash \mathrm{SL}_n(\mathbb{R})))$ as $m \to +\infty$.

Hyperbolic spaces have a rank one group of isometries and it is not hard to construct examples of large volume hyperbolic manifolds with very different topologies, see e.g. Bergeron [2017] for many examples. This allows in particular to construct counter-examples to the conclusion of Theorem 1. However recent works of Fraczyk [2016] and Fraczyk and Raimbault [n.d.] imply that this conclusion holds for *congruence arithmetic* hyperbolic manifolds. More generally they prove:

Theorem 2. *Let S be arbitrary. The growth of the Betti numbers of* congruence arithmetic S-manifolds *is given by*

$$b_k(\Gamma\backslash S) = \begin{cases} o\left(\mathrm{vol}(\Gamma\backslash S)\right) & \text{if } k \neq \frac{1}{2}\dim S \\ \frac{\chi(S^c)}{\mathrm{vol}(S^c)}\mathrm{vol}(\Gamma\backslash S) + o\left(\mathrm{vol}(\Gamma\backslash S)\right) & \text{if } k = \frac{1}{2}\dim S. \end{cases}$$

Outside the middle degree it is hard to guess what should be the 'true' growth rate of the Betti numbers. For congruence arithmetic real hyperbolic manifolds $\Gamma\backslash\mathbb{H}^n$, associated to a fixed rational group $\mathbf{H}$ (see Section 2.2), it was suggested by Gromov (see Sarnak and Xue [1991]) that

$$b_k(\Gamma\backslash\mathbb{H}^n) \ll_{\mathbf{H},\varepsilon} \mathrm{vol}(\Gamma\backslash\mathbb{H}^n)^{\frac{2k}{n-1}+\varepsilon}. \tag{4-2}$$

Cossutta and Marshall [2013] suggest – and actually prove in a quite general situation – that the best exponent is in fact $2j/n$ as long as $k \neq (n \pm 1)/2$. See Marshall [2014] for similar results on other classes of symmetric spaces.

Remark. In a way that is quite similar to Bismut's proof of Demailly's asymptotic Morse inequalities (see Bismut [1987] and Demailly [1985]) for projective varieties, the existence of an upper bound sublinear in the volume is related (see e.g. the influential Sarnak and Xue [1991]) to the existence of a *spectral gap* for the Hodge-Laplace operator acting on differential k-forms with $k \neq (n \pm 1)/2$:

Theorem 3. *Let k be different from* $(n \pm 1)/2$. *There exists a positive constant* $\varepsilon = \varepsilon(n,k)$ *such that for any congruence arithmetic real hyperbolic manifolds* $\Gamma\backslash\mathbb{H}^n$*, the first non-zero eigenvalue of the Hodge-Laplace operator of* $\Gamma\backslash\mathbb{H}^n$ *acting on differentiable k-forms is bounded below by* ε.

This was conjectured in Bergeron and Clozel [2005] and proved in Bergeron and Clozel [2013].

When $k = (n \pm 1)/2$ there is no spectral gap – the corresponding cohomological representation of G is 'tempered' – and we do not know what to expect for the growth of $b_k(\Gamma\backslash\mathbb{H}^n)$. However for particular sequences of Γ's, Calegari and Emerton [2009] were able to prove an upper bound sublinear in the volume, see also Bergeron, Linnell, Lück, and Sauer [2014].

4.3 Explicit computations. Matsuhima's formula and the classification of cohomological representations imply many restrictions on the Betti numbers (e.g. in small degree some vanishing results or equality with the corresponding Betti numbers of S^c). Apart from these restrictions, explicit computations of the Betti numbers of a fixed locally symmetric space $\Gamma\backslash S$ in terms of the algebraic data defining Γ is usually a challenge. Very few cases are known. One of the first results of this type is the computation, by J.-S. Li [1996], of the dimension of the L^2-cohomology space of degree g of certain congruence arithmetic quotients of the Siegel upper half space of genus g.

The proof is divided into two parts. First, relying on previous works of Howe, Jian-Shu Li proves that the cohomology is generated by certain theta series. Then he computes the dimension of the space generated by these theta series. More recently in Bergeron, Millson, and Moeglin [2017] and Bergeron, Z. Li, Millson, and Moeglin [2017] we were able to prove that a large part of the cohomology of certain locally symmetric spaces associated to $\mathrm{SO}_0(n,2)$ is generated by certain theta series. Using previous computations by Bruinier [2002] of dimensions of the spaces generated by these theta series we get explicit expressions for certain Betti numbers. We prove in particular:

Theorem 4. *The rank of the Picard group of the moduli space $\mathcal{K}_g$, defined in Section 2.3, is*

$$\frac{31g+24}{24} - \frac{1}{4}\alpha_g - \frac{1}{6}\beta_g - \sum_{k=0}^{g-1}\left\{\frac{k^2}{4g-4}\right\} - \sharp\left\{k \mid \frac{k^2}{4g-4} \in \mathbb{Z}, 0 \le k \le g-1\right\}$$

where

$$\alpha_g = \begin{cases} 0, & \text{if } g \text{ is even,} \\ \left(\frac{2g-2}{2g-3}\right) & \text{otherwise,} \end{cases} \qquad \beta_g = \begin{cases} \left(\frac{g-1}{4g-5}\right) - 1, & \text{if } g \equiv 1 \mod 3, \\ \left(\frac{g-1}{4g-5}\right) + \left(\frac{g-1}{3}\right) & \text{otherwise,} \end{cases}$$

and $\left(\frac{a}{b}\right)$ is Jacobi symbol.

5 Cycle theory

Let M be a (closed) manifold. So far, we have computed the cohomology of M using smooth differential forms. We could as well have used currents. The resulting cohomology groups $H^k(M,\mathbb{C})$ are the same (and similarly for the groups occurring in the Hodge-Lefschetz or Matsushima decompositions). If Z is a closed orientable submanifold of real co-dimension k, it is an integral cycle and, by Poincaré duality, it defines a class $\mathrm{cl}(Z)$ in $H^k(M,\mathbb{C})$. The integration current on Z is closed of degree k and represents the image of $\mathrm{cl}(Z)$ in $H^k(M,\mathbb{C})$.

By a classical theorem of Thom, any class in the rational cohomology groups $H^k(M,\mathbb{Q})$ is a rational multiple of the cycle class $\mathrm{cl}(Z)$ of a (maybe disconnected) co-dimension k closed submanifold. When M is locally symmetric, it is natural to ask if one can restrict our choices of closed submanifold, e.g. to certain locally symmetric subspaces associated to subgroups $H \subset G$.

5.1 Comparison with projective varieties. In case M is a projective non-singular algebraic variety $V \subset \mathbb{P}^N$ over $\mathbb{C}$, it is natural to restrict to closed analytic subspaces $Z \subset V$, or equivalenly, by Chow's theorem, to algebraic cycles. Let p be the complex co-dimension of Z in V. Two analytic subvarieties of complementary dimension meeting in isolated points have a non-negative local intersection number. Since we can find a linear subspace $\mathbb{P}^{N-p}$ in $\mathbb{P}^N$ meeting V in isolated points, it follows that the cycle class $\mathrm{cl}(Z)$ is non-zero in $H^{2p}(V,\mathbb{C})$. Now the integration current on Z is closed of type (p,p). The class $\mathrm{cl}(Z)$ in $H^{2p}(V,\mathbb{C})$ is hence of type (p,p). Rational (p,p)-classes are called *Hodge classes*. They form the group $\mathrm{Hdg}^p(V,\mathbb{Q}) = H^{2p}(V,\mathbb{Q}) \cap H^{p,p}(V)$, and Hodge posed the famous:

Hodge Conjecture. On a projective non-singular algebraic variety over $\mathbb{C}$, any Hodge class is a rational linear combination of cycle classes $\mathrm{cl}(Z)$ of algebraic cycles.

Hodge also proposed a further conjecture, characterizing the subspace of $H^\bullet(V,\mathbb{Q})$ spanned by the images of cohomology classes with support in a suitable closed analytic subspace of complex codimension k. Grothendieck observed that this further conjecture is false, and gave a corrected version of it in Grothendieck [1969].

5.2 Modular and symmetric cycle classes. Let us come back to locally symmetric manifolds $\Gamma\backslash S$. To any connected center-free semi-simple closed subgroup $H \subset G$ corresponds an embedding of the symmetric space S_H associated to H into S. If $\Gamma \cap H$ is a lattice, the inclusion $S_H \hookrightarrow S$ induces an immersion of real analytic varieties $(\Gamma \cap H)\backslash S_H \to \Gamma\backslash S$ whose associated cycle class in $H^\bullet(\Gamma\backslash S,\mathbb{C})$ we denote by C_H^Γ. We will refer to these classes as *modular classes*. When $\Gamma\backslash S$ is non-compact, C_H^Γ is sometimes compactified to give a cycle on a natural compactification of $\Gamma\backslash S$ but we won't discuss these issues here.

Examples. 1. When S is the real hyperbolic n-space $\mathbb{H}^n$, the modular classes in $\Gamma\backslash\mathbb{H}^n$ are the cycle classes of totally geodesic immersed submanifold of finite volume.

2. In complex ball quotients, cycle classes of finite volume quotients of sub-balls give examples of modular classes. These are the only modular classes that are cycle classes of algebraic cycles but there might be other modular classes: to the inclusion $\mathrm{SO}_0(n,1) \subset \mathrm{PU}(n,1)$ corresponds a totally real geodesic embedding of the real hyperbolic n-space into the complex n-ball that may projects onto a non-zero modular classes.

3. The moduli space $\mathcal{K}_g$ of genus g quasi-polarized K3 surfaces – that identifies with a locally symmetric space associated to $G = \mathrm{SO}_0(2,19)$ – can have arbitrarily large Picard group (see Theorem 4) and, more generally, many classes of cycles in their Chow groups. In particular there are many cycles coming from Noether-Lefschetz theory: the locus parametrizing the K3 surfaces with Picard number strictly greater than some positive integer $r \leq 19 = \dim_{\mathbb{C}} \mathcal{K}_g$ is indeed a countable union of subvarieties of co-dimension r. The cycle classes of the irreducible components of this locus are modular classes associated to subgroups $H \subset G$ isomorphic to $\mathrm{SO}_0(2, 19-r)$. As in the case of ball quotients there are also non-algebraic modular classes.

There are a number of results on modular classes, but our current knowledge nevertheless appears to be quite poor: a large part of the literature on modular classes is only concerned in establishing the *non-vanishing* of these classes. As in the case of analytic subspaces of projective varieties, this has been addressed using the intersection numbers of these cycles, see e.g. Millson [1976], Millson and Raghunathan [1980], and Kudla and Millson [1990]. This has also been addressed using tools coming from representation theory, see especially Tong and Wang [1989] and J.-S. Li [1992]. This non-vanishing question is usually too hard to study for a given manifold; one simplifies the problem by 'stabilizing' it, that is to say by considering towers of finite coverings rather than a single manifold. Let us say that a modular class C_H^Γ is *virtually non-zero* if there exists a finite index subgroup $\Gamma' \subset \Gamma$ such that the modular class $C_H^{\Gamma'}$ is non-zero in $H^\bullet(\Gamma'\backslash S, \mathbb{C})$.

The following conjecture – see Bergeron [2006] for more details (in particular with respect to non-compact quotients $\Gamma\backslash S$) – provides a quite general answer to the question of the virtual non-vanishing of modular classes. To our knowledge this conjecture encompasses all known results. It has been (or can be) checked in most classical situations (see especially Bergeron [2006], Bergeron [2008], and Bergeron and Clozel [2013, 2017]). To formulate it, let us first distinguish some particular modular symbols. Say that a closed subgroup $H \subset G$ is a symmetric subgroup of G if there exists an involution τ of G such that $H = G^\tau$ is the connected component of the identity in the group of fixed points of τ. We will refer to the corresponding modular classes C_H^Γ as *symmetric modular classes*. All the modular classes from the examples above are symmetric.

Conjecture 5. *Assume for simplicity that* $\Gamma\backslash S$ *is compact. A symmetric modular class* C_H^Γ *is* virtually *non-zero in* the strongly primitive part of *the cohomology of degree* $\dim S - \dim S_H$ *if and only if* $\mathrm{rank}_{\mathbb{C}}(G/H) = \mathrm{rank}_{\mathbb{C}}(K/(K \cap H))$.

5.3 Hodge types of modular classes. Keeping in mind the analogy with projective varieties, the next step is to determine on which Hodge types of the cohomology of $\Gamma\backslash S$ modular classes can project non-trivially. Up to now it seems to have been addressed only in few particular cases. As explained in his 2002 ICM talk Kobayashi [2002], jointly with Oda, Kobayashi has devised a sufficient criterion for a modular class to be annihilated by a π-component in Matsushima's decomposition (3-2). Their proof is based on a theory of discrete branching laws for unitary representations of G. The most interesting cases they can deal with are compact quotients of the symmetric space $S = \mathrm{SO}_0(2n, 2)/\mathrm{SO}_{2n} \times \mathrm{SO}_2$. If $\Gamma\backslash S$ is a compact S-manifold, the contribution of the trivial representation of G to Matsushima's formula (3-2) yields a natural injective map of cohomology groups $H^\bullet(S^c, \mathbb{C}) \subset H^\bullet(\Gamma\backslash S, \mathbb{C})$; in particular we shall see the Euler class $e \in H^{n,n}(S^c, \mathbb{C})$, defined in Section 3.3.2, as an element in $H^{n,n}(\Gamma\backslash S, \mathbb{C})$. Kobayashi and Oda then prove:

Theorem 6. *The Hodge* (n, n)*-type component of a modular class* C_H^Γ *with* $H \cong \mathrm{SO}_0(2n, 1)$ *is proportional to the Euler class* e.

These modular classes are cycle classes of totally real, totally geodesic submanifolds of real dimension $2n$ into $\Gamma\backslash S$ which is a Kähler manifold of complex dimension $2n$. In case $n = 1$ the space S is a product $\mathbb{H}^2 \times \mathbb{H}^2$ and the cycles derived from H are obtained by 'partial complex conjugation' of algebraic cycles with respect to the complex conjugation on the second factor of S. Then Theorem 6 is equivalent to the well-known fact that the cycle class of a closed analytic (complex) co-dimension 1 subspace in a compact algebraic surface over $\mathbb{C}$ has no Hodge $(2, 0) + (0, 2)$-type components.

Beside the representation theoretic method of Kobayashi and Oda, a classical work of Kudla and Millson [1990] suggests another approach. Kudla and Millson indeed provide explicit dual forms to some natural modular classes in locally symmetric spaces associated to classical groups. From this, one can derive serious restrictions on the possible Hodge types to which these modular classes can contribute. Let's describe the two main families of examples.

5.3.1 Quotients of the symmetric space associated to $\mathrm{PU}(p, q)$**.** Let notations be as in Section 3.3.1. Let $c_q \in H^{q,q}(S^c, \mathbb{C})$ be the top Chern class of the q-dimensional vector bundle over $S^c = \mathrm{U}_{p+q}/\mathrm{U}_p \times \mathrm{U}_q$ associated to the standard representation of U_q, i.e. the q-th power of the Kähler form of S^c. Here again if $\Gamma\backslash S$ is a compact S-manifold, the contribution of the trivial representation of G to Matsushima's formula (3-2) yields a natural injective map of cohomology groups $H^\bullet(S^c, \mathbb{C}) \subset H^\bullet(\Gamma\backslash S, \mathbb{C})$ and we shall see the Chern class $c_q \in H^{q,q}(S^c, \mathbb{C})$ as an element in $H^{q,q}(\Gamma\backslash S, \mathbb{C})$. Wedging with c_q corresponds to applying the q-th power of the Lefschetz operator associated to the Kähler form on $\Gamma\backslash S$, and we define the subset $SH^\bullet(\Gamma\backslash S, \mathbb{C})$ of *special cohomology classes* in $H^\bullet(\Gamma\backslash S, \mathbb{C})$ by

$$SH^\bullet(\Gamma\backslash S, \mathbb{C}) = \bigoplus_{a,b=0}^{p} \bigoplus_{k=0}^{\min(p-a,p-b)} c_q^k H^{a\times q, b\times q}(\Gamma\backslash S, \mathbb{C}), \tag{5-1}$$

where $H^{a\times q, b\times q}(\Gamma\backslash S, \mathbb{C})$ denotes the generalized Hodge subspace of the cohomology corresponding to the pair of partitions (λ, μ) with λ an a by q rectangle and μ a b by q rectangle. As with the usual Hodge-Lefschetz decomposition, we have:

$$SH^\bullet(\Gamma\backslash S, \mathbb{C}) = \bigoplus_{a,b=0}^{p} SH^{aq,bq}(\Gamma\backslash S, \mathbb{C})$$

where the (usual) *primitive* part of the subspace $SH^{aq,bq}(\Gamma\backslash S, \mathbb{C})$ is exactly $H^{a\times q, b\times q}(\Gamma\backslash S, \mathbb{C})$.

Now the proof of Bergeron, Millson, and Moeglin [2016, Theorem 8.2] implies the following:

Proposition 7. *Let r be a non-negative integer with $r \leq p$ and let C_H^Γ be a modular class in $H^{2rq}(\Gamma\backslash S, \mathbb{C})$ with $H \cong \mathrm{PU}(p-r, q)$. Then C_H^Γ is an algebraic class and it is contained in* $\mathrm{SHdg}^r(\Gamma\backslash S, \mathbb{Q}) := SH^{rq,rq}(\Gamma\backslash S, \mathbb{C}) \cap H^{2rq}(\Gamma\backslash S, \mathbb{Q})$.

5.3.2 Quotients of the symmetric space associated to $\mathrm{SO}_0(p, q)$. Similarly and with notations as in Section 3.3.2, any modular class C_H^Γ, with H isomorphic to a smaller orthogonal group fixing a positive subspace, is contained in

$$SH^\bullet(\Gamma\backslash S, \mathbb{C}) = \oplus_{r=0}^{[p/2]} \oplus_{k=0}^{p-2r} e_q^k H^{r\times q}(\Gamma\backslash S, \mathbb{C}). \tag{5-2}$$

Here e_q is zero if q is odd and is the Euler class arising from the standard representation of SO_q if q is even. We then write $\mathrm{SHdg}^r(\Gamma\backslash S, \mathbb{Q}) = SH^{rq}(\Gamma\backslash S, \mathbb{C}) \cap H^{rq}(\Gamma\backslash S, \mathbb{Q})$.

Examples 1. If $q = 1$ the space S is the p-dimensional hyperbolic real space and the subspace $SH^\bullet(\Gamma\backslash S, \mathbb{C})$ is in fact equal to the full cohomology group $H^\bullet(\Gamma\backslash S, \mathbb{C})$.

2. If $q = 2$ the space is Hermitian and we have:

$$SH^\bullet(\Gamma\backslash S, \mathbb{C}) = \oplus_{r=0}^{p} H^{r,r}(\Gamma\backslash S, \mathbb{C}).$$

Beware that in this case the Euler class e_2 is the class of the Kähler form that we denoted c_1 in Section 3.3.2.

5.4 Hodge type theorems. Modular cycle classes belong to a subspace $\mathrm{SHdg}^\bullet(\Gamma\backslash S, \mathbb{Q})$ of the full cohomology group $H^\bullet(\Gamma\backslash S, \mathbb{C})$. Everything is therefore in place to raise a question analogous to the Hodge Conjecture:

> Do modular cycle classes span the subspace $\mathrm{SHdg}^\bullet(\Gamma\backslash S, \mathbb{Q})$?

We shall see that it is too much to hope for in general, but surprisingly enough this is close to be true in several interesting cases. Let us again consider our two main families of examples. Both cases are dealt with in joint works with Millson and Moeglin. The proofs rely heavily on Arthur's classification Arthur [2013] of automorphic representations of classical groups which depends on the stabilization of the trace formula for disconnected groups discussed in Waldspurger's 2014 ICM talk Waldspurger [2014] and recently obtained by Mœglin and Waldspurger [n.d.].

5.4.1 A Hodge type theorem for quotients of the symmetric space associated to $\mathrm{PU}(p,q)$. Even in the simple case where $p = 2$ and $q = 1$ – so that S is the complex 2-ball – it was proved by Blasius and Rogawski [2000] that there exist compact quotients $\Gamma\backslash S$ such that the space of Hodge $(1,1)$-classes is not spanned by modular classes. However, vaguely stated, the main result of Bergeron, Millson, and Moeglin [2016] asserts that for congruence arithmetic quotients $\Gamma\backslash S$ (with arbitrary p and q's) the special cohomology $SH^n(\Gamma\backslash S, \mathbb{C})$ is generated, for n small enough, by cup products of three types of classes:

- classes in $SH^{q,q}(\Gamma\backslash S, \mathbb{C})$;
- holomorphic and anti-holomorphic special cohomology classes, i.e. classes in $SH^{\bullet,0}(\Gamma\backslash S, \mathbb{C})$ and $SH^{0,\bullet}(\Gamma\backslash S, \mathbb{C})$;
- modular cycle classes of Section 5.3.1.

5.4.2 A Hodge type theorem for quotients of the symmetric space associated to $\mathrm{SO}_0(p,q)$. In that case, vaguely stated, the main result of Bergeron, Millson, and Moeglin [2017] states that as long as r is less than $\frac{1}{2}p$ and $\frac{1}{3}(p+q-1)$, the 'primitive' subspace $H^{r\times q}(\Gamma\backslash S, \mathbb{C})$ of $SH^{rq}(\Gamma\backslash S, \mathbb{C})$, in the decomposition (5-2), is spanned by projections of modular cycle classes.

5.5 Applications.

5.5.1 . The most striking consequences of the above mentioned 'Hodge type theorems' concern the cases where S is a complex ball or a real hyperbolic space. Indeed, in these cases $SH^\bullet(\Gamma\backslash S, \mathbb{C}) = H^\bullet(\Gamma\backslash S, \mathbb{C})$ and we obtain the two following theorems.

We first have to define more precisely the congruence arithmetic locally symmetric space we deal with: let E be either a totally real number field or a totally imaginary quadratic extension of a totally real number field. In both cases we denote by F the maximal totally real subfield of E. Now let V be a E-vector space of dimension $n+1 \geq 3$ and let $h : V \times V \to E$ be a Hermitian form with respect to the conjugaison of E/F, such that h is of signature $(n,1)$ at one real place of F and definite at the others. Let $\mathbf{H}$ be the semi-simple algebraic $\mathbb{Q}$-group obtained from the algebraic F-group $\mathrm{SU}(h)$ by restriction of scalars. To any congruence subgroup in $\mathbf{H}(\mathbb{Q})$ we attach a congruence arithmetic quotient $\Gamma\backslash S$ where S is the real hyperbolic n-space, if $E = F$, and the complex n-ball, otherwise.

Theorem 8. *Suppose that $\Gamma\backslash S$ is a closed complex n-ball quotient and let $r \in [0,n]\backslash]\frac{n}{3}, \frac{2n}{3}[$. Then every Hodge class in $H^{2r}(\Gamma\backslash S, \mathbb{Q})$ is algebraic.*

Remarks. 1. Beware that here modular cycle classes *do not* span, even in co-dimension 1. One has to consider arbitrary $(1,1)$-classes.

2. In small degree one can even confirm Hodge's generalized conjecture in its original formulation (with $\mathbb{Q}$ coefficients).

Theorem 9. *Suppose that $\Gamma\backslash S$ is a real hyperbolic n-manifold. Then, for all $r < n/3$, the $\mathbb{Q}$-vector space $H^r(\Gamma\backslash S, \mathbb{Q})$ is spanned by classes of totally geodesic cycles.*

Remarks. 1. In Bergeron, Millson, and Moeglin [2017] we provide strong evidence that Theorem 9 should not hold above the degree $n/3$.

2. When n is even, all congruence arithmetic real hyperbolic n-manifolds are of the simple type described above. However, when n is odd, there are other types of congruence arithmetic real hyperbolic n-manifolds. These *do not* contain totally geodesic immersed co-dimension 1 submanifolds. Still, they may have a non-zero first Betti number. Theorem 9 therefore cannot hold for general (congruence arithmetic) hyperbolic manifolds.

5.5.2 . When $G = \mathrm{SO}_0(n,2)$ the space S is Hermitian and our general 'Hodge type theorem' again specializes into new cases of the Hodge conjecture. Let us emphasize the even more special case of the moduli spaces $\mathcal{K}_g$ (in which cases we have $n = 19$): a theorem of Oguiso [2009] indeed implies that any curve on $\mathcal{K}_g$ meets some of the Noether-Lefschetz (NL) divisors described in Example (3) of Section 5.2. So it is natural to ask whether the Picard group $\mathrm{Pic}_{\mathbb{Q}}(\mathcal{K}_g)$ of $\mathcal{K}_g$ with rational coefficients is spanned by NL-divisors. This was conjectured to be true by Maulik and Pandharipande, see 'Noether-Lefschetz Conjecture' Maulik and Pandharipande [2013, Conjecture 3]. More generally, one can extend this question to higher NL-loci on $\mathcal{K}_g$. In Bergeron, Z. Li, Millson, and Moeglin [2017], we prove:

Theorem 10. *For all $g \geq 2$ and all $r \leq 4$, the cohomology group $H^{2r}(\mathcal{X}_g, \mathbb{Q})$ is spanned by NL-cyles of codimension r. In particular (taking $r = 1$),* $\mathrm{Pic}_{\mathbb{Q}}(\mathcal{X}_g) \cong H^2(\mathcal{X}_g, \mathbb{Q})$ *and the Noether-Lefschetz Conjecture holds on $\mathcal{X}_g$ for all $g \geq 2$.*

Remark. Before Bergeron, Millson, and Moeglin [2017], He and Hoffman [2012] considered another interesting special case of our general 'Hodge type theorem,' that of smooth Siegel modular threefolds Y where $p = 3$ and $q = 2$. They prove that $\mathrm{Pic}(Y) \otimes \mathbb{C} \cong H^{1,1}(Y)$ is generated by Humbert surfaces.

6 Automorphic Lefschetz properties

Almost 40 years ago Oda [1981] proved that the Albanese variety of a congruence arithmetic complex ball quotient is spanned by the Hecke translates of the Jacobian of a fixed Shimura curve. This implies a version of the Lefschetz Theorem on the injection of the cohomology to Shimura curves that can arguably be considered as the starting point of the analogy between locally symmetric spaces and projective varieties that we are discussing here. Since Oda's pioneering work, a number of criteria have been developed to determine if some Hecke translate of a given cohomology class on a locally symmetric space restricts non-trivially to a given locally symmetric subspace. Venkataramana's ICM 2010 talk Venkataramana [2010] was devoted to this subject. We shall therefore insist on results obtained since then.

6.1 Comparison with projective varieties. Let $V \subset \mathbb{P}^N$ be a projective non-singular algebraic variety and $V \cap H$ a hyperplane section of V. Then we have the

Lefschetz Hyperplane Theorem. *The restriction map*

(6-1)
$$H^i(V, \mathbb{Q}) \to H^i(V \cap H, \mathbb{Q})$$

is an isomorphism for $i \leq n - 2$ and injective for $i = n - 1$.

This theorem in fact contains two quite different statements:

1. the map (6-1) is injective for $i < n$,
2. the map $H_i(V \cap H, \mathbb{Q}) \to H_i(V, \mathbb{Q})$ is injective for $i \geq n$.

6.2 Restriction to special cycles. The Lefschetz Hyperplane Theorem applies to compact quotients $\Gamma \backslash S$ of *Hermitian* symmetric spaces but modular classes are not ample. However, one may consider all the translates of these modular classes under Hecke operators and ask for a weaker Lefschetz property for the collection of these Hecke translates.

And a large number of such ‘weak Lefschetz properties’ indeed hold even when the symmetric space S is not Hermitian, see e.g. Bergeron [2006]. Since the general results require a rather forbidding amount of notation we restrict our discussion to the special situation of Section 5.5.1.

In this situation, to any non-degenerate, indefinite, subspace $W \subset V$ defined over E we attach a special cycle $\Gamma_W \backslash S_W \to \Gamma \backslash S$. It is of real dimension $m[E : F]$. The following theorem is our analogue of the first part of Lefschetz Hyperplane Theorem.

Theorem 11. *For every $m < n$, there exist $(m+1)$-dimensional subspaces $W_1, \dots, W_s$ in V such that the restriction map*

$$H^i(\Gamma \backslash S, \mathbb{Q}) \to \bigoplus_j H^i(\Gamma_{W_j} \backslash S_{W_j}, \mathbb{Q}) \tag{6-2}$$

is injective for all $i < \frac{1}{2} m[E : F]$ and for $i = \frac{1}{2} m[E : F]$ if $\Gamma \backslash S$ is closed.

The theorem can be reformulated using Hecke correspondences: to any F-rational element g of the isometry group of h we may associate a finite correspondence $(\Gamma \cap g^{-1} \Gamma g) \backslash S \rightrightarrows \Gamma \backslash S$ where the first projection is the covering projection and the second projection is induced by the multiplication by g. Write $C_g^* : H^\bullet(\Gamma \backslash S, \mathbb{Q}) \to H^\bullet(\Gamma \backslash S, \mathbb{Q})$ for the induced endomorphism. Theorem 11 then says that if α is a non-zero class in $H^i(\Gamma \backslash S, \mathbb{Q})$ of degree $i < \frac{1}{2} \dim_{\mathbb{R}} S_W$, then there exists a g such that $C_g^*(\alpha)$ pulls back non-trivially to $\Gamma_W \backslash S_W$.

For compact ball quotients, the theorem is due to Oda [1981] in degree $i = 1$, and to Venkataramana [2001] – confirming a conjecture of Harris and J.-S. Li [1998] – for all degrees. The essential point (in the case $n = m + 1$) is that a linear combination of the divisors $\Gamma_{W_i} \backslash S_{W_i} \to \Gamma \backslash S$ gives a particular ample class, the hyperplane class in the canonical projective embedding of $\Gamma \backslash S$. The Lefschetz property then follows from the hard Lefschetz theorem. For non-compact ball quotients, one can combine Venkataramana’s idea with the study of compactifications, see Nair [2017]. It may appear quite surprising that the theorem holds for *real* hyperbolic manifolds. This is again a topological consequence of the spectral gap Theorem 3. This approach gives a unified proof of Theorem 11, see Bergeron and Clozel [2013, 2017].

6.3 Another type of Lefschetz property.

As for the second part of Lefschetz Hyperplane Theorem, let us mention the following homotopical analogue of it, see Bergeron, Haglund, and Wise [2011].

Theorem 12. *A closed arithmetic hyperbolic manifold $\Gamma \backslash \mathbb{H}^n$ virtually retracts onto any of its* co-dimension 1 *modular cycle.*

In other words: if $\Lambda\backslash\mathbb{H}^{n-1} \to \Gamma\backslash\mathbb{H}^n$ is a totally geodesic immersion and if we write $\iota : \Lambda \to \Gamma$ for the corresponding (injective) morphism, there exists a finite index subgroup $\Gamma' \subset \Gamma$ and a morphism $r : \Gamma' \to \Lambda$ such that $\iota(\Lambda)$ is contained in Γ' and $r \circ \iota : \Lambda \to \Lambda$ is the identity map. In particular the induced map

$$H_i(\Lambda\backslash\mathbb{H}^{n-1}, \mathbb{Q}) \to H_i(\Gamma'\backslash\mathbb{H}^n, \mathbb{Q})$$

is injective for all $i \geq 0$.

The proof of Theorem 12 is very specific to arithmetic hyperbolic manifolds that contain co-dimension 1 modular cycles; it uses that the group Γ may be 'cubulated' (in the sense of Wise [2014]). It is a very interesting open question to decide which lattices of $SO_0(n, 1)$ can be cubulated, but it is known that lattices in all other real simple Lie groups cannot. Of course, this does not prevent Theorem 12 to hold for other locally symmetric spaces, but to my knowledge no other examples are known to (homotopically) retract onto a locally symmetric proper subspace except for a small finite number of beautiful examples, due to Deraux [2011], of complex 2-ball and 3-ball quotients that retract onto one of their totally geodesic submanifolds.

However, thanks to spectral gap properties as in Theorem 3, the homological consequences of Theorem 12 are more tractable in general, see Bergeron [2006]. In the special situation of Section 5.5.1 one can for example prove the following analogue of the second aspect of Lefschetz Hyperplane Theorem, see Bergeron and Clozel [2013].

Theorem 13. *Suppose that $\Gamma\backslash S$ is closed. Let W be a subspace of V. There exists a finite index subgroup $\Gamma' \subset \Gamma$ such that the natural map*

$$H_i(\Gamma'_W\backslash S_W, \mathbb{Q}) \to H_i(\Gamma'\backslash S, \mathbb{Q}) \tag{6-3}$$

is injective for all $i \geq \frac{1}{2}\dim_{\mathbb{R}} S$.

6.4 Some refined analogies with specific projective varieties: Abelian varieties. Theorem 9 is an analogue, in constant negative curvature, of the classical fact that cycle classes of totally geodesic flat sub-tori span the cohomology groups of flat tori. In fact if A is an Abelian variety, in most interesting cohomology theories $H^\bullet(A)$ is an exterior algebra on $H^1(A)$. In particular, if A is sufficiently general, the algebra of Hodge classes is generated in degree 1 and the Hodge conjecture follows.

Quite surprisingly, in small degrees, the cohomology rings of congruence arithmetic locally symmetric manifolds enjoy structural properties very analogous to those of Abelian varieties. Here again we discuss only the special situation of Section 5.5.1. Suppose furthermore that $\Gamma\backslash S$ is closed and write $\mathrm{Hdg}^\bullet(\Gamma\backslash S, \mathbb{Q}) = H^\bullet(\Gamma\backslash S, \mathbb{Q})$ if $E = F$, i.e. if S is a real hyperbolic space $\mathbb{H}^n$. First, the proofs of Theorems 8 and 9 imply:

Theorem 14. *The natural morphism of algebras*

$$\wedge^\bullet \mathrm{Hdg}^1(\Gamma\backslash S, \mathbb{Q}) \to \mathrm{Hdg}^\bullet(\Gamma\backslash S, \mathbb{Q}) \tag{6-4}$$

is onto in degree $< n/3$.

As opposed to what happens with Abelian varieties, the map (6-4) is not injective in general (already when $\Gamma\backslash S$ is a real hyperbolic surface). The next theorem – see Bergeron and Clozel [2013, 2017] – nevertheless shows that it is injective 'up to Hecke correspondences.'

Theorem 15. *Let* α *and* β *two cohomology classes in* $H^\bullet(\Gamma\backslash S, \mathbb{Q})$ *of respective degrees* k *and* ℓ *with* $k+\ell \leq \frac{1}{2}\dim_{\mathbb{R}} S$. *Then, there exists some rational element* g *of the isometry group of* h *such that*

$$C_g^*(\alpha) \wedge \beta \neq 0 \text{ in } H^{k+\ell}(M, \mathbb{Q}).$$

For complex ball quotients Theorem 15 is due to Venkataramana [2001]. Parthasarathy [1982], Clozel [1992, 1993] and Venkataramana [2010] have general results of this type for other Hermitian spaces, see also Bergeron [2004]. In Bergeron [2006] we consider more general non Hermitian locally symmetric spaces. Here again the key input is a spectral gap theorem.

7 Periods

Algebraic varieties admit a panoply of cohomology theories, related over $\mathbb{C}$ by comparison isomorphisms. These give rise to different structures on the cohomology groups. Comparing two such structures leads in particular to the rich theory of periods.

When dealing with general locally symmetric manifolds we don't have all these cohomology theories at our disposal anymore. However, using the canonical Riemannian structure on S, we can extract some numerical invariants from the cohomology, which we call 'period matrices.'

7.1 Comparison with projective varieties. If V is a smooth projective variety defined over $\mathbb{Q}$, the vector space $H^k(V, \mathbb{C})$ has a natural $\mathbb{Q}$-structure $H^k_{\mathrm{dR}}(X/\mathbb{Q})$: choose a cover of V by Zariski affine open sets defined over $\mathbb{Q}$ and use algebraic differential forms with coefficients in $\mathbb{Q}$. A comparison theorem, due to Grothendieck, gives a natural isomorphism $H^k_{\mathrm{dR}}(X/\mathbb{Q}) \otimes \mathbb{C} \cong H^k(V, \mathbb{C})$.

One calls *periods* the matrix coefficients of the comparison isomorphism

$$H^k_{\mathrm{dR}}(X/\mathbb{Q}) \otimes \mathbb{C} \xrightarrow{\cong} H^k(V, \mathbb{Q}) \otimes \mathbb{C}$$

between algebraic de Rham cohomology and singular cohomology after choosing $\mathbb{Q}$-bases in both groups. In general these two different $\mathbb{Q}$-structures are transcendent with respect to each other and periods are fundamental numerical invariants, see e.g. Kontsevich and Zagier [2001].

7.2 Period matrices of locally symmetric spaces. Let us come back to locally symmetric manifolds $\Gamma\backslash S$. Through the isomorphism (3-1), the Riemannian structure on S induces a positive definite quadratic form on each cohomology group $H^j(\Gamma\backslash S, \mathbb{Z})$ modulo torsion. Letting $b = b_j(\Gamma\backslash S)$, we encode the above data into a matrix

$$M = \left(\int_{\gamma_k} \omega_\ell \right)_{1 \le k, \ell \le b} \in \mathrm{GL}_b(\mathbb{R})$$

where the $\gamma_k \in H_j(\Gamma\backslash S, \mathbb{Z})$ project to a basis for $H_j(\Gamma\backslash S, \mathbb{Z})$ modulo torsion and the ω_ℓ's are an orthonormal basis for the space of harmonic j-forms on $\Gamma\backslash S$. The matrix M is well-defined up to multiplication on the left by $\mathrm{GL}_b(\mathbb{Z})$ and on the right by an orthogonal matrix.

As an element of $\mathrm{GL}_b(\mathbb{Z})\backslash\mathrm{GL}_b(\mathbb{R})/\mathrm{O}_b$, the matrix M is characterized by its determinant and its image in the locally symmetric space that parametrizes the space of flat b-dimensional tori of unit volume. In analogy with the classical Schottky problem, it would be interesting to analyse the locus of the latter as Γ varies. Let us restrict our attention to the apparently simpler question of bounding the determinant.

7.3 Regulators. Following Bergeron and Venkatesh [2013] and Bergeron, Şengün, and Venkatesh [2016] we call 'degree j regulator' the determinant of the degree j period matrix of $\Gamma\backslash S$; we denote it by $R_j(\Gamma\backslash S)$.

Note that $|R_0(\Gamma\backslash S)| = 1/\sqrt{\mathrm{vol}(\Gamma\backslash S)}$, $|R_n(\Gamma\backslash S)| = \sqrt{\mathrm{vol}(\Gamma\backslash S)}$, and by Poincaré duality, we have $|R_j(\Gamma\backslash S) R_{n-j}(\Gamma\backslash S)| = 1$. We propose the following:

Conjecture 16. *Fix S and j. The growth of the degree j regulators of* congruence arithmetic *of S-manifolds is given by*

$$\log |R_j(\Gamma\backslash S)| = o(\mathrm{vol}(\Gamma\backslash S)).$$

In the next paragraph we relate Conjecture 16 to the geometric complexity of cycles needed to generate $H_j(\Gamma\backslash S, \mathbb{R})$. 'Hodge type theorems' like Theorem 9 suggest that the conjecture could be tractable when j is far enough from the middle degree. In general one can think of Conjecture 16 as an attempt to shed little light on the mysterious cycle theory of locally symmetric spaces near the middle degree.

7.4 Back to cycles. Our reason to believe in Conjecture 16 is that, roughly speaking, we expect homology classes on congruence arithmetic manifolds to be represented by cycles of low complexity. In our general situation, these cycles are not algebraic at all but one may still hope that their *topological* complexity reflects the *arithmetic* complexity of their (Langlands-)associated varieties.

In Bergeron, Şengün, and Venkatesh [2016] we formulate and study the following precise conjecture in a simple interesting case, namely, that of congruence arithmetic hyperbolic 3-manifolds.

Conjecture 17. *There is an absolute constant C such that, for any congruence arithmetic hyperbolic 3-manifold $\Gamma\backslash\mathbb{H}^3$, there exist immersed surfaces S_i of genus less that $\mathrm{vol}(\Gamma\backslash\mathbb{H}^3)^C$ such that the $[S_i]$'s span $H_2(\Gamma\backslash\mathbb{H}^3,\mathbb{R})$.*

To relate Conjecture 17 with $R_2(\Gamma\backslash\mathbb{H}^3)$, we study the relationship between two norms on the second homology group: the purely topological Gromov-Thurston norm and the more geometric 'harmonic' norm. Refining Bergeron, Şengün, and Venkatesh [ibid., Proposition 4.1] Brock and Dunfield [2017] show that these two norms are roughly proportional with explicit constants depending only on the volume and injectivity radius[4] of $\Gamma\backslash\mathbb{H}^3$. Now, assuming Conjecture 17, each $[S_j]$ has Gromov-Thurston norm – and therefore harmonic norm – which is bounded by a polynomial in $\mathrm{vol}(\Gamma\backslash\mathbb{H}^3)$. Thus Hadamard's inequality shows that $|R_2(\Gamma\backslash\mathbb{H}^3)| \ll \mathrm{vol}(\Gamma\backslash\mathbb{H}^3)^{Cb_1(\Gamma\backslash\mathbb{H}^3)}$.

Remarks. 1. Conjectures 16 and 17 are false if the manifolds are not assumed to be congruence arithmetic: Brock and Dunfield [ibid., Theorem 1.5] indeed construct a sequence of closed hyperbolic 3-manifolds M_n (whose injectivity radii stay bouded away from 0) with

$$\mathrm{vol}(M_n) \to \infty,\ b_1(M_n) = 1 \text{ and } \limsup_n \frac{\log|R_2(M_n)|}{\mathrm{vol}(M_n)} > 0.$$

2. Under well believed number theoretic assumptions, in Bergeron, Şengün, and Venkatesh [2016] we notably verify Conjecture 17 when $\Gamma\backslash\mathbb{H}^3$ is a congruence cover of a Bianchi manifold with 1-dimensional cuspidal cohomology associated to a non-CM elliptic curve. In that case the proof indeed relate the complexity of the H_2-cycle to the height of the associated elliptic curve (i.e., the minimal size of A, B so that its equation can be expressed as $y^2 = x^3 + Ax + B$). That this might be a general phenomenon was also suggested in Calegari and Venkatesh [2012].

[4] which is expected to be uniformly bounded away from 0 on arithmetic manifolds

8 Some regrets

Many other interesting questions could (should?) have been discussed in this survey. Hyperbolic 3-manifolds form a particularly rich and interesting family of locally symmetric manifolds. However: Matsushima's formula gives no restriction on their cohomology and most of these manifolds do not contain totally geodesic immersed submanifolds. It may therefore appear that hyperbolic 3-manifolds are not really connected with our general story. This is not quite true: Agol [2013, 2014] proof of the celebrated 'Virtual Haken Conjecture' suggests considering 'almost geodesic' cycles rather than just geodesic ones. We haven't addressed the rich relation between the cohomology of locally symmetric spaces and number theory. Let us simply say that our original motivation for Conjectures 16 and 17 came from the study of torsion homology and its relation with Galois representations Scholze [2014]. Finally Venkatesh's program Venkatesh [2017] suggests fascinating relations between the period matrices of Section 7.2 and periods (in the usual sense) of automorphic forms.

Acknowledgments. I would like to thank Miklos Abert, Tsachik Gelander, Laurent Clozel, Étienne Ghys, Frédéric Haglund, Zhiyuan Li, John Millson, Colette Moeglin, Peter Sarnak, T.N. Venkataramana, Akshay Venkatesh, Claire Voisin and Dani Wise for many very helpful conversations over the years on the material related to this survey.

COMPLEX BRUNN–MINKOWSKI THEORY AND POSITIVITY OF VECTOR BUNDLES

Bo Berndtsson

Abstract

This is a survey of results on positivity of vector bundles, inspired by the Brunn-Minkowski and Prékopa theorems. Applications to complex analysis, Kähler geometry and algebraic geometry are also discussed.

1 Introduction

The classical Brunn-Minkowski theorem is an inequality for the volumes of convex sets. It can be formulated as a statement about how the volumes of the vertical n-dimensional sections of a convex body in $\mathbb{R}^{n+m}$ vary with the section; more precisely it says that the n:th root of the volumes define a concave function on $\mathbb{R}^m$. The theorem has many applications, and it has also been generalized in many different directions (see e. g. the survey, Gardner [2002]).

One important generalization is Prékopa's theorem, Prékopa [1973], which can be seen as a version of the Brunn-Minkowski theorem for convex functions instead of convex sets. Let $\phi(x,t)$ be a convex function on $\mathbb{R}^n_x \times \mathbb{R}^m_t$, satisfying some mild extra conditions. We define a new function on $\mathbb{R}^m$ by

$$e^{-\tilde{\phi}(t)} = \int_{\mathbb{R}^n} e^{-\phi(t,x)} dx.$$

Then Prékopas theorem says that $\tilde{\phi}$ is also convex. Measures of the type

$$e^{-\phi} dx,$$

where ϕ is convex, are called *log concave* , and in this terminology Prékopa's theorem says that the marginals, or push forwards, of log concave measures are log concave. If we

MSC2010: primary 32L05; secondary 14D06.

admit convex functions that attain the value ∞, the Brunn-Minkowski theorem is a direct consequence of Prékopa's theorem, corresponding to the case when ϕ is the indicator function of a convex body, i.e. the function which is zero on the convex body and infinity outside. (Properly speaking we get a version of the Brunn-Minkowski theorem with n:th roots replaced by logarithms. This is the 'multiplicative version' of the Brunn-Minkowski theorem, and is easily seen to be equivalent to the 'additive version'.)

Among the many different proofs of Prékopa's theorem, the one that is relevant to us here is the proof of Brascamp and Lieb [1976]. It goes by first proving the *Brascamp-Lieb inequality*, which is a Poincaré inequality for the d-operator (on functions). In the case when $n = 1$ (which is really the main case) it says the following: Let u be a smooth function on $\mathbb{R}$, satisfying

$$\int_{\mathbb{R}} u e^{-\phi(x)} dx = 0,$$

where ϕ is a smooth function, which is strictly convex in the sense that $\phi'' > 0$. Then

$$\int_{\mathbb{R}} |u|^2 e^{-\phi} dx \leq \int_{\mathbb{R}} \frac{|u'|^2}{\phi''} e^{-\phi} dx.$$

From this, Prékopa's theorem (and therefore also the Brunn-Minkowski theorem) follows just by differentiating $\tilde{\phi}$ twice, and applying the Brascamp-Lieb inequality to estimate the result. Actually, the two results are 'equivalent' in the sense that the Brascamp-Lieb theorem follows from Prékopa's theorem too. (See Cordero-Erausquin and Klartag [2012], which also gives a nice complement to the oversimplified historical picture described above.)

Now we observe that the Brascamp-Lieb inequality is the real variable version of Hörmander's L^2-estimate for the $\bar\partial$-operator, Hörmander [1965], Demailly [1997]. (This point of view was probably first stated clearly in Cordero-Erausquin [2005].) To describe the simplest case of Hörmander's estimate we let ϕ be a smooth strictly subharmonic function in $\mathbb{C}$. Then we let u be a smooth function on $\mathbb{C}$, satisfying

$$\int_{\mathbb{C}} u \bar{h} e^{-\phi} d\lambda = 0,$$

for all holomorphic functions h satisfying the appropriate L^2-condition ($d\lambda$ denotes Lebesgue measure). Note that this is a direct counterpart to the condition on u in the real case. Then u was assumed to be orthogonal to all constant functions, i.e. all functions in the kernel of d, whereas in the complex case u is assumed to be orthogonal to all functions in the kernel of $\bar\partial$. The conclusion of Hörmander's estimate is now that

$$\int_{\mathbb{C}} |u|^2 e^{-\phi} d\lambda \leq \int_{\mathbb{C}} \frac{|\bar\partial u|^2}{\Delta\phi} d\lambda,$$

which clearly is very similar to the conclusion of the Brascamp-Lieb inequality. The condition that u is orthogonal to all holomorphic functions, means that u is the L^2-minimal solution to a $\bar\partial$-equation, and this is how Hörmander's theorem is mostly thought of; as an estimate for solutions to the $\bar\partial$-equation. (There is also an even more important existence part of Hörmander's theorem, but that plays no role here.) In the same way, the Brascamp-Lieb theorem is an L^2-estimate for the d-equation, and it can be obtained as a special case of Hörmander's theorem, when the functions involved do not depend on the imaginary part of z.

Given the importance of Prékopa's theorem in convex geometry, it now becomes a natural question if there are any analogous consequences of Hörmander's theorem in the complex setting, that generalize the real theory. This is the subject of the work that we will now describe.

The most naive generalization would be that letting ϕ be plurisubharmonic (i.e. subharmonic on each complex line) in $\mathbb{C}^n \times \mathbb{C}^m$, and defining $\tilde\phi$ as we did in the real case, we get a plurisubharmonic function. This is however in general not the case as shown by a pertinent example of Kiselman [1978],

$$\phi((t,z) := |z-\bar t|^2 - |t|^2 = |z|^2 - 2\mathrm{Re}\, zt$$

(in $\mathbb{C}^2$). It turns out that instead we should think of the volume of a (convex) domain as the squared L^2-norm of the function 1, and the integrals of $e^{-\phi}$ as squared weigthed L^2-norms. Then it becomes natural to consider L^2-norms of holomorphic functions in the complex case, i.e. to look at norms

$$\|h\|_t^2 := \int_{\mathbb{C}^n} |h(z)|^2 e^{-\phi(t,z)} d\lambda(z),$$

or similar expressions where we integrate over slices of pseudoconvex domains in $\mathbb{C}^n$ instead of the total space. Let A_t^2 be the (Bergman) space of holomorphic functions with finite norm. Then we get a family of Hilbert spaces, indexed by t, i.e. a vector bundle, or at least a 'vector bundle like' object (the bundles obtained are in general not locally trivial). The theorems that we are going to discuss amount to saying that the curvature of these bundles is positive, or at least non negative, under natural assumptions. If, intuitively, we think of the curvature as (the negative of) the Hessian of the (logarithm of) the metric, this can be seen as a counterpart to the Brunn-Minkowski-Prékopa theorem. One can also recover Prékopa's theorem as a special case, see Section 2.

Let us add one remark on the relation of positive curvature to convexity in the real setting. A convex function on $\mathbb{R}^n$ is the same thing as a plurisubharmonic function on $\mathbb{C}^n$ that does not depend on the imaginary part of z. But, it is *not* the case that

$$-\log \|h_t\|_t^2,$$

is plurisubharmonic in t if h_t is a holomorphic section of a holomorphic hermitian vector bundle of positive curvature. This does however hold if the rank of the vector bundle is 1, so that we have a line bundle, if we also assume that $h_t \neq 0$ for all t. This is precisely the situation in the real setting: The bundle of constants has rank 1 and the 'section' 1 is never zero, and that is why we get simpler statements in the real setting. If we imagine a vector valued Brunn-Minkowski theory (see Raufi [n.d.]) we would get a situation similar to the complex case since

$$-\log \sum_1^N e^{-\phi_j}$$

is in general not convex for convex ϕ_j, except when $N = 1$.

Looking at the complex situation, it is clear that the restriction to linear sections of a domain in Euclidean space is not as natural as in the real case. The general picture involves two complex manifolds X and Y of dimensions $n+m$ and m respectively, and a holomorphic surjective map $p : X \to Y$ between them. This corresponds to the previous situation when $X = \mathbb{C}^n \times \mathbb{C}^m$, $Y = U \subset \mathbb{C}^m$ and p is the linear projection from $\mathbb{C}^n \times \mathbb{C}^m$ to $\mathbb{C}^m$. The role of the linear sections is played by the fibers $X_y = p^{-1}(y)$ of the map. To get enough holomorphic objects to apply the theory to, we will also replace holomorphic functions by holomorphic sections of a line bundle, L, over X, and the plurisubharmonic function ϕ now corresponds to a hermitian metric of non negative curvature on L. We then have almost all the ingredients for the complex theory, but one item remains to sort out: How do we define L^2-norms over the fibers?

For a general complex manifold, like the fibers of the map p, there is of course no substitute for Lebesgue measure. The way out is to consider, instead of sections of L, $(n,0)$-forms on the fibers with values in L. Such forms with values in L have natural L^2-norms, defined by wedge product and the metric on L. The bundle metric we get is

$$\|u\|_y^2 = c_n \int_{X_y} u \wedge \bar{u} e^{-\phi}.$$

Again, in our model situation of Euclidean space, this corresponds to integration with respect to Lebesgue measure. With this list of translations we obtain a counterpart to Prékopa's theorem in the complex setting, under natural convexity assumptions on X.

As it turns out, the nicest situation is when the map is proper, so that the fibers are compact, and also a submersion, so that the fibers are manifolds. In this case, and assuming also that the line bundle is trivial, the theorem was already known. Indeed it is a part of Griffiths' monumental theory of variations of Hodge structures, Griffiths and Tu [1984], Fujita [1978]. Griffiths' point of view however was rather different. He considered the vector bundle that we are discussing, with fibers $H^{n,0}(X_y)$, as a subbundle of the Hodge bundle with fibers $H^n_{dRh}(X_y)$, with connection induced by the Gauss-Manin connection on the Hodge bundle. It seems difficult to generalize this approach completely to the twisted case, when L is nontrivial, since e.g. there is no twisted counterpart to the Hodge bundle (see however Kawamata [1998]). It is also interesting to notice the different roles played by holomorphic forms: Griffiths was interested in holomorphic forms per se because of their relation to the period map. Here the forms are forced upon us in order to define L^2-norms.

In the next section we will give more precise formulations of the basic results. After that we will turn to applications; to L^2-extension problems for holomorphic functions, the (Mabuchi) space of Kähler metrics in a fixed cohomology class, variations of complex strucures, and finally positivity of direct image bundles in algebraic geometry.

Acknowledgments. The work described here has been influenced by discussions with many people. In particular I owe a great debt to Robert Berman, Sebastien Boucksom, Dario Cordero-Erausquin, Bo'az Klartag, Mihai Paun, Yanir Rubinstein and Xu Wang.

2 The basic results

We begin with non proper maps, and start by looking at the simplest case. We let Ω be a domain in $\mathbb{C}^n$ and U a domain in $\mathbb{C}^m$. We then let $X = \Omega \times U$ and let $p : X \to U$ be the linear projection on the second factor. We will assume that Ω is pseudoconvex (meaning that it has a smooth strictly plurisubharmonic exhaustion function). Let $\phi = \phi(z,t)$ be plurisubharmonic and smooth up to the boundary. Let

$$A^2(\Omega, \phi) = \{u \in H(\Omega); \int_\Omega |u|^2 e^{-\phi(\cdot,t)} < \infty\},$$

be the corresponding Bergman space of holomorphic functions, equipped with the norm

$$\|u\|_t^2 = \int_\Omega |u|^2 e^{-\phi(\cdot,t)}.$$

Since ϕ is bounded, all the Bergman spaces are the same as linear spaces, but their norms vary with t. We therefore get a trivial vector bundle $E = A^2 \times U$ over U with a non trivial Hermitian metric. We define its complex structure by saying that a section $t \to h(t, \cdot)$ is holomorphic if h is holomorphic on $\Omega \times U$.

Theorem 2.1. *(Berndtsson [2009]) The bundle $(E, \|\cdot\|_t)$ has non negative (Chern) curvature in the sense of Nakano.*

There are two main notions of positivity for Hermitian vector bundles; positivity in the sense of Griffiths and in the sense of Nakano. Positivity in the sense of Griffiths is defined in terms of the curvature tensor in the following way. Recall that the curvature is a $(1,1)$-form, Θ, with values in the space of endomorphisms of E. Then, if $u_t \in E_t$,

$$\langle \Theta u_t, u_t \rangle_t$$

is a scalar valued $(1,1)$-form. Positivity in the sense of Griffiths means that it is a positive form for any u_t. For the definition of positivity in the sense of Nakano, which is a stronger notion, we refer to Demailly [1997] or Berndtsson [2009]. We should also point out that we are here in the somewhat non standard situation of infinite rank bundles; this is also discussed in Berndtsson [ibid.].

We first discuss the proof very briefly. Let F be the bundle $(L^2(\Omega,\phi), \|\cdot\|_t)$, whose fibers are general L^2-functions, not necessarily holomorphic. It is also a trivial bundle, and we define a section $t \to u_t$ to be holomorphic if the dependence on t is holomorphic. Then E is a subbundle of F. It is easy to see that the curvature of F is the $(1,1)$-form $\sum_1^m \phi_{t_j,\bar{t}_k} dt_j \wedge d\bar{t}_k$, where the coefficients should be interpreted as the endomorphisms

$$u_t \to \phi_{t_j,\bar{t}_k} u_t.$$

Then it is immediately clear that F has non negative curvature as soon as ϕ is plurisubharmonic in t for z fixed. By general principles (Demailly [1997]), the curvature of the subbundle E is given by

$$\langle \Theta^E u_t, u_t \rangle_t = \langle \Theta^F u_t, u_t \rangle_t - \|\pi_{E^\perp} \theta^F u_t\|_t^2.$$

Here θ^F is the connection form for the Chern connection of F, and $\pi_{E^\perp}$ is the orthogonal projection on the orthogonal complement of E in F. The important thing to notice is now that, since $\pi_{E^\perp}\theta^F u_t$ lies in the orthogonal complement of the space of holomorphic functions, it is the L^2-minimal solution of some $\bar\partial$-equation, and we can apply Hörmander's estimate (for pseudoconvex domains in $\mathbb{C}^n$). This allows us to control the second, negative, term by the first, positive, one, and that gives the theorem.

It is well known that positivity in the sense of Griffiths, is equivalent to negativity of the dual bundle, E^*. On the other hand, negativity in the sense of Griffiths, is equivalent to saying that

$$\log \|v_t\|_t$$

is plurisubharmonic for any holomorphic section of E^*.

This leads to a more concrete reformulation of the first theorem. For t in U, let $t \to \mu_t$ be a family of complex measures on Ω. Assume there is a compact subset, K, of Ω, such that all μ_t are supported on K. Then

$$u_t \to \int_\Omega u_t d\mu_t =: \mu_t(u_t)$$

defines a secion of the dual bundle E^* and it gets a norm inherited from the norm on E_t.

Corollary 2.2. *Assume that the section μ_t is holomorphic in the sense that*

$$t \to \mu_t(h(t, \cdot)$$

is holomorphic for any h holomorphic on X. Then

$$\log \|\mu_t\|_t$$

is plurisubharmonic.

But this statement makes sense in a much more general situation.

Theorem 2.3. *Let D be a pseudoconvex domain in $\mathbb{C}^n \times \mathbb{C}^m$, and denote by $D_t = \{z \in \mathbb{C}^n; (z, t) \in D\}$ its vertical slices. Let μ_t be a family of measures on D_t that are all locally supported in a compact subset of D, and depend on t in a holomorphic way so that*

$$t \to \mu_t(h(t, \cdot))$$

is holomorphic in t if h is holomorphic in D. Then

$$\log \|\mu_t\|_t$$

is plurisubharmonic in t.

This way we have implicitly defined positivity of curvature for the 'bundle of Bergman spaces' $A^2(D_t, \phi)$, even though this is not properly speaking a vector bundle, since it is not locally trivial. Here we also note that Theorem 2.3 and Corollary 2.2 imply Prékopa's theorem: Take $D = (\mathbb{C}^*)^n$ (where $\mathbb{C}^* = \mathbb{C} \setminus \{0\}$), and define μ by taking averages over the n-dimensional real torus

$$\mu(h) = \int_{T^n} h(e^{i\theta_1} z_1, ..e^{i\theta_n} z_n) d\theta$$

(it does not depend on z). Computing the norm of μ as a functional on $A^2(D, e^{-\phi(t,\cdot)})$, where ϕ only depends on $|z_j|$, we recover Prékopa's theorem.

One main case of Theorem 2.3 is when the measures μ_t are all Dirac delta functions.

Theorem 2.4. *(Berndtsson [2006]) Let D be a pseudoconvex domain in $\mathbb{C}^n \times \mathbb{C}^m$ and let ϕ be plurisubharmonic in D. For each t in the projection of D to $\mathbb{C}^m$ let $B_t(z) = B_t(z, z)$ be the diagonal Bergman kernel for $A^2(D_t, \phi)$. Then $\log B_t(z)$ is plurisubharmonic in D.*

This theorem was obtained earlier when $n = 1$ and $\phi = 0$ by Maitani and Yamaguchi in Maitani and Yamaguchi [2004]. It is a consequence of the previous result. Let $t \to f(t)$

be a holomorphic map such that $f(t) \in D_t$, and let μ_t be a Dirac mass at $f(t)$. It is immediate that $t \to \mu_t(h) = h(t, f(t))$ is holomorphic if h is holomorphic on the product space. Moreover,

$$\|\mu_t\|_t^2 = B_t(f(t)),$$

so by the theorem, $\log B_t(f(t))$ is plurisubharmonic for any such map. This means that $B_t(z)$ is plurisubharmonic in D.

The proof of Theorem 2.3 uses the corollary, applied to a sequence of weights that tend to infinity outside of D. It is given in detail in Berndtsson [2006] for the situation of Bergman kernels, but the same proof gives the more general result too. See also Wang [2017] for a detailed analysis of a curvature operator defined in the setting of Theorem 2.3 (under one extra assumption) and conditions for when the curvature vanishes.

We next turn to general surjective holomorphic maps between complex manifolds, and there we will restrict to the case of proper maps, to fix ideas. Let X be a complex manifold of dimension $n+m$ and U a complex manifold of dimension m. Since our results are mostly local we can here think of U as a domain in $\mathbb{C}^m$. Let $p : X \to U$ be a holomorphic and surjective map. We say that p is smooth if its differential is surjective at every point. Then the fibers $X_t = p^{-1}(t)$ are smooth manifolds, and when the map is proper they are also compact. Let $L \to X$ be a holomorphic line bundle over X, equipped with a an Hermitian metric $e^{-\phi}$.

For t in the base, U, we let

$$E_t = H^{n,0}(X_t, L),$$

be the space of holomorphic L-valued $(n, 0)$-forms on X_t. We can also think of this space as

$$E_t = H^0(X_t, K_{X_t} + L),$$

the space of holomorphic sections over X_t of the canonical bundle of X_t twisted with the bundle L. Equivalently

$$E_t = H^0(X_t, K_{X/U} + L),$$

is the space of holomorphic sections over X_t of the relative canonical bundle $K_{X/U}$ twisted with L. (The relative canonical bundle, defined as $K_{X/U} = K_X - K_U$, is a line bundle over the total space X that restricts to K_{X_t} on every fiber X_t.) Let

$$E = \cup_{t \in U}\{t\} \times E_t.$$

It turns out that, when the metric on L has semipositive curvature, so that $i\partial\bar{\partial}\phi \geq 0$, then E is a holomorphic vector bundle over U. A section u_t of E is defined to be holomorphic if

$$u_t \wedge dt$$

is a holomorphic $(n+m,0)$ -form on X, where $(t_1, ...t_m)$ are holomorphic coordinates on U and $dt = dt_1 \wedge ...dt_m$. Finally, the L^2-norm

$$\|u_t\|_t^2 := c_n \int_{X_t} u_t \wedge \bar{u}_t e^{-\phi},$$

defines an Hermitian structure on E. We are then in a situation analogous to the one in Theorem 2.1, with the advantage that we now get a bona fide vector bundle of finite rank.

Theorem 2.5. *(Berndtsson [2009]) Assume that the curvature of L is nonnegative ($i\partial\bar{\partial}\phi \geq 0$) and that the total space is Kähler. Then E is a holomorphic vector bundle with non-negative curvature in the sense of Nakano (and hence also in the sense of Griffiths).*

Notice that what corresponds to pseudoconvexity here is the assumption that X is Kähler, so somewhat curiously the Kähler assumption appears as a convexity condition. If we look at the global picture and assume that X is even projective this is rather natural, since we may then remove a divisor from X and get a total space that is Stein, hence pseudoconvex. Since a divisor is removable for L^2-holomorphic forms, it appears that projectivity is related to (pseudo)convexity for these problems, but as it turns out, Kähler is enough.

When the fibration is trivial, so that $X = Z \times U$, the theorem can be proved in much the same way as Theorem 2.1, at least when the curvature of $e^{-\phi}$ is strictly positive on fibers. The proof in the general case is based on the formalism of pushforwards of currents. We write the norm squared of a holomorphic section as the pushforward of a form on the total space under p, compute $i\partial\bar{\partial}\|u_t\|_t^2$ using this formalism, and can then identify the curvature.

Theorem 2.5 can be developed in two different ways, by either adding more, or assuming less, assumptions. Let us first assume that the curvature form of the metric on L, $i\partial\bar{\partial}\phi$ restricts to a strictly positive form on each fiber. Then we have a Kähler metric $\omega_t := i\partial\bar{\partial}\phi|_{X_t}$ on each fiber, and thus an associated Laplace operator, $\Box_t = \bar{\partial}\bar{\partial}^* + \bar{\partial}^*\bar{\partial}$ on L-valued forms on each fiber. We can then give an 'explicit' formula for the curvature. To formulate the result we also assume that the base dimension $m = 1$; the general case follows by restricting to lines or curves in the base. We then define a $(1,1)$-form

$$C(\phi) = c(\phi) i dt \wedge d\bar{t},$$

by

$$(i\partial\bar{\partial}\phi)^{n+1}/(n+1)! = C(\phi) \wedge (i\partial\bar{\partial}\phi)^n/n!$$

(we will come back to this form later in sections 4 and 5).

Theorem 2.6. *(Berndtsson [2011]) Assume that $\omega_t = i\partial\bar{\partial}\phi|X_t > 0$ on each fiber X_t. Then the curvature, Θ of $(E, \|\cdot\|_t)$ is given by*

$$\langle \Theta_{\partial/\partial t, \partial/\partial \bar{t}} u_t, u_t \rangle_t = c_n \int_{X_t} c(\phi) u_t \wedge \bar{u}_t e^{-\phi} + \langle (1+\Box_t)^{-1} \kappa_\phi \cup u_t, \kappa_\phi \cup u_t \rangle_t$$

(where we define $\kappa_\phi \cup$ below).

To define κ_ϕ, we first have to define the notion of 'horizontal lift' of a vector field, $\partial/\partial t$ on the base, as introduced by Schumacher [2012], generalizing the earlier notion of 'harmonic lift' of Siu [1986]. A vector field on the total space X is said to be vertical, if it maps to zero under p. It is horizontal if it is orthogonal to all vertical fields under the (possibly degenerate, possible indefinite) metric $i\partial\bar\partial\phi$. As shown in Schumacher [2012], any vector field on the base U has a unique horizontal lift. In our case, the vector field on the base is $\partial/\partial t$, and there is a unique horisontal field V_ϕ (depending on $i\partial\bar\partial\phi$) which maps to $\partial/\partial t$ under p. Taking $\bar\partial V_\phi$ and restricting to fibers we get κ_ϕ; it is a $\bar\partial$-closed $(0,1)$-form on each fiber, with values in $T^{1,0}(X_t)$. The cohomology class of κ_ϕ in $H^{0,1}(X_t, T^{1,0}(X_t))$ is the Kodaira-Spencer class, but here it is important to look at this particular representative of the class. The cup product $\kappa_\phi \cup u_t$ is obtained by contracting with the vector part of κ_ϕ and wedging with the form part.

From the formula we see that if $i\partial\bar\partial\phi \geq 0$ and the curvature is zero, then $c(\phi) = 0$ and κ_ϕ is zero on each fiber. These two conditions imply that the horizontal lift of $\partial/\partial t$ is a holomorphic field, whose flow maps fibers to fibers. In fact, we have

Corollary 2.7. *Assume that $i\partial\bar\partial\phi \geq 0$, $i\partial\bar\partial\phi > 0$ on fibers and that the curvature Θ vanishes. Then there is a holomorphic vector field V on X whose flow lifts to L, such that its flow maps fibers of p to fibers and is an isometry on L. In particular, the flow maps ω_t to $\omega_{t'}$.*

In general terms, this means that the curvature can only vanish if the fibration $p : X \to U$ is trivial, holomorphically and metrically. This is proved under the assumption that the curvature of L is strictly positive on each fiber, and it does not hold in general without this assumtion (see Berndtsson [2011]).

It is also interesting to compare again to Prékopa's theorem. There, if the function $\tilde\phi$ is not strictly convex but linear (and if we assume that $m = 1$), then ϕ must have the form

$$\phi(t,x) = \psi(x + tv) + ct,$$

where ψ is a convex function on $\mathbb{R}^n$, v is a vector in $\mathbb{R}^n$ and c is a constant, Dubuc [1977]. Thus, the variation of ϕ with respect to t comes from the flow of a constant vector field applied to a fixed function ψ, 'lifted' to the line bundle $\mathbb{R}^n \times \mathbb{R}$ by adding ct. This is similar to what happens in the complex setting, except that there we get a holomorphic vector field instead.

We next discuss versions of Theorem 2.5 in the more general setting when the metric on the line bundle L is allowed to be singular, and the map p is no longer assumed to be smooth (in the sense described above) but only surjective. On the other hand, we now assume that X is projective and that $p : X \to Y$, where Y is a compact manifold.

By Sard's theorem, p is smooth outside of $p^{-1}(Y_1)$, where Y_1 is a proper analytic subvariety of Y, and there we can define the L^2-metric as before. There is a counterpart of the Bergman kernel here. It is first defined for $a \in p^{-1}(Y_1)$ as the norm of the evaluation functional at a on $E_{p(a)}$,

$$B(a) = \sup |u(a)|^2/\|u\|^2_{p(a)},$$

where the supremum is taken over all sections u in $H^0(X_{p(a)}, K_{X/Y} + L)$ that are square integrable with respect to the metric $e^{-\phi}$ (if there are no nontrivial such section, we let $B(a) = 0$). This definition however depends on the trivialization of $K_{X/Y} + L$ chosen near a, so the Bergman kernel is not a function but defines a metric on $K_{X/Y} + L$ – the Bergman kernel metric $B^{-1} = e^{-\log B}$.

Theorem 2.8. *(Berndtsson and Păun [2008])If the singular metric $e^{-\phi}$ has semipositive curvature (i.e. $i\partial\bar\partial\phi \geq 0$ in the sense of currents), and the Bergman kernel metric is not identically equal to 0, it defines a singular metric of semipositive curvature on $p^{-1}(Y_1)$. Moreover, this metric extends to a singular metric on $K_{X/Y} + L$ over all of X.*

Briefly, if L is pseudoeffective, i.e. has a singular metric of nonnegative curvature, $K_{X/Y} + L$ is also pseudoeffective, provided that it has a non trivial L^2-section over at least one fiber.

This result can be seen as a counterpart to Theorem 2.3 in this setting. The more difficult problem of counterparts of Theorem 2.5 is discussed in the last section.

3 The Suita conjecture and L^2-extension

Let D be a (say smoothly) bounded domain in $\mathbb{C}$ and suppose $0 \in D$. The Bergman space of D is

$$A^2(D) = \{h \in H(D); \|h\|^2 := \int_D |h|^2 d\lambda < \infty\},$$

and the Bergman kernel at 0 is

$$B(0) = \sup_{\|h\| \leq 1} |h(0)|^2.$$

To state Suita's conjecture we also need the Green's function $G(z)$ which is a subharmonic function in D, vanishing at the boundary, with a logarithmic pole at 0;

$$G(z) = \log|z|^2 - v(z),$$

where v is harmonic and chosen so that G vanishes at the boundary. By definition, $v(0) := c_D(0) = c_D$ is the Robin constant of D at 0. Suita's conjecture, which was proved in

Błocki [2013], Guan and Zhou [2015], says that

$$B(0) \geq \frac{e^{-c_D}}{\pi}.$$

When D is a disk with center 0 it is clear that equality holds, and it was proved in Guan and Zhou [ibid.] that equality holds only then. In Błocki [2015], Błocki gave a much simpler proof of the conjecture, based on variations of domains and the 'tensor power trick'. In connection with this, László Lempert proposed an even simpler proof, using (pluri)subharmonic variation of Bergman kernels from Maitani and Yamaguchi [2004], Berndtsson [2006], that we shall now describe (see Błocki [2015], Berndtsson and Lempert [2016]).

Let for $t \leq 0$,

$$D_t = \{z \in D; G(z) < t\},$$

and $B_t(0)$ be the Bergman kernel for D_t. Since

$$\mathfrak{D} := \{(\tau, z) \in \mathbb{C} \times D; G(z) - \operatorname{Re} \tau < 0\}$$

is a pseudoconvex domain in $\mathbb{C}^2$, and $D_t = \mathfrak{D}_\tau$, the vertical slice of $\mathfrak{D}$, if $t = \operatorname{Re} \tau$, it follows from Maitani and Yamaguchi [2004], Berndtsson [2006] (cf Theorem 2.4) that $\log B_t(0)$ is convex. When t approaches $-\infty$, D_t is very close to a disk centered at the origin with radius $e^{(t+c_D)/2}$, so

$$B_t \sim \frac{e^{-t-c_D}}{\pi}.$$

In particular, the function

$$k(t) := \log B_t(0) + t$$

is convex and bounded on the negative half axis. Therefore, it must be increasing. Hence

$$B(0) = e^{k(0)} \geq \lim_{t \to -\infty} e^{k(t)} = \frac{e^{-c_D}}{\pi},$$

which proves Suita's conjecture.

It is clear that similar proofs work in higher dimensions and also for weighted Bergman spaces with a plurisubharmonic weight function. The main new observation in Berndtsson and Lempert [2016] is that the same technique can be used to give a proof of the Ohsawa-Takegoshi extension theorem, Ohsawa and Takegoshi [1987].

We first recall a simple version of this important result. We let D be a bounded pseudoconvex domain in $\mathbb{C}^n$ and ϕ a plurisubharmonic function in D. Let V be a linear subspace of $\mathbb{C}^n$ of codimension m which intersects D. The Ohsawa-Takegoshi theorem says that in this situation (and actually under much more general conditions), for any holomorphic function f on $V \cap D$, there is a holomorphic function F in D, such that $f = F$ on V and

$$\int_D |F|^2 e^{-\phi} d\lambda_n \leq C \int_{V\cap D} |f|^2 e^{-\phi} d\lambda_{n-m},$$

where C is a constant depending only on the diameter of D. What makes this theorem so powerful is that even though there is no assumption of strict plurisubharmonicity or smoothness, we get an estimate with an absolute constant. Note that, when V is just a point, we get the existence of a function F in D with good L^2-estimates and prescribed value at the origin; this is equivalent to an estimate for the Bergman kernel.

Just as in Suita's conjecture, one can now ask for optimal estimates. Such estimates were given in Błocki [2013] and more generally by Guan and Zhou [2015]. We shall now see that results of this type also follow from Theorem 2.3. We also point out that, conversely, Guan and Zhou show that results along the line of Theorem 2.3 and Theorem 2.5 follow from sharp versions of the Ohsawa-Takegoshi extension theorem, so in very general terms the two types of results are perhaps 'equivalent'.

Write for z in $\mathbb{C}^n$, $z = (z_1, ...z_m, z_{m+1}, ...z_n) = (z', z'')$, and say that V is defined by the equation $z' = 0$. Let

$$G(z) = \log |z'|^2,$$

and let

$$D_t = \{z \in D; G(z) < t\}.$$

We may assume that $|z'| \leq 1$ in D. For each $t \in (-\infty, 0)$ we let F_t be the extension of f to D_t of minimal norm. Such a minimal element exists by general Hilberts space theory. The following result is not explicitly stated in Berndtsson and Lempert [2016], but implicitly contained there.

Proposition 3.1.

$$e^{-mt}\|F_t\|_t^2 = e^{-mt} \int_{D_t} |F_t|^2 e^{-\phi} d\lambda$$

is a decreasing function of t.

It follows that

$$\|F_0\|^2 \leq \lim_{t\to-\infty} e^{-mt}\|F_t\|_t^2.$$

It is not hard to see that the last limit equals (with σ_m the volume of the m-dimensional unit ball)

$$\sigma_m \int_{V\cap D} |f|^2 e^{\phi} d\lambda_{n-m},$$

at least when ϕ is smooth in a neighbourhood of the closure of D. This gives the sharp extension theorem in this setting, and the general case is obtained by the usual approximation procedures.

Proposition 3.1 can be proved much like the Suita conjecture, but using the general Theorem 2.3 instead of plurisubharmonic variation of Bergman kernels. First note that since any function f on $V \cap D$ extends to D, the space of holomorphic functions on $V \cap D$ can be identified with the quotient space $H(D)/J(V)$, or $H(D_t)/J(V)$, where $J(V)$ is the subspace of functions that vanish on V. The quantity that we want to estimate, $\|F_t\|_t$, is the norm of f in $A^2(D_t)/J(V)$. The space of measures with compact support in $V \cap D$ is dense in the dual of $H(D_t)/J(V)$. We first prove a dual estimate on such measures:

$$\|\mu\|_t^2 e^{mt}$$

is increasing, with

$$\|\mu\|_t^2 = \sup_F \frac{|\int F d\mu|^2}{\int_{D_t} |F|^2 e^{-\phi} d\lambda}.$$

This is proved in almost exactly the same way as in the Suita case, when V is a point, and Proposition 3.1 follows.

4 The space of Kähler metrics

In this section we will look at fibrations with $X = Z \times U$ where Z is a compact complex manifold, U is a domain in $\mathbb{C}$ and $p : X \to U$ is the projecion on the second factor. We also assume given a complex line bundle, L over Z. Pulling it back to X by the projection on the first factor we get a line bundle over X, that we denote by the same letter, sometimes writing $L \to X$ or $L \to Z$, to make the meaning clear. Mostly we assume that $L \to Z$ is positive, in the sense that it has some smooth metric of positive curvature, but we don't fix any metric – instead we will use this set up to study the space M_L of positively curved metrics on L.

Here all the fibers $X_t = Z$ are the same and the line bundles $L|_{X_t}$ are also the same. A metric on $L \to X$ can be interpreted as a complex curve of metrics on L, parametrized by τ in U. Of particular interest for us is the case when $U = \{\tau \in \mathbb{C}; 0 < \operatorname{Re}\tau < 1\}$ is a strip and ϕ only depends on the real part of τ; then we can interpret ϕ as a real curve in M_L.

The space M_L was introduced by Mabuchi [1987]. It is an open subset of an affine space modeled on $C^\infty(Z)$, therefore the tangent space of M_L at any point ϕ is naturally identified with $C^\infty(Z)$. Mabuchi defined a Riemannian structure on M_L by

$$\|\chi\|_\phi^2 := \int_Z |\chi|^2 \omega_\phi^n,$$

for $\chi \in C^\infty(Z)$, with $\omega_\phi := i\partial\bar\partial\phi$, see also Semmes [1988] and S. K. Donaldson [1999]. As proved in these papers, a curve in M_L, i.e. a metric on L depending only on $t = \operatorname{Re}\tau$

is a geodesic for the Riemannian metric if and only if $i\partial\bar\partial\phi \geq 0$ on X, and it satisfies the homogenous complex Monge-Ampère equation

$$(i\partial\bar\partial\phi)^{n+1} = 0.$$

In our terminology in Section 2, this means that $c(\phi) = 0$, and in general, $c(\phi)$ can be interpreted as the geodesic curvature of the curve. Since honest geodesics are scarce, see Lempert and Vivas [2013], Darvas and Lempert [2012], Ross and Nyström [2015], Ross and Nyström [n.d.] for problems encountered in solving the homogenous complex Monge-Ampère equation involved, we will also use 'generalized geodesics'. These are metrics on L as above that are only assumed to be locally bounded, such that $i\partial\bar\partial\phi \geq 0$ and $(i\partial\bar\partial\phi)^{n+1} = 0$ in the sense of pluipotential theory (Bedford and Taylor [1976]). It is easy to see (Berndtsson [2011]) that any two metrics in M_L can be connected with a generalized geodesic in this sense, and by a famous result of Chen [2000b], Janeczko [1996], the geodesic has in fact higher regularity, so that $\partial\bar\partial\phi$ is a current with bounded coefficients. We will say that such geodesics are of class $C^{(1,1)}$. There is by now an extensive theory on these matters, for which we refer to Mabuchi [1987], Semmes [1988], S. K. Donaldson [1999], Phong and Sturm [2009] and S. K. Donaldson [2005].

We first consider the case when $L = -K_Z$ is the anticanonical bundle of Z. The positivity of L then means that Z is a Fano manifold. The fibers of the vector bundle E, defined in Section 2,

$$E_\tau = H^0(X_\tau, K_{X_\tau} + L) = H^0(Z, \mathbb{C})$$

are then just the space of constant functions on Z (so E is a line bundle). A metric $e^{-\phi}$ on $L \to Z$ can be identified with a volume form on Z that we also denote $e^{-\phi}$, and with this somewhat abusive notation we have for the element '1' in $H^0(Z, \mathbb{C})$,

$$\|1\|^2_\phi = \int_Z e^{-\phi}.$$

We are therefore in the situation described in the introduction when E is a line bundle with a nonvanishing section. Therefore we get a Prékopa type theorem for Fano manifolds.

Theorem 4.1. *(Berndtsson [2015]) Let $e^{-\phi}$ be a locally bounded metric on $L \to Z \times U$, where $L \to Z$ is the anticanonical bundle of Z. Assume that U is a strip and that ϕ depends only on the real part of $\tau \in U$. Suppose also that $i\partial\bar\partial\phi \geq 0$ in the sense of currents. Let*

$$\tilde\phi(t) = -\log \int_Z e^{-\phi(t,\cdot)}.$$

Then $\tilde\phi$ is a convex function of t. If $\tilde\phi$ is linear, then there is a holomorphic vector field V on U, which is a lift of $\partial/\partial\tau$ on U, whose flow maps fibers X_τ to fibers and $i\partial\bar\partial\phi|_{X_\tau}$ to $i\partial\bar\partial\phi|_{X_\tau}$.

When ϕ is smooth the first part of the theorem follows immediately from Theorem 2.5, and the general case is easily obtained by approximation. The second part is clearly of the same vein as Corollary 2.7, but it does not follow directly from there because of the lack of smoothness and strict positivity.

The main interest of this result lies in its connection with Kähler-Einstein metrics. To explain this we also need to introduce the Monge-Ampère energy, $\mathcal{E}(\phi)$, of a metric. This is a real valued function on M_L, which can be defined (up to a constant) by the property that for any curve $t \to \phi_t \in M_L$,

$$\frac{d}{dt}\mathcal{E}(\phi_t) = \frac{1}{Vol(L)} \int_Z \dot{\phi}_t \omega_{\phi_t}^n / n!,$$

where $\dot{\phi} = d\phi/dt$ and the volume of the line bundle is

$$Vol(L) := \int_Z \omega_\phi^n / n!$$

(it does not depend on the metric). One then defines the Ding functional, Ding [1988], as

$$D(\phi) := \log \int_Z e^{-\phi} + \mathcal{E}(\phi).$$

The critical points of the Ding functional are the metrics that satisfy

$$e^{-\phi} = C\omega_\phi^n.$$

This means precisely that the Ricci curvature of the Kähler metric ω_ϕ equals ω_ϕ, i.e. that ω_ϕ is a Kähler-Einstein metric (of positive curvature). It is well known that the Monge-Ampère energy is linear along (even generalized) geodesics, so the Ding functional is linear along a geodesic precisely when its first term

$$t \to \log \int_Z e^{-\phi_t}$$

is linear. As noted by Berman [n.d.], this gives a proof of the Bando-Mabuchi uniqueness theorem (Bando and Mabuchi [1987]), for Kähler-Einstein metrics on Fano manifolds. Indeed, suppose $e^{-\phi_0}$ and $e^{-\phi_1}$ are metrics on the anticanonical bundle of Z, and that $i\partial\bar{\partial}\phi_0$ and $i\partial\bar{\partial}\phi_1$ are both Kähler-Einstein. Connect them by a generalized geodesic. Since both endpoints are critical points for the Ding functional, and the Ding functional is concave along the geodesic, it must in fact be linear. Then Theorem 4.1 implies that ω_{ϕ_0} and ω_{ϕ_1} are connected via the flow of a holomorphic vector field, i.e. an element in the identity component of the automorphism group. This is the Bando-Mabuchi theorem.

As also noted by Berman [n.d.], similar arguments prove a variant of the Moser-Trudinger-Onofri inequality (Moser [1970/71], Onofri [1982]) for Kähler-Einstein Fano manifolds (the original case of the theorem was for Z equal to the Riemann sphere). The (variant of) the theorem says, in our terminology, that Kähler-Einstein metrics are global maxima for the Ding functional on the space of all positively curved metrics, which is clear from the concavity, since Kähler-Einstein metrics are critical points. The original version of the theorem, for the Riemann sphere, deals with metrics that are not necessarily positively curved, but as shown by Berman, this follows in one dimension from the positively curved case by an elegant trick.

The formalism described here can easily be generalized. We fix a metric $e^{-\psi}$ on a pseudoeffective $\mathbb{R}$-line bundle L' and study metrics $e^{-\phi}$ on an $\mathbb{R}$-line bundle L'', such that $L' + L'' = L = -K_Z$. With this we define the twisted Ding functional

$$D_\psi(\phi) := \log \int_Z e^{-\phi-\psi} + \mathcal{E}(\phi),$$

where $\mathrm{Vol}(L)$ is replaced by $\mathrm{Vol}(L'')$ in the definition of $\mathcal{E}$. The critical points of D_ψ satisfy

$$e^{-\phi-\psi} = C\omega_\phi^n.$$

Hence the Ricci curvature of ω_ϕ satisfies

$$Ric(\omega_\phi) = \omega_\phi + i\partial\bar\partial\psi,$$

so ω_ϕ is a 'twisted Kähler-Einstein metric'. It is clear that if ψ is assumed to be bounded, the same argument as before gives uniqueness modulo automorphisms, but actually the argument can be generalized to when $i\partial\bar\partial\psi = \beta[\Delta]$ is a multiple of a current defined by a divisor in Z. This leads to a uniqueness theorem for Kähler-Einstein metrics with conical singularities, introduced by S. K. Donaldson [2012], as a tool for the solution of the Yau-Tian-Donaldson conjecture, see Chen, S. Donaldson, and S. Sun [2014] and subsequent papers. In these papers it was also shown that this generalized version of Theorem 4.1 can be used to prove reductivity of the group of automorphisms of the pair (Z, Δ). Furthermore, the theorem was generalized to 'log-Fano' manifolds, that arise naturally in this context, in Eyssidieux, Guedj, and Zeriahi [2009]. In this context, see also Berman [2016] for applications to the converse direction of the Yau-Tian-Donaldson conjecture.

So far we have discussed only the case when L is the anticanonical bundle of Z, and the resulting convexity preperties of the Ding functional, but it turns out that the formalism is also useful in connection with other functionals in Kähler geometry. A case in point is the Mabuchi K-energy, Mabuchi [1986], $\mathfrak{M}$. The K-energy of a metric $e^{-\phi}$ on a positive line bundle L can be defined (again up to a constant) by

$$\frac{d}{dt}\mathfrak{M}(\phi_t) = \int_Z \dot{\phi}(S_\phi - \hat{S}_\phi)\omega_\phi^n/n!,$$

where $t \to \phi_t$ is any smooth curve in M_L, S_ϕ is the scalar curvature of the Kähler metric ω_ϕ, and $\hat{S}_\phi$ is the average of S_ϕ over Z. The raison d'être of $\mathfrak{M}$ is that its critical points are precisely (the potentials of) the metrics of constant scalar curvature. It was proved by Mabuchi [1986], that $\mathfrak{M}$ is convex along smooth geodesics, but, again, in applications there is a need to consider also generalized geodesics. It was proved by Chen [2000a], that the K-energy can be defined along any generalized geodesic of class $C^{(1,1)}$, which is crucial since any two points in the space can be connected by such geodesics. (For this, he rewrites the definition of $\mathfrak{M}$ since the original definition involves four derivatives of ϕ.) Chen also conjectured that $\mathfrak{M}$ would be convex along any generalized geodesic of class $C^{(1,1)}$. This was proved in a joint paper with Berman and Berndtsson [2017].

Theorem 4.2. *The Mabuchi K-energy is convex along any generalized geodesic of class $C^{(1,1)}$.*

(An alternative proof was later given in Chen, Li, and Păuni [2016].) Using this we proved the uniqueness of metrics of constant scalar curvature up to flows of holomorphic vector fields:

Theorem 4.3. *Let Z be a compact manifold and $L \to Z$ a positive line bundle. Let ω_0 and ω_1 be two Kähler metrics on of constant scalar curvature in $c_1[L]$. Then there is a holomorphic vector field on Z, with time 1 flow F, such that $F^*(\omega_1) = \omega_0$.*

Uniqueness was proved earlier, in case Z has discrete automorphism group in S. K. Donaldson [2001]. Our result is in fact more general; it treats not only metrics of constant scalar curvature, but general 'extremal metrics', and does not assume that the cohomology class of the metrics is integral. For this, and a discussion of previous work, we refer to Berman and Berndtsson [2017].

5 Variation of complex structure

In this section we will mainly consider families of canonically polarized manifolds. We assume that $p : X \to U$ is a smooth proper fibration, that U is a domain in $\mathbb{C}$, and that the fibers X_t have positive canonical bundle. In this setting, X is automatically Kähler, since we may find a smooth metric $e^{-\psi}$ on $K_{X/U}$ which is positively curved on fibers, and take a Kähler form as $i\partial\bar{\partial}\psi + p^*(\omega)$ where ω is sufficiently positive on the base. Hence the results from Section 2 apply.

By the Aubin-Yau theorem, S. T. Yau [1978], Aubin [1982], each fiber has a unique Kähler-Einstein metric (now with Ricci curvature equal to -1). This metric can be written

$$\omega = i\partial\bar\partial\phi,$$

where $e^{-\phi}$ is a metric on the canonical bundle. Then e^{ϕ} is a metric on the anticanonical bundle, which as in the previous section can be identified with a volume form, and the metric is unique if we normalize so that

$$e^{\phi} = (\omega_\phi)^n/n!.$$

Applying this to each fiber X_t we get a metric on the relative canonical bundle $K_{X/U}$ that we also denote by $e^{-\phi}$. An important theorem of Schumacher [2012] implies that $i\partial\bar\partial\phi$ is semipositively curved not only along the fibers, but on the total space:

Theorem 5.1. *If $e^{-\phi}$ is the normalized Kähler-Einstein potential described above, and $c(\phi)$ is defined as in Section 2, then*

$$\Box c(\phi) + c(\phi) = |\kappa_\phi|^2$$

on each fiber. As a consequence, $c(\phi)$ is semipositive and strictly positive on each fiber where κ_ϕ does not vanish identically.

Here $\Box = \bar\partial^*\bar\partial$ is the Laplace operator on functions on a fiber, for the Kähler metric $\omega_\phi|_{X_t}$, and κ_ϕ, as defined as in Section 2 turns out to be the harmonic representative of the Kodaira-Spencer class. The non negativity part of the statement follows immediately from the differential equation, since $\Box c(\phi) \leq 0$ at a minimum point, and the strict positivity part is also a well known property of elliptic equations. Since $i\partial\bar\partial\phi > 0$ along the fibers, the positivity of $c(\phi)$ implies that $i\partial\bar\partial\phi$ is positive on the total space.

This result can be seen as an analog of Theorem 2.8, when L is trivial or a power of the relative canonical bundle. Indeed, that theorem says the Bergman kernel defines a semipositive metric on the relative canonical bundle, at least if it is not identically zero. Tsuji [2010], independently proved the semipositivity part of Theorem 5.1, using Theorem 2.8 and iteration:

Theorem 5.2. *Let X be a family of canonically polarized manifolds. For any sufficiently positive line bundle $(L, e^{-\psi})$ on X, let $e^{-s(\psi)}$ be the Bergman kernel metric on $K_{X/U}+L$. Define iteratively a sequence of metrics $h_m = e^{-s^m(\psi)}$ on $mK_{X/U} + L$ in this way. Then an appropriate renormalization of $h_m^{1/m}$ tends to the metric on $K_{X/U}$ defined by the Kähler-Einstein potentials.*

Since all the metrics in the iteration have semipositive curvature by Theorem 2.8, this gives a different proof of the semipositivity part of Theorem 5.1. Tsuji also applied these arguments to situations when we assume much less positivity along the fibers.

Both Schumacher's theorem and Theorem 2.8 give some positivity of $K_{X/Y}$ under assumptions of fiberwise positivity. Schumacher's theorem was generalized by Paun [n.d.], to twisted relative canonical bundles, and even to general adjoint classes, not necessarily integral. He also applied this result to solve a long standing conjecture about the surjectivity of the Albanese map for compact Kähler manifolds with nef anticanonical bundle.

Theorem 5.3. *Let $p : X \to Y$ be a holomorphic surjective map between compact Kähler manifolds. Let β be a semipositive closed $(1,1)$-form on on X and assume that the cohomology class $c_1[K_{X/Y}] + [\beta]$ contains a $(1,1)$-form Ω which is strictly positive on all fibers X_y, for y outside a proper analytic subset, Y_0, of Y. Then $c_1[K_{X/Y}] + \beta$ contains a closed semipositive current, which is smooth outside $p^{-1}(Y_0)$.*

Let us now consider the particular case of a fibration $p : X \to U$ where the fibers are Riemann surfaces of a certain genus $g \geq 2$. If we choose $L = K_{X/U}$, our vector bundle E with fibers

$$E_t = H^{1,0}(X_t, K_{X/Y}) = H^0(X_t, 2K_{X/U})$$

is the dual of the bundle with fibers

$$E_t^* = H^{0,1}(X_t, T^{1,0}(X_t)),$$

which is the space of infinitesimal deformations of the complex structure on X_t. Any positively curved metric on E therefore induces a negatively curved metric on the space of deformations (along U). In particular, taking the L^2-metric on E, defined by the metric on $K_{X/U}$ given by the Kähler-Einstein potentials, $e^{-\phi}$, we get the Weil-Peterson metric on U. By Schumacher's theorem, $e^{-\phi}$ is (semi)positively curved on X, so we get the classical fact that the Weil-Peterson metric has seminegative curvature, and negative curvature where the Kodaira-Spencer class does not vanish, Ahlfors [1961/1962], Royden [1975], Wolpert [1986]. Moreover, from Theorem 2.6, we get an explicit formula for the curvature. Using Schumacher's theorem again (now the differential equation for $c(\phi)$), we can rewrite the formula so that it coincides with the formula found by Wolpert [ibid.], see Berndtsson [2011]. The same argument works when U has higher dimension, and then Theorem 2.5 shows that the Weil-Peterson metric has dual Nakano-negative curvature, cf Liu, X. Sun, and S.-T. Yau [2009]. This is stronger than negative bisectional curvature, which corresponds to Griffiths negativity.

The case of families of higher dimensional canonically polarized manifolds is significantly more complicated. We are then primarily interested in vector bundles $\mathcal{H}^{1,n-1}$ with fibers

$$H^{1,n-1}(X_t, K_{X/U})$$

and their positivity properties. The reason for this is that the dual of $H^{1,n-1}(X_t, K_{X/U}) = H^{n,n-1}(X_t, (T^*)^{1,0}(X_t))$ is $H^{0,1}(X_t, T^{1,0})$, the space of infinitesimal deformations of the complex structure on X_t. The Kodaira-Spencer map sends the tangent bundle of U into this space, and therefore any metric on $\mathcal{H}^{1,n-1}$ induces a metric on the base. The Weil-Peterson metric on the base (which can be obtained this way) was first studied by Siu [1986], who found an explicit formula for its curvature. This was generalized by Schumacher [2012], who found a curvature formula for the bundle $\mathcal{H}^{1,n-1}$ and also for the other higher direct image bundles $\mathcal{H}^{p,q}$, with $p+q = n$. Both Siu's and Schumacher's formulas contain terms that give an apparent positive contribution to the curvature of the Weil-Peterson metric, but as shown in Schumacher [ibid.] and To and Yeung [2015], the metrics on all the higher direct images bundles can be combined to give a Finsler metric of strictly negative sectional curvature that can partly substitute for the Weil-Peterson metric.

All these works focus on the relative canonical bundle and the metric on it given by the Kähler-Einstein potential, and in the case of one dimensional fibers they are special cases Theorem 2.6. The generalization to general line bundles L with metrics of fiberwise positive curvature was obtained in Naumann [n.d.] and Berndtsson, Paun, and Wang [n.d.]. In Berndtsson, Paun, and Wang [ibid.], the formalism was also extended to families of Calabi-Yau manifolds (where related results have also been announced by To and Yeung). Finally, we also mention that, building on work by Lu [2001], Wang [n.d.], has found a different approach to these problems, which so far works for Calabi-Yau families and then produces a Hermitian version of the Weil-Peterson metric, with negative bisectional curvature. The main idea is to embed the tangent bundle of U, not in the dual of $\mathcal{H}^{1,n-1}$ as above, but in the endomorphism bundle of the sum of all the $\mathcal{H}^{p,q}$.

6 Positivity of direct image sheaves

We shall finally discuss extensions of Theorem 2.5 under less restrictive assumptions. Let $p : X \to Y$ be a surjective holomorphic map between two projective varieties, and let $L \to X$ be a holomorphic line bundle equipped with a singular metric $e^{-\phi}$ with semi-positive curvature current $i\partial\bar{\partial}\phi \geq 0$. The 'multiplier ideal sheaf' $\mathcal{I}(\phi)$ is the sheaf of holomorphic functions on X that are square integrable against $e^{-\phi}$. The first problem is that under these general circumstances we no longer get a vector bundle on the base. The role of the vector bundle E is instead played by the (zeroth) direct image sheaf,

$$\mathcal{E} := p_*((K_{X/Y} + L) \otimes \mathcal{I}(\phi)).$$

$\mathcal{E}$ is a sheaf over Y whose sections over an open set U in the base are the sections of $(K_{X/Y} + L) \otimes \mathcal{I}(\phi)$ over $p^{-1}(U)$. By a classical theorem of Grauert, $\mathcal{E}$ is coherent and it is also torsion free. The consequence of this that we will use is that it is locally free outside of a subvariety, Y_0, of Y of codimension at least two. This means that outside of Y_0, $\mathcal{E}$ is the sheaf of sections of a vector bundle E. In the setting of Theorem 2.5, Y_0 is empty and $\mathcal{E}$ coincides with the sheaf of sections of E as defined there. In general, let Y_1 be a proper subvariety of Y such that p is a submersion outside $p^{-1}(Y_1)$. We can now define a L^2-metric on E over $p^{-1}(Y \setminus (Y_0 \cup Y_1))$ as we did when $e^{-\phi}$ was assumed to be smooth. The new feature that appears is that this is now a singular metric. For singular metrics on a vector bundle it seems impossible to define positivity and negativity in terms of a curvature current (cf Raufi [2015]), but we can circumvent this problem in a way similar to what we did in Theorem 2.3: We say that a singular metric is negatively curved if the logarithm of the norm of any holomorphic section is plurisubharmonic, and it is positively curved if the dual is negative (cf Berndtsson and Păun [2008]).

Paun and Takayama extended the notion of singular metrics on vector bundles to the setting of coherent, torsion free sheaves. The definition is simply that a singular metric on such a sheaf is a singular metric on the vector bundle defined by the sheaf outside of Y_0. Since negativity (and positivity) of the curvature is defined in terms of plurisubharmonic functions, and since plurisubharmonic functions extend over varieties of codimension at least 2, it turns out that this is a useful definition. Given all this, we have the following theorem of Păun and Takayama [n.d.], and Hacon, Popa, and Schnell [n.d.], which seems to be the most general theorem on (metric) positivity of direct images.

Theorem 6.1. *The L^2-metric on $E = p_*((K_{X/Y} + L) \otimes \mathcal{I}(\phi))$ over the complement of $Y_0 \cup Y_1$ extends to a (singular) metric of nonnegative curvature on the coherent and torsion free sheaf $\mathcal{E}$.*

(Paun and Takayama proved this when $\mathcal{I}(\phi)$ is trivial on a generic fiber.) The next theorem is also due to Paun and Takayama:

Theorem 6.2. *Any coherent torsion free sheaf which has a (singular) metric of nonnegative curvature is weakly positive in the sense of Viehweg [1995]. Hence, by Theorem 6.1,*

$$\mathcal{E} := p_*((K_{X/Y} + L) \otimes \mathcal{I}(\phi))$$

is weakly positive.

In very general terms, the notion of 'positivity' in algebraic geometry, is often given in terms of the existence of certain holomorphic or algebraic objects. Thus, e. g. the positivity of a line bundle means that a high power of it has enough sections to give an embedding into projective space. Similarily, Viehweg's weak positivity of a sheaf $\mathcal{F}$ means that certain associated sheaves are generated by global sections. From the analytic point of view, the existence of such sections should be a consequence of the metric positivity of curvature, and the previous theorem gives a very general version of this. We will not go into more details on these matters or give the exact definition of positivity in the sense of Viehweg – it would require another article (and another author.)

Instead we end by a major application of these results, due to Cao and Păun [2017].

Theorem 6.3. *Let $p : X \to A$ be a surjective holomorphic map, where X is smooth projective and A is an Abelian variety. Then we have the inequality for the Kodaira dimensions of X and a generic fiber, F,*

$$\kappa(X) \geq \kappa(F).$$

This proves the case of the famous 'Itaka conjecture', $\kappa(X) \geq \kappa(F) + \kappa(Y)$, when Y is an Abelian variety (and hence has Kodaira dimension zero). For a simplification of the proof and a generalization of the result we refer to Hacon, Popa, and Schnell [n.d.], which is also a beautiful survey of the field.

CANNON–THURSTON MAPS

Mahan Mj

Abstract

We give an overview of the theory of Cannon-Thurston maps which forms one of the links between the complex analytic and hyperbolic geometric study of Kleinian groups. We also briefly sketch connections to hyperbolic subgroups of hyperbolic groups and end with some open questions.

1 Kleinian groups and limit sets

The Lie group $PSL_2(\mathbb{C})$ can be viewed from three different points of view:

1. As a Lie group or a matrix group (**group-theoretic**).
2. As the isometry group of hyperbolic 3-space $\mathbf{H}^3$–the upper half space $\{(x, y, z) : z > 0\}$ equipped with the metric $ds^2 = \frac{dx^2+dy^2+dz^2}{z^2}$, or equivalently the open ball $\{(x, y, z) : (x^2 + y^2 + z^2) = r^2 < 1\}$ equipped with the metric $ds^2 = \frac{4(dx^2+dy^2+dz^2)}{(1-r^2)^2}$ (**geometric**).
3. As the group of Möbius transformations of the Riemann sphere $\hat{\mathbb{C}}$ (**complex dynamic/analytic**).

A finitely generated discrete subgroup $\Gamma \subset PSL_2(\mathbb{C})$ is called a *Kleinian group*. Depending on how we decide to look at $PSL_2(\mathbb{C})$, the group Γ can accordingly be thought of as a discrete subgroup of a Lie group, as the fundamental group of the complete hyperbolic 3-manifold $\mathbf{H}^3/\Gamma$, or in terms of its action by holomorphic automorphisms of $\hat{\mathbb{C}}$. If Γ is not virtually abelian, it is called *non-elementary*. Henceforth, unless explicitly stated otherwise, we shall assume that *all Kleinian groups in this article are non-elementary*. If Γ can be conjugated by an element of $PSL_2(\mathbb{C})$ to be contained in $PSL_2(\mathbb{R})$ it is referred

Research partly supported by a DST JC Bose Fellowship.
MSC2010: primary 57M50; secondary 30F40, 20F65, 20F67.

to as a *Fuchsian group*[1]. If Γ is abstractly isomorphic to $\pi_1(S)$, the fundamental group of a closed surface S, we shall refer to it as a *surface Kleinian group*.

In the 1960's Ahlfors and Bers studied deformations of Fuchsian surface groups in $PSL_2(\mathbb{C})$, giving rise to the theory of quasi-Fuchsian groups. Their techniques were largely complex analytic in nature. In the 1970's and 80's, the field was revolutionized by Thurston, who brought in a rich and varied set of techniques from three-dimensional hyperbolic geometry. A conjectural picture of the deep relationships between the analytic and geometric points of view was outlined by Thurston in his visionary paper Thurston [1982]. Perhaps the most well-known problem (predating Thurston) in this line of study was the Ahlfors' measure zero conjecture, resolved in the last decade by Brock-Canary-Minsky Brock, Canary, and Y. N. Minsky [2012]. Another (more topological) well-known problem that also predates Thurston asks if limit sets of Kleinian groups are locally connected. This is the specific problem that will concern us here. We need to fix some terminology and notation first. Identify the Riemann sphere $\hat{\mathbb{C}}$ with the sphere at infinity S^2 of $\mathbf{H}^3$. Thus, S^2 encodes the 'ideal' boundary of $\mathbb{H}^3$, consisting of asymptote classes of geodesics. By adjoining S^2 to $\mathbf{H}^3$, we obtain the closed 3-ball $\mathbf{D}^3$. The topology on S^2 is the usual one induced by the round metric given by the angle subtended at the origin $0 \in \mathbf{D}^3$. The geodesics turn out to be semicircles meeting the boundary S^2 at right angles.

Definition 1.1. *The* limit set Λ_Γ *of the Kleinian group* Γ *is the collection of accumulation points of a* Γ*-orbit* $\Gamma \cdot z$ *for some (any)* $z \in \hat{\mathbb{C}}$.

The limit set Λ_Γ is independent of z and may be regarded as the locus of chaotic dynamics of Γ on $\hat{\mathbb{C}}$. For non-elementary Γ and any $z \in \Lambda_\Gamma$, $\Gamma \cdot z$ is dense in Λ_Γ. Hence Λ_Γ is the smallest closed non-empty $\Gamma-$invariant subset of $\hat{\mathbb{C}}$. If we take $z \in \mathbf{H}^3$ instead, then the collection of accumulation points of any Γ-orbit $\Gamma \cdot z \subset \mathbf{D}^3$ is also Λ_Γ.

Definition 1.2. *The complement of the limit set* $\hat{\mathbb{C}} \setminus \Lambda_\Gamma$ *is called the domain of discontinuity* Ω_Γ *of* Γ.

The Kleinian group Γ acts freely and properly discontinuously on Ω_Γ and Ω_Γ/Γ is a (possibly disconnected) Riemann surface.

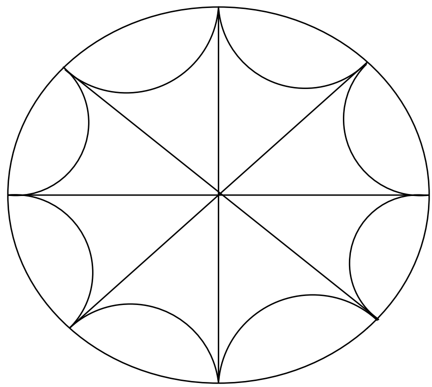
1.1 Fuchsian and Quasi-Fuchsian Groups.

We first give an explicit example of a Fuchsian group.

An example of a Fuchsian group: Consider the standard identification space description of the genus two orientable surface Σ_2 as an octagon with edge labels $a_1, b_1, a_1^{-1}, b_1^{-1}, a_2, b_2, a_2^{-1}, b_2^{-1}$. A hyperbolic metric on Σ_2 is one where each point has a small neighborhood isometric to a small disk in $\mathbf{H}^2$. By the Poincaré polygon theorem, it suffices to find a

[1]Both Fuchsian and Kleinian groups were discovered by Poincaré.

regular hyperbolic octagon (with all sides equal and all angles equal) with each interior angle equal to $\frac{2\pi}{8}$. Now, the infinitesimal regular octagon at the tangent space to the origin has interior angles equal to $\frac{3\pi}{4}$. Also the ideal regular octagon in $\mathbb{H}^2$ has all interior angles zero. See figure below.



By the Intermediate Value Theorem, there exists an intermediate regular octagon with all interior angles equal to $\frac{\pi}{4}$. The group G that results from side-pairing transformations corresponds to a Fuchsian group, or equivalently, a discrete faithful representation ρ of $\pi_1(\Sigma_2)$ into $PSL_2(\mathbb{R})$. Equivalently we may regard ρ as a representation of $\pi_1(\Sigma_2)$ into $PSL_2(\mathbb{C})$ with image that can be conjugated to lie in $PSL_2(\mathbb{R})$. Alternately, $\rho(\pi_1(\Sigma_2))$ preserves a totally geodesic plane in $\mathbf{H}^3$. The limit set of $G = \rho(\pi_1(\Sigma_2))$ is then a round circle.

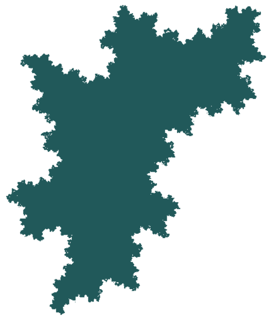
Quasi-Fuchsian groups: If we require the limit set to be only topologically a circle, i.e. a Jordan curve, then we obtain a more general class of Kleinian groups:

Definition 1.3. *Let $\rho : \pi_1(S) \to PSL_2(\mathbb{C})$ be a discrete faithful representation such that the limit set of $G = \rho(\pi_1(S))$ is a Jordan curve in S^2. Then G is said to be* quasi-Fuchsian. *The collection of conjugacy classes of quasi-Fuchsian with the complex analytic structure inherited from $PSL_2(\mathbb{C})$ is denoted as $QF(S)$.*

The domain of discontinuity Ω of a quasi-Fuchsian G consists of two open invariant topological disks Ω_1, Ω_2 in $\hat{\mathbb{C}}$. Hence the quotient Ω/G is the disjoint union $\Omega_1/G \sqcup \Omega_2/G$ and we have a map $\tau : QF(S) \to Teich(S) \times Teich(S)$, where $Teich(S)$ denotes the Teichmüller space of S–the space of marked hyperbolic (or complex) structures on S. The *Bers simultaneous Uniformization Theorem* asserts:

Theorem 1.4. *$\tau : QF(S) \to Teich(S) \times Teich(S)$ is bi-holomorphic.*

Thus, given any two conformal structures T_1, T_2 on a surface, there is a unique discrete quasi-Fuchsian G (up to conjugacy) whose limit set Λ_G is topologically a circle, and the quotient of whose domain of discontinuity is $T_1 \sqcup T_2$. See figure below Kabaya [2016], where the inside and the outside of the Jordan curve correspond to Ω_1, Ω_2.



1.2 Degenerate groups and the Ending Lamination Theorem. Quasi-Fuchsian were studied by Ahlfors and Bers analytically as deformations of Fuchsian groups. Thurston [1980] introduced a new set of geometric techniques in the study.

Definition 1.5. *The* convex hull CH_G *of* Λ_G *is the smallest non-empty closed convex subset of* $\mathbb{H}^3$ *invariant under* G.

Let $M = \mathbf{H}^3/G$. *The quotient of* CH_G *by* G *is called the convex core* $CC(M)$ *of* M.

The convex hull CH_G can be constructed by joining all distinct pairs of points on Λ_G by bi-infinite geodesics, iterating this construction and finally taking the closure. It can also be described as the closure of the union of all ideal tetrahedra, whose vertices lie in Λ_G. The convex core $CC(M)$ is homeomorphic to $S \times [0,1]$.

The distance between the boundary components $S \times \{0\}$ and $S \times \{1\}$ in the convex core $CC(M)$, measured with respect to the hyperbolic metric, is a crude geometric measure of the complexity of the quasi Fuchsian group G. We shall call it the *thickness* t_G of $CC(M)$, or of the quasi Fuchsian group G. (We note here parenthetically that the notions of convex hull CH_G and convex core $CC(M)$ go through for any Kleinian group G and the associated complete hyperbolic manifold $\mathbf{H}^3/G$.) For quasi-Fuchsian groups, we ask:

Question 1.6. *What happens as thickness tends to infinity?*

To address this question more precisely we need to introduce a topology on the space of representations.

Definition 1.7. *A sequence of representations $\rho_n : \pi_1(S) \to PSL_2(\mathbb{C})$ is said to converge* algebraically *to $\rho_\infty : \pi_1(S) \to PSL_2(\mathbb{C})$ if for all $g \in \pi_1(S)$, $\rho_n(g) \to \rho_\infty(g)$ in $PSL_2(\mathbb{C})$. The collection of conjugacy classes of discrete faithful representations of $\pi_1(S)$ into $PSL_2(\mathbb{C})$ equipped with the algebraic topology is denoted as $AH(S)$.*

It is not even clear a priori that, as t_G tends to infinity, limits exist in $AH(S)$. However, Thurston's *Double Limit Theorem* Thurston [1986], M. Kapovich [2001], and Otal [2001] guarantees that if we have a sequence G_n with thickness t_{G_n} tending to infinity, subsequential limits (in the space of discrete faithful representations with a suitable topology, see Definition 5.7) do in fact exist.

Geodesic Laminations:

Definition 1.8. *A geodesic lamination on a hyperbolic surface is a foliation of a closed subset with geodesics, i.e. it is a closed set given as a disjoint union of geodesics (closed or bi-infinite).*

A geodesic lamination on a surface may further be equipped with a transverse (non-negative) measure to obtain a *measured lamination*. The space of measured (geodesic) laminations on S is then a positive cone in a vector space and is denoted as $\mathfrak{ML}(S)$. It can be projectivized to obtain the space of projectivized measured laminations $\mathfrak{PML}(S)$. It was shown by Thurston Fathi, Laudenbach, and Poenaru [1979] that $\mathfrak{PML}(S)$ is homeomorphic to a sphere and can be adjoined to $Teich(S)$ compactifying it to a closed ball.

Definition 1.9. *Thurston [1980, Definition 8.8.1] A* pleated surface *in a hyperbolic three-manifold N is a complete hyperbolic surface S of finite area, together with an isometric map $f : S \to N$ such that every $x \in S$ is in the interior of some geodesic segment (in S) which is mapped by f to a geodesic segment (in N). Also, f must take every cusp (corresponding to a maximal parabolic subgroup) of S to a cusp of N*

The pleating locus *of the pleated surface $f : S \to M$ is the set $\gamma \subset S$ consisting of those points in the pleated surface which are in the interior of unique geodesic segments mapped to geodesic segments.*

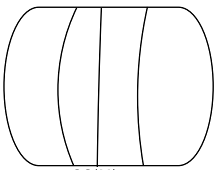
Proposition 1.10. *Thurston [ibid., Proposition 8.8.2] The pleating locus γ is a geodesic lamination on S. The map f is totally geodesic in the complement of γ.*

Thurston further shows Thurston [ibid., Ch. 8] that the boundary components of the convex core $CC(M)$ are pleated surfaces.

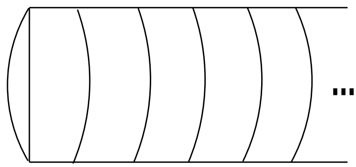
As thickness (Question 1.6) tends to infinity, the convex core may converge (up to extracting subsequences) to one of two kinds of convex manifolds $CC(M_\infty)$ (see schematic diagram below):

1. $CC(M_\infty)$ is homeomorphic to $S \times [0, \infty)$. Here $S \times \{0\}$ is the single boundary component of the convex core $CC(M_\infty)$. Such a manifold is called *simply degenerate* and the corresponding Kleinian group a simply degenerate surface Kleinian group. In this case the limit set Λ_G is a dendrite (topologically a tree) and the domain of discontinuity Ω_Γ is homeomorphic to an open disk with Ω_Γ/G a Riemann surface homeomorphic to $S \times \{0\}$. The end of M_∞ facing Ω_Γ/G is called a *geometrically finite end*.

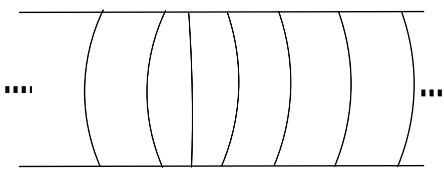
2. $CC(M_\infty)$ is homeomorphic to $S \times (-\infty, \infty)$. Such a manifold is called *doubly degenerate* and the corresponding Kleinian group a doubly degenerate surface Kleinian group. In this case the limit set Λ_G is all of S^2 and the domain of discontinuity Ω_Γ is empty.



CC(M) compact



CC(M) for simply degenerate



CC(M) for doubly degenerate

The ends (one for simply degenerate and two for doubly degenerate) of $CC(M_\infty)$ are called the *degenerate end(s)* of M. Thurston [1980] and Bonahon [1986] show that any such degenerate end E is *geometrically tame*, i.e. there is a sequence of simple closed curves $\{\sigma_n\}$ on S such that their geodesic realizations in $CC(M_\infty)$ exit E as n tends to ∞. Further Thurston [1980, Ch. 9], the limit of any such exiting sequence (in $\mathcal{PML}(S)$; the topology on $\mathcal{PML}(S)$ is quite close to the Hausdorff topology on S) is a unique lamination λ called the *ending lamination* of E. Thus a doubly degenerate manifold has two ending laminations, one for each degenerate end, while a simply degenerate manifold has a geometrically finite end corresponding to a Riemann surface $\Omega_\Gamma/G (\in Teich(S))$ at infinity and a degenerate end corresponding to an ending lamination.

These two pieces of information–Riemann surfaces at infinity and ending laminations–give the *end-invariants* of M. The ending lamination for a geometrically infinite end does not depend on the reference hyperbolic structure on S. It may be regarded as a purely topological piece of data associated to such an end.

We may thus think of the ending lamination as the analog, in the case of geometrically infinite ends, of the conformal structure at infinity for a geometrically infinite end.

The Ending Lamination Theorem of Brock-Canary-Minsky then takes the place of the Bers' simultaneous uniformization theorem and asserts:

Theorem 1.11. *Y. Minsky [2010] and Brock, Canary, and Y. N. Minsky [2012] Let M be a simply or doubly degenerate manifold. Then M is determined up to isometry by its end-invariants.*

Thus, the Ending Lamination Theorem justifies the following and may be considered an analog of Mostow Rigidity for infinite covolume Kleinian groups.

Slogan 1.12. *Topology implies Geometry.*

In order to complete the picture of the Ahlfors-Bers theory to study degenerate surface Kleinian groups G in terms of the dynamics of G on the Riemann sphere $\hat{\mathbb{C}}$, the following issue remains to be addressed:

Question 1.13. *Can the data of the ending lamination(s) be extracted from the dynamics of G on $\hat{\mathbb{C}}$?*

In more informal terms,

Question 1.14. *Is the geometric object "at infinity" of the quotient manifold $\mathbf{H}^3/\Gamma$ (i.e. the ending lamination) determined by the dynamics of Γ at infinity (i.e. the action of Γ on S^2)?*

We will make these questions precise below. The attempt to make Question 1.13 precise brings us to the following.

2 Cannon-Thurston maps

2.1 The main theorem for closed surface Kleinian groups.

In Thurston [1982, Problem 14], Thurston raised the following question, which is at the heart of the work we discuss here:

Question 2.1. *Suppose Γ has the property that $(\mathbf{H}^3 \cup \Omega_\Gamma)/\Gamma$ is compact. Then is it true that the limit set of any other Kleinian group Γ' isomorphic to Γ is the continuous image of the limit set of Γ, by a continuous map taking the fixed points of an(y) element γ to the fixed points of the corresponding element γ'?*

A special case of Question 2.1 was answered affirmatively in seminal work of Cannon and Thurston [1985, 2007]:

Theorem 2.2. *Cannon and Thurston [2007] Let M be a closed hyperbolic 3-manifold fibering over the circle with fiber Σ. Let $\widetilde{\Sigma}$ and $\widetilde{M}$ denote the universal covers of F and M respectively. After identifying $\widetilde{\Sigma}$ (resp. $\widetilde{M}$) with $\mathbf{H}^2$ (resp. $\mathbf{H}^3$), we obtain the compactification $\mathbb{D}^2 = \mathbf{H}^2 \cup S^1$ (resp. $\mathbb{D}^3 = \mathbf{H}^3 \cup S^2$) by attaching the circle S^1 (resp. the sphere S^2) at infinity. Let $i : \Sigma \to M$ denote the inclusion map of the fiber and $\widetilde{i} : \widetilde{\Sigma} \to \widetilde{M}$ the lift to the universal cover. Then $\widetilde{i}$ extends to a continuous map $\hat{i} : \mathbb{D}^2 \to \mathbb{D}^3$.*

An amazing implication of Theorem 2.2 is that $\widetilde{\Sigma}$ is an embedded disk in (the ball model) of $\mathbf{H}^3$ such that its boundary on the sphere S^2 is space-filling! See the following diagram by Thurston Thurston [1982, Figure 10] that illustrates 'a pattern of identification of a circle, here represented as the equator, whose quotient is topologically a sphere. This defines, topologically a sphere-filling curve.'

A version of Question 2.1 was raised by Cannon and Thurston in the context of closed surface Kleinian groups:

Question 2.3. *Cannon and Thurston [2007, Section 6] Suppose that a closed surface group $\pi_1(S)$ acts freely and properly discontinuously on $\mathbb{H}^3$ by isometries such that the quotient manifold has no accidental parabolics (here this just means that the image of $\pi_1(S)$ in $PSL_2(\mathbb{C})$ has no parabolics). Does the inclusion $\tilde{i} : \widetilde{S} \to \mathbb{H}^3$ extend continuously to the boundary?*

Continuous boundary extensions as in Question 2.3, if they exist, are called *Cannon-Thurston maps*. Question 2.3 is intimately related to a much older question c.f. Abikoff [1976] asking if limit sets are locally connected:

Question 2.4. *Let Γ be a finitely generated Kleinian group such that the limit set Λ_Γ is connected. Is Λ_Γ locally connected?*

It is shown in Cannon and Thurston [2007] that for simply degenerate surface Kleinian groups, Questions 2.3 and 2.4 are equivalent, via the Caratheodory extension Theorem.

The following Theorem of Mj [2014a] Mj [2014b] answers questions 2.3 and 2.4 affirmatively:

Theorem 2.5. *Let $\rho(\pi_1(S)) = G \subset PSL_2(\mathbb{C})$ be a simply or doubly degenerate (closed) surface Kleinian group. Let $M = \mathbf{H}^3/G$ and $i : S \to M$ be an embedding inducing a homotopy equivalence. Let $\widetilde{i} : \widetilde{S} \to \mathbf{H}^3$ denote a lift of i between universal covers. Let $\mathbb{D}^2, \mathbb{D}^3$ denote the compactifications. Then a Cannon-Thurston map $\hat{i} : \mathbb{D}^2 \to \mathbb{D}^3$ exists.*

Let $\partial i : S^1 \to S^2$ denote the restriction of $\hat{i}$ to the ideal boundaries. Then for $p \neq q$, $\partial i(p) = \partial i(q)$ if and only if p, q are the ideal end-points of a leaf of an ending lamination or ideal end-points of a complementary ideal polygon of an ending lamination.

The second part of Theorem 2.5 shows that the data of the ending lamination can be recovered from the Cannon-Thurston map and so we have an affirmative answer to Question 1.13. In conjunction with the Ending Lamination Theorem 1.11, this establishes the slogan:

Slogan 2.6. *Dynamics on the limit set determines geometry in the interior.*

A number of authors have contributed to the resolution of the above questions. Initially it was believed Abikoff [1976] that Question 2.4 had a negative answer for simply degenerate Kleinian groups. Floyd [1980] proved the corresponding theorem for geometrically finite Kleinian groups. Then in the early 80's Cannon and Thurston [1985] proved Theorem 2.2. This was extended by Y. N. Minsky [1994], Klarreich [1999], Alperin, Dicks, and Porti [1999], B. H. Bowditch [2013] and B. H. Bowditch [2007], McMullen [2001], Miyachi [2002] and the author 1998; 2010; 2009-2010; 2016 for various special cases. The general surface group case was accomplished in Mj [2014a] and the general Kleinian group case in Mj [2017a].

2.2 Geometric Group Theory. We now turn to a generalization of Question 2.3 to a far more general context. After the introduction of hyperbolic metric spaces by Gromov [1987], Question 2.3 was extended by the author Mitra [1997b], Bestvina [2004], and Mitra [1998c] to the context of a hyperbolic group H acting freely and properly discontinuously by isometries on a hyperbolic metric space X. Any hyperbolic X has a (Gromov) boundary ∂X given by asymptote-classes of geodesics. Adjoining ∂X to X we get the Gromov compactification $\widehat{X}$.

There is a natural map $i : \Gamma_H \to X$, sending vertices of Γ_H to the $H-$orbit of a point $x \in X$, and connecting images of adjacent vertices by geodesic segments in X. Let $\widehat{\Gamma_H}, \widehat{X}$ denote the Gromov compactification of Γ_H, X respectively. The analog of Question 2.3 is the following:

Question 2.7. *Does $i : \Gamma_H \to X$ extend continuously to a map $\hat{i} : \widehat{\Gamma_H} \to \widehat{X}$?*

Continuous extensions as in Question 2.7 are also referred to as *Cannon-Thurston maps* and make sense when Γ_H is replaced by an arbitrary hyperbolic metric space Y. A simple and basic criterion for the existence of Cannon-Thurston maps was established in Mitra [1998a,b]:

Lemma 2.8. *Let $i : (Y, y) \to (X, x)$ be a proper map between (based) Gromov-hyperbolic spaces. A continuous extension (also called a Cannon-Thurston map) $\hat{i} : \widehat{Y} \to \widehat{X}$ exists if and only if the following holds:*
There exists a non-negative proper function $M : \mathbb{N} \to \mathbb{N}$, such that if $\lambda = [a, b]_Y$ is a geodesic lying outside an N-ball around y, then any geodesic segment $[i(a), i(b)]_X$ in X joining $i(a), i(b)$ lies outside the $M(N)$-ball around $x = i(y)$.

In the generality above Question 2.7 turns out to have a negative answer. An explicit counterexample to Question 2.7 was recently found by Baker and T. R. Riley [2013] in the context of small cancellation theory. The counterexample uses Lemma 2.8 to rule out the existence of Cannon-Thurston maps. Further, Matsuda and Oguni [2014] further developed Baker and Riley's counterexample to show that given a(ny) non-elementary hyperbolic group H, there exists hyperbolic group G such that $H \subset G$ and there is no Cannon-Thurston map for the inclusion. We shall furnish positive answers to Question 2.7 in a number of special cases in Section 6.

3 Closed 3-manifolds

3.1 3-manifolds fibering over the circle. We start by giving a sketch of the proof of Theorem 2.2, The proof is coarse-geometric in nature and follows Mitra [1998a,b]. We recall a couple of basic Lemmata we shall be needing from Mitra [1998b]. The following says that nearest point projection onto a geodesic in a hyperbolic space is coarsely Lipschitz.

Lemma 3.1. *Let (X, d) be a δ-hyperbolic metric space. Then there exists a constant $C \geq 1$ such that the following holds:*
Let $\lambda \subset X$ be a geodesic segment and let $\Pi : X \to \lambda$ be a nearest point projection. Then $d(\Pi(x), \Pi(y)) \leq C d(x, y)$ for all $x, y \in X$.

The next Lemma says that nearest point projections and quasi-isometries almost commute.

Lemma 3.2. *Let (X, d) be a δ-hyperbolic metric space. Given (K, ϵ), there exists C such that the following holds:*

Let $\lambda = [a, b]$ be a geodesic segment in X. Let $p \in X$ be arbitrary and let q be a nearest point projection of p onto λ. Let ϕ be a $(K, \epsilon)-$quasi-isometry from X to itself and let $\Phi(\lambda) = [\phi(a), \phi(b)]$ be a geodesic segment in X joining $\phi(a), \phi(b)$. Let r be a nearest point projection of $\phi(p)$ onto $\Phi(\lambda)$. Then $d(r, \phi(q)) \leq C$.

Sketch of Proof: The proof of Lemma 3.2 follows from the fact that a geodesic tripod T (built from $[a, b]$ and $[p, q]$) is quasiconvex in hyperbolic space and that a quasi-isometric image $\phi(T)$ of T lies close to a geodesic tripod T' built from $[\phi(a), \phi(b)]$ and $[\phi(p), r]$. Hence the image $\phi(q)$ of the centroid q of T lies close to the centroid r of T'. □

3.2 The key tool: hyperbolic ladder. The key idea behind the proof of Theorem 2.2 and its generalizations in Mitra [1998a,b] is the construction of a *hyperbolic ladder* $\mathfrak{L}_\lambda \subset \widetilde{M}$ for *any* geodesic in $\widetilde{\Sigma}$. The universal cover $\widetilde{M}$ fibers over $\mathbb{R}$ with fibers $\widetilde{\Sigma}$. Since the context is geometric group theory, we discretize this as follows. Replace $\widetilde{\Sigma}$ and $\widetilde{M}$ by quasi-isometric models in the form of Cayley graphs $\Gamma_{\pi_1(\Sigma)}$ and $\Gamma_{\pi_1(M)}$ respectively. Let us denote $\Gamma_{\pi_1(\Sigma)}$ by Y and $\Gamma_{\pi_1(M)}$ by X. The projection of $\widetilde{M}$ to the base $\mathbb{R}$ is discretized accordingly giving a model that can be thought of as (and is quasi-isometric to) a *tree T of spaces*, where

1. T is the simplicial tree underlying $\mathbb{R}$ with vertices at $\mathbb{Z}$.
2. All the vertex and edge spaces are (intrinsically) isometric to Y.
3. The edge space to vertex space inclusions are qi-embeddings.

We summarize this by saying that X is a tree T of spaces satisfying the *qi-embedded condition* Bestvina and Feighn [1992].

Given a geodesic segment $[a, b] = \lambda = \lambda_0 \subset Y$, we now sketch the promised construction of the *ladder* $\mathfrak{L}_\lambda \subset X$ containing λ. Index the vertices by $n \in \mathbb{Z}$. Since the edge-to-vertex space inclusions are quasi-isometries, this induces a quasi-isometry ϕ_n from the vertex space Y_n to the vertex space Y_{n+1} for $n \geq 0$. A similar quasi-isometry ϕ_{-n} exists from Y_{-n} to the vertex space $Y_{-(n+1)}$. These quasi-isometries are defined on the vertex sets of Y_n, $n \in \mathbb{Z}$. ϕ_n induces a map Φ_n from geodesic segments in Y_n to geodesic segments in Y_{n+1} for $n \geq 0$ by sending a geodesic in Y_n joining a, b to a geodesic in Y_{n+1} joining $\phi_n(a), \phi_n(b)$. Similarly, for $n \leq 0$. Inductively define:

- $\lambda_{j+1} = \Phi_j(\lambda_j)$ for $j \geq 0$,
- $\lambda_{-j-1} = \Phi_{-j}(\lambda_{-j})$ for $j \geq 0$,
- $\mathfrak{L}_\lambda = \bigcup_j \lambda_j$.

$\mathfrak{L}_\lambda$ turns out to be quasiconvex in X. To prove this, we construct a coarsely Lipschitz retraction $\Pi_\lambda : \bigcup_j Y_j \to \mathfrak{L}_\lambda$ as follows.

On Y_j define $\pi_j(y)$ to be a nearest-point projection of y onto λ_j and define

$$\Pi_\lambda(y) = \pi_j(y),\ for\ y \in Y_j.$$

The following theorem asserts that Π_λ is coarsely Lipschitz.

Theorem 3.3. *Mitra [1998a,b] and Mj [2010] There exists $C \geq 1$ such that for any geodesic $\lambda \subset Y$,*

$$d_X(\Pi_\lambda(x), \Pi_\lambda(y)) \leq C d_X(x, y)$$

for $x, y \in \bigcup_i Y_i$.

Sketch of Proof:
The proof requires only the hyperbolicity of Y, but not that of X. It suffices to show that for $d_X(x, y) = 1$, $d_X(\Pi_\lambda(x), \Pi_\lambda(y)) \leq C$. Thus x, y may be thought of as

1. either lying in the same Y_j. This case follows directly from Lemma 3.1.

2. or lying vertically one just above the other. Then (up to a bounded amount of error), we can assume without loss of generality, that $y = \phi_j(x)$. This case now follows from Lemma 3.2.

Since a coarse Lipschitz retract of a hyperbolic metric space is quasiconvex, we immediately have:

Corollary 3.4. *If (X, d_X) is hyperbolic, there exists $C \geq 1$ such that for any λ, $\mathfrak{L}_\lambda$ is $C-$quasiconvex.*

Note here that we have not used any feature of Y except its hyperbolicity. In particular, we do not need the specific condition that $Y = \widetilde{\Sigma}$. We are now in a position to prove a generalization of Theorem 2.2.

Theorem 3.5. *Mj [2010] Let (X, d) be a hyperbolic tree (T) of hyperbolic metric spaces satisfying the qi-embedded condition, where T is $\mathbb{R}$ or $[0, \infty)$ with vertex and edge sets Y_j as above, $j \in \mathbb{Z}$. Assume (as above) that the edge-to-vertex inclusions are quasi-isometries. For $i : Y_0 \to X$ there is a Cannon-Thurston map $\hat{i} : \widehat{Y_0} \to \widehat{X}$.*

Proof. Fix a basepoint $y_0 \in Y_0$. By Lemma 2.8 and quasiconvexity of $\mathfrak{L}_\lambda$ (Corollary 3.4), it suffices to show that for all $M \geq 0$ there exists $N \geq 0$ such that if a geodesic segment λ lies outside the N-ball about $y_0 \in Y_0$, then $\mathfrak{L}_\lambda$ lies outside the M-ball around $y_0 \in X$. Equivalently, we need a proper function $M(N) : \mathbb{N} \to \mathbb{N}$.

Since Y_0 is properly embedded in X, there exists a proper function $g : \mathbb{N} \to \mathbb{N}$ such that λ lies outside the $g(N)$-ball about $y_0 \in X$.

Let p be any point on $\mathfrak{L}_\lambda$. Then $p = p_j \in Y_j$ for some j. Assume without loss of generality that $j \geq 0$. It is not hard to see that there exists C_0, depending only on X, such that for any such p_j, there exists $p_{j-1} \in Y_{j-1}$ with $d(p_j, p_{j-1}) \leq C_0$. It follows inductively that there exists $y \in \lambda = \lambda_0$ such that $d_X(y, p) \leq C_0 j$. Hence, by the triangle inequality, $d_X(y_0, p) \geq g(N) - C_0 j$.

Next, looking at the 'vertical direction', $d_X(y_0, p) \geq j$ and hence

$$d_X(y_0, p) \geq \max(g(N) - C_0 j, j) \geq \frac{g(N)}{A+1}.$$

Defining $M(N) = \frac{g(N)}{A+1}$, we see that $M(N)$ is a proper function of N and we are done. □

3.3 Quasiconvexity. The structure of Cannon-Thurston maps in Section 3.1 can be used to establish quasiconvexity of certain subgroups of $\pi_1(M)$. Let $H \subset \pi_1(\Sigma)$ be a finitely generated infinite index subgroup of the fiber group. Then, due to the LERF property for surface subgroups, a Theorem of Scott P. Scott [1978], there is a finite sheeted cover where H is geometric, i.e. it is carried by a proper embedded subsurface of (a finite sheeted cover of) Σ. But such a proper subsurface cannot carry a leaf of the stable or unstable foliations $\mathfrak{F}_s$ or $\mathfrak{F}_u$. This gives us the following Theorem of Scott and Swarup:

Theorem 3.6. *G. P. Scott and Swarup [1990] Let M be a closed hyperbolic 3-manifold fibering over the circle with fiber Σ. Let $H \subset \pi_1(\Sigma)$ be a finitely generated infinite index subgroup of the fiber group in $\pi_1(M)$. Then H is quasiconvex in $\pi_1(M)$.*

Theorem 3.6 has been generalized considerably to the context of convex cocompact subgroups of the mapping class group and $Out(F_n)$ by a number of authors Dowdall, Kent, and C. J. Leininger [2014], Dowdall, I. Kapovich, and Taylor [2016], Dowdall and Taylor [2018, 2017], and Mj and Rafi [2015].

4 Kleinian surface groups: Model Geometries

In this section we shall describe a sequence of models for degenerate ends of 3-manifolds following Y. N. Minsky [2001, 1994] and Mj [2010, 2009-2010, 2016] and Y. Minsky [2010], Brock, Canary, and Y. N. Minsky [2012], and Mj [2014a] and indicate how to generalize the ladder construction of Section 3.2 incorporating electric geometry Farb [1998]. Let X be a hyperbolic metric space, e.g. $\mathbf{H}^3$. Let $\mathcal{H}_X$ be a collection of disjoint convex subsets. Roughly speaking, electrification equips each element of $\mathcal{H}_X$ with the zero metric, while preserving the metric on $X \setminus (\bigcup_{H \in \mathcal{H}_X} H)$. The resulting electrified space $\mathcal{E}(X, \mathcal{H}_X)$ is still Gromov hyperbolic under extremely mild conditions and hyperbolic geodesics in X can be recovered from electric geodesics in the electrified space $\mathcal{E}(X, \mathcal{H}_X)$. This will allow us to establish the existence of Cannon-Thurston maps. We shall focus on closed surfaces and follow the summary in Lecuire and Mj [2016] for the exposition.

The topology of each building block is simple: it is homeomorphic to $S \times [0, 1]$, where S is a closed surface of genus greater than one. Geometrically, the top and bottom boundary components in the first three model geometries are uniformly bi-Lipschitz to a fixed hyperbolic structure on S. Assume therefore that S is equipped with such a fixed hyperbolic structure. We do so henceforth. The different types of geometries of the blocks make for different model geometries of ends.

Definition 4.1. *A model E_m is said to be built up of blocks of some prescribed geometries* glued end to end*, if*

1. *E_m is homeomorphic to $S \times [0, \infty)$*
2. *There exists $L \geq 1$ such that $S \times [i, i+1]$ is $L-$bi-Lipschitz to a block of one of the three prescribed geometries: bounded, i-bounded or amalgamated (see below).*

*$S \times [i, i+1]$ will be called the $(i+1)$*th block *of the model E_m.*

The thickness *of the $(i+1)$th block is the length of the shortest path between $S \times \{i\}$ and $S \times \{i+1\}$ in $S \times [i, i+1] (\subset E_m)$.*

4.1 Bounded geometry.

Y. N. Minsky [2001, 1994] calls an end E of a hyperbolic 3-manifold to be of bounded geometry if there are no arbitrarily short closed geodesics in E.

Definition 4.2. *Let $B_0 = S \times [0, 1]$ be given the product metric. If B is $L-$bi-Lipschitz homeomorphic to B_0, it is called an $L-$*thick block.

An end E is said to have a model of bounded geometry if there exists L such that E is bi-Lipschitz homeomorphic to a model manifold E_m consisting of gluing $L-$thick blocks end-to-end.

It follows from work of of Minsky Y. N. Minsky [1993] that if E is of bounded geometry, it has a model of bounded geometry. The existence of Cannon-Thurston maps in this setup is then a replica of the proof of Theorem 3.5.

4.2 i-bounded Geometry.

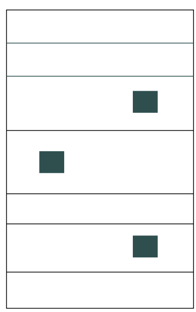
Definition 4.3. *Mj [2009-2010] An end E of a hyperbolic 3-manifold M has* i-bounded geometry *if the boundary torus of every Margulis tube in E has bounded diameter.*

We give an alternate description. Fix a closed hyperbolic surface S. Let $\mathcal{C}$ be a finite collection of (not necessarily disjoint) simple closed geodesics on S. Let $N_\epsilon(\sigma_i)$ denote an ϵ neighborhood of σ_i, $\sigma_i \in \mathcal{C}$, were ϵ is small enough to ensure that lifts of $N_\epsilon(\sigma_i)$ to $\widetilde{S}$ are disjoint.

Definition 4.4. *Let $I = [0,3]$. Equip $S \times I$ with the product metric. Let $B^c = (S \times I - \cup_j N_\epsilon(\sigma_j) \times [1,2])$, equipped with the induced path-metric. Here $\{\sigma_j\}$ is a subcollection of $\mathcal{C}$ consisting of disjoint curves. Perform Dehn filling on some $(1,n)$ curve on each resultant torus component of the boundary of B^c (the integers n are quite arbitrary and may vary: we omit subscripts for expository ease). We call n the* twist coefficient. *Foliate the relevant torus boundary component of B^c by translates of $(1,n)$ curves. Glue in a solid torus Θ, which we refer to as a* Margulis tube, *with a hyperbolic metric foliated by totally geodesic disks bounding the $(1,n)$ curves.*

The resulting copy of $S \times I$ thus obtained, equipped with the above metric is called a thin block.

Definition 4.5. *A model manifold E_m of* i-bounded geometry *is built out of gluing $L-$thick and thin blocks end-to-end (for some L) (see schematic diagram below where the black squares indicate Margulis tubes and the horizontal rectangles indicate the blocks).*



It follows from work in Mj [ibid.] that

Proposition 4.6. *An end E of a hyperbolic 3-manifold M has* i-bounded geometry *if and only if it is bi-Lipschitz homeomorphic to a model manifold E_m of i-bounded geometry.*

We give a brief indication of the construction of $\mathcal{L}_\lambda$ and the proof of the existence of Cannon-Thurston maps in this case. First electrify all the Margulis tubes, i.e. equip them with a zero metric (see Farb [1998] for details on relative hyperbolicity and electric geometry). This ensures that in the resulting electric geometry, each block is of bounded geometry. More precisely, there is a (metric) product structure on $S \times [0,3]$ such that each $\{x\} \times [0,3]$ has uniformly bounded length in the electric metric.

Further, since the curves in $\mathcal{C}$ are electrified in a block, Dehn twists are isometries from $S \times \{1\}$ to $S \times \{2\}$ in a thin block. This allows the construction of $\mathcal{L}_\lambda$ to go through as before and ensures that it is quasiconvex in the resulting electric metric.

Finally given an electric geodesic lying outside large balls modulo Margulis tubes one can recover a genuine hyperbolic geodesic tracking it outside Margulis tubes. A relative version of the criterion of Lemma 2.8 can now be used to prove the existence of Cannon-Thurston maps.

4.3 Amalgamation Geometry. Again, as in Definition 4.4, start with a fixed closed hyperbolic surface S, a collection of simple closed curves $\mathcal{C}$ and set $I = [0,3]$. Perform Dehn surgeries on the Margulis tubes corresponding to $\mathcal{C}$ as before. Let $K = S \times [1,2] \subset S \times [0,3]$ and let $K^c = (S \times I - \cup_i N_\epsilon(\sigma_i) \times [1,2])$. Instead of fixing the product metric on the complement K^c of Margulis tubes in K, allow these complementary components to have *arbitrary geometry* subject only to the restriction that the geometries of $S \times \{1,2\}$ are fixed. Equip $S \times [0,1]$ and $S \times [2,3]$ with the product metrics. The resulting block is said to be a *block of amalgamation geometry*. After lifting to the universal cover, complements of Margulis tubes in the lifts $\widetilde{S} \times [1,2]$ are termed *amalgamation components*.

Definition 4.7. *An end E of a hyperbolic 3-manifold M has* amalgamated geometry *if*

1. *it is bi-Lipschitz homeomorphic to a model manifold E_m consisting of gluing $L-$thick and amalgamation geometry blocks end-to-end (for some L).*
2. *Amalgamation components are (uniformly) quasiconvex in $\widetilde{E}_m$.*

To construct the ladder $\mathcal{L}_\lambda$ we electrify amalgamation components as well as Margulis tubes. This ensures that in the electric metric,

1. Each amalgamation block has bounded geometry
2. The mapping class element taking $S \times \{1\}$ to $S \times \{2\}$ induces an isometry of the electrified metrics.

Quasiconvexity of $\mathcal{L}_\lambda$ in the electric metric now follows as before. To recover the data of hyperbolic geodesics from quasigeodesics lying close to $\mathcal{L}_\lambda$, we use (uniform) quasiconvexity of amalgamation components and existence of Cannon-Thurston maps follows.

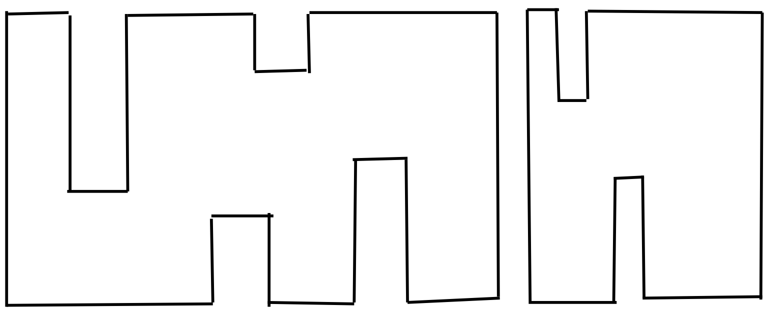
4.4 Split Geometry. We need now to relax the assumption that the boundary components of model blocks are of (uniformly) bounded geometry. Roughly speaking, split geometry is a generalization of amalgamation geometry where

1. A Margulis tube is allowed to travel through a uniformly bounded number of contiguous blocks and split them.

2. The complementary pieces, now called split components, are quasiconvex in a somewhat weaker sense (see Definition 4.8 below).

Each split component is allowed to contain Margulis tubes, called *hanging tubes* that do not go all the way across from the top to the bottom, i.e. they do not split both $\Sigma_i^s, \Sigma_{i+1}^s$.

A split component $B^s \subset B = S \times I$ is topologically a product $S^s \times I$ for some, necessarily connected $S^s (\subset S)$. However, the upper and lower boundaries of B^s need only be be split subsurfaces of S^s to allow for hanging tubes starting or ending (but not both) within the split block.



Split Block with hanging tubes

An end E of a hyperbolic 3-manifold M has *weak split geometry* if it is bi-Lipschitz homeomorphic to a model manifold E_m consisting of gluing $L-$thick and split blocks as above end-to-end (for some L). Electrifying split components as in Section 4.3, we obtain a new electric metric called the *graph metric* d_G on E.

Definition 4.8. *A model of weak split geometry is said to be of* split geometry *if the convex hull of each split component has uniformly bounded d_G-diameter.*

5 Cannon-Thurston Maps for Kleinian groups and Applications

5.1 Cannon-Thurston maps for degenerate manifolds. Let M be a hyperbolic 3-manifold homotopy equivalent to a closed hyperbolic surface S. Once we establish that M has split geometry, the proof proceeds as in Section 4.3 by electrifying split components, constructing a hyperbolic ladder $\mathcal{L}_\lambda$ and finally recovering a hyperbolic geodesic from an electric one. We shall therefore dwell in this subsection on showing that any degenerate end has split geometry. We shall do this under two simplifying assumptions, directing the reader to Mj [2014a] (especially the Introduction) for a more detailed road-map.

We borrow extensively from the hierarchy and model manifold terminology and technology of Masur and Y. N. Minsky [2000] and Y. Minsky [2010]. The model manifold of Y. Minsky [2010] and Brock, Canary, and Y. N. Minsky [2012] furnishes a resolution, or equivalently, a sequence $\{P_m\}$ of pants decompositions of S exiting E and hence a *hierarchy path*. Let τ_m denote the simple multicurve on S constituting P_m. The P_m in turn furnish split level surfaces $\{S_m\}$ exiting E: a *split level surface* S_m is a collection of (nearly) totally geodesic embeddings of the pairs of pants comprising P_m. Next, corresponding to the hierarchy path $\{\tau_m\}$, there is a tight geodesic in $\mathcal{C}(S)$ consisting of the bottom geodesic $\{\eta_i\}$ of the hierarchy. We proceed to extract a subsequence of the resolution τ_m using the bottom geodesic $\{\eta_i\}$ under two key simplifying assumptions:

1. For all i, the length of exactly one curve in η_i is sufficiently small, less than the Margulis constant in particular. Call it η_i for convenience.

2. Let S_i correspond to the first occurrence of the vertex η_i in the resolution τ_m. Assume further that the S_i's are actually split surfaces and not just split level surfaces, i.e. they all have injectivity radius uniformly bounded below,

It follows that the Margulis tube η_i splits both S_i and S_{i+1} and that the tube T_i is trapped entirely between S_i and S_{i+1}. The product region B_i between S_i and S_{i+1} is therefore a split block for all i and T_i splits it. The model manifold thus obtained is one of weak split geometry. In a sense, this is a case of 'pure split geometry', where all blocks have a split geometry structure (no thick blocks). To prove that the model is indeed of split geometry, it remains to establish the quasiconvexity condition of Definition 4.8.

Let K be a split component and $\widetilde{K}$ an elevation to $\widetilde{E}$. Let v be a boundary short curve for the split component and let T_v be the Margulis tube corresponding to v abutting K. Denote the hyperbolic convex hull by $CH(\widetilde{K})$ and pass back to a quotient in M. A crucial observation that is needed here is the fact that any pleated surface has bounded d_G-diameter. This is because thin parts of pleated surfaces lie inside Margulis tubes that get electrified in the graph metric. It therefore suffices to show that any point in $CH(K)$ lies close to a pleated surface passing near the fixed tube T_v. This last condition follows from the Brock-Bromberg drilling theorem Brock and Bromberg [2004] and the fact that the convex core of a quasi-Fuchsian group is filled by pleated surfaces Fan [1997]. This completes our sketch of a proof of the following main theorem of Mj [2014a]:
Theorem 2.5: Let $\rho : \pi_1(S) \to PSL_2(\mathbb{C})$ be a simply or doubly degenerate (closed) surface Kleinian group. Then a Cannon-Thurston map exists.

It follows that the limit set of $\rho(\pi_1(S))$ is a continuous image of S^1 and is therefore locally connected. As a first application of Theorem 2.5, we shall use the following Theorem of Anderson and Maskit [1996] to prove that connected limit sets of Kleinian groups without parabolics are locally connected.

Theorem 5.1. *Anderson and Maskit [ibid.] Let Γ be an analytically finite Kleinian group with connected limit set. Then the limit set $\Lambda(\Gamma)$ is locally connected if and only if every simply degenerate surface subgroup of Γ without accidental parabolics has locally connected limit set.*

Combining the remark after Theorem 2.5 with Theorem 5.1, we immediately have the following affirmative answer to Question 2.4.

Theorem 5.2. *Let Γ be a finitely generated Kleinian group without parabolics and with a connected limit set Λ. Then Λ is locally connected.*

Theorem 2.5 can be extended to punctured surfaces Mj [2014a] and this allows Theorem 5.2 to be generalized to arbitrary finitely generated Kleinian groups.

5.2 Finitely generated Kleinian groups. In Mj [2014b], we show that the point preimages of the Cannon-Thurston map for a simply or doubly degenerate surface Kleinian group given by Theorem 2.5 corresponds to end-points of leaves of ending laminations. In particular, the ending lamination corresponding to a degenerate end can be recovered from the Cannon-Thurston map. This was extended further in Das and Mj [2016] and Mj [2017a] to obtain the following general version for finitely generated Kleinian groups.

Theorem 5.3. *Mj [ibid.] Let G be a finitely generated Kleinian group. Let $i : \Gamma_G \to \mathbb{H}^3$ be the natural identification of a Cayley graph of G with the orbit of a point in $\mathbb{H}^3$. Further suppose that each degenerate end of $\mathbf{H}^3/G$ can be equipped with a Minsky model Y. Minsky [2010].*[2] *Then i extends continuously to a Cannon-Thurston map $\hat{i} : \widehat{\Gamma_G} \to \mathbb{D}^3$, where $\widehat{\Gamma_G}$ denotes the (relative) hyperbolic compactification of Γ_G.*

Let ∂i denote the restriction of $\hat{i}$ to the boundary $\partial \Gamma_G$ of Γ_G. Let E be a degenerate end of $N^h = \mathbb{H}^3/G$ and $\widetilde{E}$ a lift of E to $\widetilde{N^h}$ and let M_{gf} be an augmented Scott core of N^h. Then the ending lamination $\mathfrak{L}_E$ for the end E lifts to a lamination on $\widetilde{M_{gf}} \cap \widetilde{E}$. Each such lift $\mathfrak{L}$ of the ending lamination of a degenerate end defines a relation $\mathfrak{R}_{\mathfrak{L}}$ on the (Gromov) boundary $\partial \widetilde{M_{gf}}$ (or equivalently, the relative hyperbolic boundary $\partial_r \Gamma_G$ of Γ_G), given by $a \mathfrak{R}_{\mathfrak{L}} b$ iff a, b are end-points of a leaf of $\mathfrak{L}$. Let $\{\mathfrak{R}_i\}$ be the entire collection of relations on $\partial \widetilde{M_{gf}}$ obtained this way. Let $\mathfrak{R}$ be the transitive closure of the union $\bigcup_i \mathfrak{R}_i$. Then $\partial i(a) = \partial i(b)$ iff $a \mathfrak{R} b$.

[2] This hypothesis is satisfied for all ends without parabolics as well as for ends incompressible away from cusps - see Y. Minsky [2010] and Brock, Canary, and Y. N. Minsky [2012] and Mj [2017a, Appendix]. That the hypothesis is satisfied in general would follow from unpublished work of B. H. Bowditch [2016] and B. Bowditch [2005].

5.3 Primitive Stable Representations. In Y. N. Minsky [2013] Minsky introduced an open subset of the $PSL_2(\mathbb{C})$ character variety for a free group, properly containing the Schottky representations, on which the action of the outer automorphism group is properly discontinuous. He called these *primitive stable representations.* Let F_n be a free group of rank n. An element of F_n is primitive if it is an element of a free generating set. Let $\mathcal{P} = \cdots www \cdots$ be the set of bi-infinite words with w cyclically reduced primitive. A representation $\rho : F_n \to PSL_2(\mathbb{C})$ is primitive stable if all elements of $\mathcal{P}$ are mapped to uniform quasigeodesics in $\mathbb{H}^3$.

Minsky conjectured that primitive stable representations are characterized by the feature that every component of the ending lamination is blocking.

Using Theorem 5.3, Jeon and Kim [2010], and Jeon, Kim, Ohshika, and Lecuire [2014] resolved this conjecture. We briefly sketch their argument for a degenerate free Kleinian group without parabolics.

Let $\{D_1, \cdots, D_n\} = \mathfrak{D}$ be a finite set of essential disks on a handlebody H cutting H into a 3-ball. A free generating set of F_n is dual to $\mathfrak{D}$. For a lamination $\mathfrak{L}$, the *Whitehead graph* $Wh(\Lambda, \mathfrak{D})$ is defined as follows. Cut ∂H along $\partial \mathfrak{D}$ to obtain a sphere with $2n$ holes, labeled by $D_i^{\pm}$. The vertices of $Wh(\mathfrak{L}, \mathfrak{D})$ are the boundary circles of ∂H, with an edge whenever two circles are joined by an arc of $\mathfrak{L} \setminus \mathfrak{D}$. For the ending lamination $\mathfrak{L}_E$ of a degenerate free group without parabolics, $Wh(\mathfrak{L}_E, \Delta)$ is connected and has no cutpoints.

Let ρ_E be the associated representation. If ρ is not primitive stable, then there exists a sequence of primitive cyclically reduced elements w_n such that $\rho(w_n^*)$ is not an $n-$ quasigeodesic. After passing to a subsequence, w_n and hence w_n^* converges to a bi-infinite geodesic w_∞ in the Cayley graph with two distinct end points w_+, w_- in the Gromov boundary of F_n. The Cannon-Thurston map identifies w_+, w_-. Hence by Theorem 5.3 they are either the end points of a leaf of $\mathfrak{L}_E$ or ideal end-points of a complementary ideal polygon of $\mathfrak{L}_E$. It follows therefore that $Wh(w_\infty, \mathfrak{D})$ is connected and has no cutpoints. Since w_n's converge to w_∞, $Wh(w_n, \mathfrak{D})$ is connected and has no cutpoints for large enough n. A Lemma due to Whitehead says that if $Wh(w_n, \mathfrak{D})$ is connected and has no cutpoints, then w_n cannot be primitive, a contradiction.

5.4 Discreteness of Commensurators. In C. Leininger, Long, and Reid [2011] and Mj [2011], Theorems 2.5 and 5.3 are used to prove that commensurators of finitely generated, infinite covolume, Zariski dense Kleinian groups are discrete. The basic fact that goes into the proof is that commensurators preserve the structure of point pre-images of Cannon-Thurston maps. The point pre-image structure is known from Theorem 5.3.

5.5 Radial and horospherical limit sets.

Definition 5.4. *A point $\xi \in S^2$ is a radial or conical limit point of Kleinian group Γ, if for any base-point $o \in \widetilde{M}$ and any geodesic γ_ξ ending at ξ, there exist $C \geq 0$ and infinitely many translates $g.o \in N_C(\gamma_\xi)$, $g \in \Gamma$.*

A point $\xi \in S^2$ is a horospherical limit point of Kleinian group Γ, if for any base-point $o \in \widetilde{M}$ and any horoball B_ξ based at ξ, there exist infinitely many translates $g.o \in B_\xi$, $g \in \Gamma$.

The collection of radial (resp. horospherical) limit points of Γ is called the radial (resp. horospherical) limit set of Γ and is denoted by Λ_r (resp. Λ_h).

The multiple limit set Λ_m consists of those point of S^2 that have more than one pre-image under the Cannon-Thurston map.

Several authors M. Kapovich [1995], Gerasimov [2012], and Jeon, I. Kapovich, C. Leininger, and Ohshika [2016] worked on the relationship between Λ_m and Λ_r. They concluded that the conical limit set is strictly contained in the set of injective points of the Cannon-Thurston map, i.e. $\Lambda_r \subset \Lambda_m^c$, but the inclusion is proper.

In Lecuire and Mj [2016], we showed:

Theorem 5.5. $\Lambda_m^c = \Lambda_h$.

5.6 Motions of limit sets. We discuss the following question in this section, which paraphrases the second part of of Thurston [1982, Problem 14]. A detailed survey appears in Mj [2017b].

Question 5.6. *Let G_n be a sequence of Kleinian groups converging to a Kleinian group G. Does the corresponding dynamics of G_n on the Riemann sphere S^2 converge to the dynamics of G on S^2?*

To make Question 5.6 precise, we need to make sense of 'convergence' both for Kleinian groups and for their dynamics on S^2. There are three different notions of convergence for Kleinian groups.

Definition 5.7. *Let $\rho_i : H \to PSL_2(\mathbb{C})$ be a sequence of Kleinian groups. We say that that ρ_i converges to ρ_∞* algebraically *if for all $h \in H$, $\rho_i(h) \to \rho_\infty(h)$.*

Let $\rho_j : H \to PSL_2(\mathbb{C})$ be a sequence of discrete, faithful representations of a finitely generated, torsion-free, nonabelian group H. If $\{\rho_j(H)\}$ converges as a sequence of closed subsets of $PSL_2(\mathbb{C})$ to a torsion-free, nonabelian Kleinian group Γ, Γ is called the geometric limit of the sequence.

$G_i (= \rho_i(H))$ converges strongly *to $G (= \rho_\infty(H))$ if the convergence is both geometric and algebraic.*

Question 5.6 then splits into the following three questions.

Question 5.8. *1. If $G_n \to G$ geometrically, then do the corresponding limit sets converge in the Hausdorff topology on S^2?*

2. If $G_n \to G$ strongly then do the corresponding Cannon-Thurston maps converge uniformly?

3. If $G_n \to G$ algebraically then do the corresponding Cannon-Thurston maps converge pointwise?

We give the answers straight off and then proceed to elaborate.

Answers 5.9. *1. The answer to Question 5.8 (1) is Yes.*

2. The answer to Question 5.8 (2) is Yes.

3. The answer to Question 5.8 (3) is No, in general.

The most general answer to Question 5.8 (1) is due to R. A. Evans [2000], R. Evans [2004]:

Theorem 5.10. *R. A. Evans [2000], R. Evans [2004] Let $\rho_n : H \to G_n$ be a sequence of weakly type-preserving isomorphisms from a geometrically finite group H to Kleinian groups G_n with limit sets Λ_n, such that ρ_n converges algebraically to $\rho_\infty : H \to G^a_\infty$ and geometrically to G^g_∞. Let Λ_a and Λ_g denote the limit sets of G^a_∞ and G^g_∞. Then $\Lambda_n \to \Lambda_g$ in the Hausdorff metric. Further, the sequence converges strongly if and only $\Lambda_n \to \Lambda_a$ in the Hausdorff metric.*

The answer to Question 5.8 (2) is due to the author and Series Mj and Series [2017] in the case that $H = \pi_1(S)$ for a closed surface S of genus greater than one. This can be generalized to arbitrary finitely generated Kleinian groups as in Mj [2017b]:

Theorem 5.11. *Let H be a fixed group and $\rho_n(H) = \Gamma_n$ be a sequence of geometrically finite Kleinian groups converging strongly to a Kleinian group Γ. Let M_n and M_∞ be the corresponding hyperbolic manifolds. Let K be a fixed complex with fundamental group H.*

Consider embeddings $\phi_n : K \to M_n, n = 1, \cdots, \infty$ such that the maps ϕ_n are homotopic to each other by uniformly bounded homotopies (in the geometric limit). Then Cannon-Thurston maps for $\widetilde{\phi_n}$ exist and converge uniformly to the Cannon-Thurston map for $\widetilde{\phi_\infty}$.

Finally we turn to Question 5.8 (3), which turns out to be the subtlest. In Mj and Series [2013] we showed that the answer to Question 5.8 (3) is 'Yes' if the geometric limit is geometrically finite. We illustrate this with a concrete example due to Kerckhoff and Thurston Kerckhoff and Thurston [1990]

Theorem 5.12. *Fix a closed hyperbolic surface S and a simple closed geodesic σ on it. Let tw^i denote the automorphism of S given by an i-fold Dehn twist along σ. Let G_i be the quasi-Fuchsian group given by the simultaneous uniformization of $(S, tw^i(S))$. Let G_∞ denote the geometric limit of the G_i's. Let S_{i-} denote the lower boundary component of the convex core of G_i, $i = 1, \cdots, \infty$ (including ∞). Let $\phi_i : S \to S_{i-}$ be such that if $0 \in \mathbb{H}^2 = \widetilde{S}$ denotes the origin of $\mathbb{H}^2$ then $\widetilde{\phi_i}(0)$ lies in a uniformly bounded neighborhood of $0 \in \mathbb{H}^3 = \widetilde{M_i}$. We also assume (using the fact that M_∞ is a geometric limit of M_i's) that S_{i-}'s converge geometrically to $S_{\infty-}$. Then the Cannon-Thurston maps for $\widetilde{\phi_i}$ converge pointwise, but not uniformly, on $\partial\mathbb{H}^2$ to the Cannon-Thurston map for $\widetilde{\phi_\infty}$.*

However, if the geometric limit is geometrically infinite, then the answer to Question 5.8 (3) may be negative. We illustrate this with certain examples of geometric limits constructed by Brock in Brock [2001].

Theorem 5.13. *Mj and Series [2017] Fix a closed hyperbolic surface S and a separating simple closed geodesic σ on it, cutting S up into two pieces S_- and S_+. Let ϕ denote an automorphism of S such that $\phi|_{S_-}$ is the identity and $\phi|_{S_+} = \psi$ is a pseudo-Anosov of S_+ fixing the boundary. Let G_i be the quasi-Fuchsian group given by the simultaneous uniformization of $(S, \phi^i(S))$. Let G_∞ denote the geometric limit of the G_i's. Let S_{i0} denote the lower boundary component of the convex core of G_i, $i = 1, \cdots, \infty$ (including ∞). Let $\phi_i : S \to S_{i0}$ be such that if $0 \in \mathbb{H}^2 = \widetilde{S}$ denotes the origin of $\mathbb{H}^2$ then $\widetilde{\phi_i}(0)$ lies in a uniformly bounded neighborhood of $0 \in \mathbb{H}^3 = \widetilde{M_i}$. We also assume (using the fact that M_∞ is a geometric limit of M_i's) that S_{i0}'s converge geometrically to $S_{\infty 0}$.*

Let Σ be a complete hyperbolic structure on S_+ such that σ is homotopic to a cusp on Σ. Let $\mathfrak{L}$ consist of pairs (ξ_-, ξ) of ideal endpoints (on $\mathbb{S}^1_\infty$) of stable leaves λ of the stable lamination of ψ acting on $\widetilde{\Sigma}$. Also let $\partial\widetilde{\mathfrak{H}}$ denote the collection of ideal basepoints of horodisks given by lifts (contained in $\widetilde{\Sigma}$) of the cusp in Σ corresponding to σ. Let

$$\Xi = \{\xi : \text{There exists } \xi_- \text{ such that } (\xi_-, \xi) \in \mathfrak{L}; \xi_- \in \partial\widetilde{\mathfrak{H}}\}.$$

Let $\partial\phi_i$, $i = 1 \cdots, \infty$ denote the Cannon-Thurston maps for $\widetilde{\phi_i}$. Then

1. *$\partial\phi_i(\xi)$ does not converge to $\partial\phi_\infty(\xi)$ for $\xi \in \Xi$.*
2. *$\partial\phi_i(\xi)$ converges to $\partial\phi_\infty(\xi)$ for $\xi \notin \Xi$.*

In Mj and Ohshika [2017], we identify the exact criteria that lead to the discontinuity phenomenon of Theorem 5.13.

6 Gromov-Hyperbolic groups

6.1 Applications and Generalizations.

6.1.1 Normal subgroups and trees. The ladder construction of Section 3.2 has been generalized considerably. We work in the context of an exact sequence $1 \to N \to G \to Q \to 1$, with N hyperbolic and G finitely presented. We observe that for the proof of Theorem 3.5 to go through it suffices to have a qi-section of Q into G to provide a 'coarse transversal' to flow. Such a qi-section was shown to exist by Mosher [1996]. We then obtain the following.

Theorem 6.1. *Mitra [1998a] Let G be a hyperbolic group and let H be a hyperbolic normal subgroup that is normal in G. Then the inclusion of Cayley graphs $i : \Gamma_H \to \Gamma_G$ gives a Cannon-Thurston map $\hat{i} : \widehat{\Gamma_H} \to \widehat{\Gamma_G}$.*

The ladder construction can also be generalized to the general framework of a tree of hyperbolic metric spaces.

Theorem 6.2. *Mitra [1998b] Let (X, d) be a tree (T) of hyperbolic metric spaces satisfying the qi-embedded condition (i.e. edge space to vertex space inclusions are qi-embeddings). Let v be a vertex of T and (X_v, d_v) be the vertex space corresponding to v. If X is hyperbolic then the inclusion $i : X_v \to X$ gives a Cannon-Thurston map $\hat{i} : \widehat{X_v} \to \widehat{X}$.*

Theorem 6.1 was generalized by the author and Sardar to a purely coarse geometric context, where no group action is present. The relevant notion is that of a metric bundle for which we refer the reader to Mj and Sardar [2012]. Roughly speaking, the data of a metric bundle consists of vertex and edge spaces as in the case of a tree of spaces, with two notable changes:

1. The base T is replaced by an arbitrary graph B.
2. All edge-space to vertex space maps are quasi-isometries rather than just quasi-isometric embeddings.

With these modifications in place we have the following generalizations of Mosher's qi-section Lemma Mosher [1996] and Theorem 6.1:

Theorem 6.3. *Mj and Sardar [2012] Suppose $p : X \to B$ is a metric graph bundle satisfying the following:*

1. *B is a Gromov hyperbolic graph.*
2. *Each fiber F_b, for b a vertex of B is δ-hyperbolic (for some $\delta > 0$) with respect to the path metric induced from X.*
3. *The barycenter maps $\partial^3 F_b \to F_b$, $b \in B$, sending a triple of distinct points on the boundary ∂F_b to their centroid, are (uniformly, independent of b) coarsely surjective.*

4. X is hyperbolic.

Then there is a qi-section $B \to X$. The inclusion map $i_b : F_b \to X$ gives a Cannon-Thurston map $\hat{i} : \widehat{F_b} \to \widehat{X}$.

6.2 Point pre-images: Laminations. In Section 3.1, it was pointed out that the Cannon-Thurston map $\hat{i}$ identifies $p, q \in S^1$ if and only if p, q are end-points of a leaf or ideal end-points of a complementary ideal polygon of the stable or unstable lamination.

In Mitra [1997a] an algebraic theory of ending laminations was developed based on Thurston's theory Thurston [1980]. The theory was developed in the context of a normal hyperbolic subgroup of a hyperbolic group G and used to give an explicit structure for the Cannon-Thurston map in Theorem 6.1.

Definition 6.4. *Bestvina, Feighn, and Handel [1997], Coulbois, Hilion, and Lustig [2007, 2008a,b], I. Kapovich and Lustig [2010, 2015], and Mitra [1997a] An* algebraic lamination *for a hyperbolic group H is an H-invariant, flip invariant, closed subset $\mathcal{L} \subseteq \partial^2 H = (\partial H \times \partial H \setminus \Delta)/\sim$, where $(x, y) \sim (y, x)$ denotes the flip and Δ the diagonal in $\partial H \times \partial H$.*

Let
$$1 \to H \to G \to Q \to 1$$
be an exact sequence of finitely presented groups with H, G hyperbolic. It follows by work of Mosher [1996] that Q is hyperbolic. In Mitra [1997a], we construct algebraic ending laminations naturally parametrized by points in the boundary ∂Q. We describe the construction now.

Every element $g \in G$ gives an automorphism of H sending h to $g^{-1}hg$ for all $h \in H$. Let $\phi_g : \mathcal{V}(\Gamma_H) \to \mathcal{V}(\Gamma_H)$ be the resulting bijection of the vertex set $\mathcal{V}(\Gamma_H)$ of Γ_H. This induces a map Φ_g sending an edge $[a, b] \subset \Gamma_H$ to a geodesic segment joining $\phi_g(a), \phi_g(b)$.

For some (any) $z \in \partial\Gamma_Q$ we shall describe an algebraic ending lamination Λ_z. Fix such a z and let

1. $[1, z) \subset \Gamma_Q$ be a geodesic ray starting at 1 and converging to $z \in \partial\Gamma_Q$.

2. $\sigma : Q \to G$ be a qi section.

3. z_n be the vertex on $[1, z)$ such that $d_Q(1, z_n) = n$.

4. $g_n = \sigma(z_n)$.

For $h \in H$, let $\mathcal{S}_n^h$ be the H–invariant collection of all free homotopy representatives (or equivalently, shortest representatives in the same conjugacy class) of $\phi_{g_n^{-1}}(h)$ in Γ_H.

Identifying equivalent geodesics in $\mathcal{S}_n^h$ one obtains a subset $\mathbb{S}_n^h$ of unordered pairs of points in $\widehat{\Gamma_H}$. The intersection with $\partial^2 H$ of the union of all subsequential limits (in the Hausdorff topology) of $\{\mathbb{S}_n^h\}$ is denoted by Λ_z^h.

Definition 6.5. *The set of* algebraic ending laminations corresponding to $z \in \partial\Gamma_Q$ *is given by*

$$\Lambda_{EL}(z) = \bigcup_{h \in H} \Lambda_z^h.$$

Definition 6.6. *The set Λ of all algebraic ending laminations is defined by*

$$\Lambda_{EL} = \bigcup_{z \in \partial\Gamma_Q} \Lambda_{EL}(z).$$

The following was shown in Mitra [1997a]:

Theorem 6.7. *The Cannon-Thurston map $\hat{i}$ of Theorem 6.1 identifies the end-points of leaves of Λ_{EL}. Conversely, if $\hat{i}(p) = \hat{i}(q)$ for $p \neq q \in \partial\Gamma_H$, then some bi-infinite geodesic having p, q as its end-points is a leaf of Λ_{EL}.*

6.2.1 Finite-to-one. The classical Cannon-Thurston map of Theorem 2.2 is finite-to-one. Swarup asked (cf. Bestvina's Geometric Group Theory problem list Bestvina [2004, Prolem 1.20]) if the Cannon-Thurston maps of Theorem 6.1 are also finite-to-one. Kapovich and Lustig answered this in the affirmative in the following case.

Theorem 6.8. *I. Kapovich and Lustig [2015] Let $\phi \in Out(F_N)$ be a fully irreducible hyperbolic automorphism. Let $G_\phi = F_N \rtimes_\phi \mathbb{Z}$ be the associated mapping torus group. Let ∂i denote the Cannon-Thurston map of Theorem 6.1 in this case. Then for every $z \in \partial G_\phi$, the cardinality of $(\partial i)^{-1}(z)$ is at most $2N$.*

Bestvina, Feighn, and Handel [1997] define a closely related set Λ_{BFH} of algebraic laminations in the case covered by Theorem 6.8 using train-track representatives of free group automorphisms. Any algebraic lamination $\mathcal{L}$ defines a relation $\mathcal{R}_\mathcal{L}$ on ∂F_N by $a\mathcal{R}_\mathcal{L}b$ if $(a,b) \in \mathcal{L}$. The transitive closure of $\mathcal{L}$ will be called its diagonal closure. In I. Kapovich and Lustig [2015], Kapovich and Lustig further show that in the case covered by Theorem 6.8, Λ_{EL} precisely equals the diagonal closure of Λ_{BFH}.

6.3 Relative hyperbolicity. The notion of a Cannon-Thurston map can be extended to the context of relative hyperbolicity. This was done in Mj and Pal [2011]. Let X and Y be relatively hyperbolic spaces, hyperbolic relative to the collections $\mathcal{H}_X$ and $\mathcal{H}_Y$ of 'horosphere-like sets' respectively. Let us denote the *horoballifications* of X and Y with respect to $\mathcal{H}_X$ and $\mathcal{H}_Y$ by $\mathcal{G}(X, \mathcal{H}_X), \mathcal{G}(Y, \mathcal{H}_Y)$ respectively (see B. H. Bowditch [2012] for details). The horoballification of an H in $\mathcal{H}_X$ or $\mathcal{H}_Y$ is denoted as H^h. Note that $\mathcal{G}(X, \mathcal{H}_X), \mathcal{G}(Y, \mathcal{H}_Y)$ are hyperbolic. The electrifications will be denoted as $\mathcal{E}(X, \mathcal{H}_X), \mathcal{E}(Y, \mathcal{H}_Y)$.

Definition 6.9. *A map $i : Y \to X$ is strictly type-preserving if*

1. *for all $H_Y \in \mathcal{H}_Y$ there exists $H_X \in \mathcal{H}_X$ such that $i(H_Y) \subset H_X$, and*

2. *images of distinct horospheres-like sets in Y lie in distinct horosphere-like sets in X.*

Let $i : Y \to X$ be a strictly type-preserving proper embedding. Then i induces a proper embedding $i_h : \mathcal{G}(Y, \mathcal{H}_Y) \to \mathcal{G}(X, \mathcal{H}_X)$.

Definition 6.10. *A Cannon-Thurston map exists for a strictly type-preserving inclusion $i : Y \to X$ of relatively hyperbolic spaces if a Cannon-Thurston map exists for the induced map $i_h : \mathcal{G}(Y, \mathcal{H}_Y) \to \mathcal{G}(X, \mathcal{H}_X)$.*

Lemma 2.8 generalizes to the following.

Lemma 6.11. *A Cannon-Thurston map for $i : Y \to X$ exists if and only if there exists a non-negative proper function $M : \mathbb{N} \to \mathbb{N}$ such that the following holds:*
Fix a base-point $y_0 \in Y$. Let $\hat{\lambda}$ in $\mathcal{E}(Y, \mathcal{H}_Y)$ be an electric geodesic segment starting and ending outside horospheres. If $\lambda^b = \hat{\lambda} \setminus \bigcup_{K \in \mathcal{H}_Y} K$ lies outside $B_N(y_0) \subset Y$, then for any electric quasigeodesic $\hat{\beta}$ joining the end points of $\hat{i}(\hat{\lambda})$ in $\mathcal{E}(X, \mathcal{H}_X)$, $\beta^b = \hat{\beta} \setminus \bigcup_{H \in \mathcal{H}_X} H$ lies outside $B_{M(N)}(i(y_0)) \subset X$.

Theorem 6.2 then generalizes to:

Theorem 6.12. *Mj and Pal [2011] Let $P : X \to T$ be a tree of relatively hyperbolic spaces satisfying the qi-embedded condition. Assume that*

1. *the inclusion maps of edge-spaces into vertex spaces are strictly type-preserving*

2. *the induced tree of electrified (coned-off) spaces continues to satisfy the qi-embedded condition*

3. *X is strongly hyperbolic relative to the family $\mathcal{C}$ of maximal cone-subtrees of horosphere-like sets.*

Then a Cannon-Thurston map exists for the inclusion of relatively hyperbolic spaces $i : X_v \to X$, where (X_v, d_{X_v}) is the relatively hyperbolic vertex space corresponding to v.

6.4 Problems. The above survey is conditioned and limited by the author's bias on the one hand and space considerations on the other. In particular we have omitted the important work on quasigeodesic foliations by Calegari [2006, 2000], Fenley [2012], and Frankel [2015] and the topology of ending lamination spaces by Gabai and others Gabai [2014, 2009], C. J. Leininger, Mj, and Schleimer [2011], and Hensel and Przytycki [2011] as this would be beyond the scope of the present article. A more detailed survey appears in Papadopoulos [2007]. We end with some open problems.

6.4.1 Higher dimensional Kleinian groups. As a test-case we propose:

Question 6.13. *Let S be a closed surface of genus greater than one and let $\Gamma = \pi_1(S)$ act freely, properly discontinuously by isometries on $\mathbf{H}^n$, $n > 3$ (or more generally a rank one symmetric space). Does a Cannon-Thurston map exist in general?*

Can the small cancellation group of Baker-Riley in Baker and T. R. Riley [2013] act geometrically on a rank one symmetric space thus giving a negative answer to Question 6.13 with surface group replaced by free group? Work of Wise [2009] and Wise [2004] guarantees linearity of such small cancellation groups.

The critical problem in trying to answer Question 6.13 is the absence of new examples in higher dimensions. It would be good to find new examples or prove that they do not exist. A version of a question due to M. Kapovich [2008] makes this more precise and indicates our current state of knowledge/ignorance:

Question 6.14. *Let S be a closed surface of genus greater than one and let Γ be a discrete subgroup of $SO(n,1)$ (or more generally a rank one Lie group)) abstractly isomorphic to $\pi_1(S)$) acting by isometries on $\mathbf{H}^n$, $n > 3$ (more generally the associated symmetric space) such that*

1. *orbits are not quasiconvex,*
2. *no element of Γ is a parabolic.*

Does ρ factor through a representation to a simply or doubly degenerate (3-dimensional) Kleinian group followed by a deformation of $SO(3,1)$ in $SO(n,1)$?

A closely related folklore question asks:

Question 6.15. *Can a closed higher dimensional $n > 3$ rank one manifold fiber? In particular over the circle?*

It is known, from the Chern-Gauss-Bonnet theorem that a $2n$ dimensional rank one manifold cannot fiber over the circle. Unpublished work of M. Kapovich [1998] shows that a complex hyperbolic 4-manifold cannot fiber over a 2-manifold.

6.4.2 Surface groups in higher rank. A topic of considerable current interest is higher dimensional Teichmüller theory and Anosov representations of surface groups Labourie [2006], M. Kapovich, Leeb, and Porti [2017], and Guéritaud, Guichard, Kassel, and Wienhard [2017]. Kapovich, Leeb and Porti give an equivalent definition of Anosov representations in purely coarse geometric terms as representations that are *asymptotic embeddings*. It will take us too far afield to define these notions precisely here. What we will say however is that if $\rho : \pi_1(S) \to \mathcal{G}$ is a discrete faithful representation into a semi-simple Lie group $\mathcal{G}$ and $\mathcal{G}/\mathcal{P} = \mathcal{B}$ is the Furstenberg boundary, then the Anosov property implies that an orbit $\rho(\pi_1(S)).o$ 'extends' to a $\rho(\pi_1(S))$−equivariant embedding of $\partial\Gamma_{\pi_1(S)}(= S^1)$ into $\mathcal{B}$. Thus the boundary map $\Delta : S^1 \to \mathcal{B}$ maybe thought of as a *higher rank Cannon-Thurston map*. For the representation to be Anosov, Δ is thus an embedding M. Kapovich, Leeb, and Porti [2017].

Question 6.16. *What class of representations do we get if we require only that Δ is continuous?*

Question 6.16 is basically asking for a 'nice' characterization of representations that admit a higher rank Cannon-Thurston map. The core problem in addressing it again boils down to finding some rich class of examples. Question 6.14 has a natural generalization to this context where we replace $SO(n, 1)$ by $\mathcal{G}$.

6.4.3 Geometric group theory. As we have seen in Section 6.1, normal hyperbolic subgroups and trees of spaces provide examples where there is a positive answer to Question 2.7. Some sporadic new examples have also been found, e.g. hydra groups Baker and T. Riley [2012]. However no systematic theory exists. In the light of the counterexample in Baker and T. R. Riley [2013], the general answer to Question 2.7 is negative. Are there necessary and/or sufficient conditions beyond Lemma 2.8 to guarantee existence of Cannon-Thurston maps?

As illustrated in Mitra [1998b] and Baker and T. Riley [2012], distortion of subgroups Gromov [1993] is irrelevant. Distortion captures the relationship between $d_H(1, h)$ with $d_G(1, h)$. On the other hand Cannon-Thurston maps capture the corresponding relationship between $d_H(1, [h_1, h_2]_H)$ with $d_G(1, [h_1, h_2]_G)$, i.e. existence of Cannon-Thurston maps is equivalent to a proper embedding of 'pairs of points' (coding geodesic segments). The function associated with such a proper embedding is closely related to the modulus of continuity of the Cannon-Thurston map Baker and T. Riley [2012].

Acknowledgments. I would like to thank Benson Farb and Thomas Koberda for several helpful comments on an earlier draft.

GROUPS ACTING ACYLINDRICALLY ON HYPERBOLIC SPACES

Denis V. Osin

Abstract

The goal of this article is to survey some recent developments in the study of groups acting on hyperbolic spaces. We focus on the class of *acylindrically hyperbolic groups*; it is broad enough to include many examples of interest, yet a significant part of the theory of hyperbolic and relatively hyperbolic groups can be generalized in this context. In particular, we discuss group theoretic Dehn filling and small cancellation theory in acylindrically hyperbolic groups. Many results discussed here rely on the new generalization of relative hyperbolicity based on the notion of a *hyperbolically embedded subgroup*.

1 Introduction

Suppose that a group G acts by isometries on a metric space S. If the action is sufficiently "nice", many properties of G can be revealed by studying the geometric structure of G-orbits in S. This approach works especially well if S satisfies certain negative curvature condition.

Systematic research in this direction began in late 1980s when Gromov [1987] introduced the notion of an abstract hyperbolic metric space. Groups acting properly and cocompactly on hyperbolic spaces are called *word hyperbolic*. More generally, replacing properness with its relative analogue modulo a fixed collection of subgroups leads to the notion of a *relatively hyperbolic group*. The study of hyperbolic and relatively hyperbolic groups was initiated by Gromov [ibid.] and since then it has been one of the most active areas of research in geometric group theory.

A further generalization, the class of *acylindrically hyperbolic groups*, was suggested by Osin [2016] and received considerable attention in the past few years. It includes many examples of interest: non-elementary hyperbolic and relatively hyperbolic groups, all but

MSC2010: primary 20F65; secondary 20F67, 20F69.

finitely many mapping class groups of punctured closed surfaces, $Out(F_n)$ for $n \geq 2$, most 3-manifold groups, groups of deficiency at least 2, and the Cremona group of birational transformations of the complex projective plane, just to name a few. On the other hand, the property of being acylindrically hyperbolic is strong enough to allow one to apply powerful geometric techniques.

A significant part of the theory of relatively hyperbolic groups can be generalized to acylindrically hyperbolic groups using the notion of a *hyperbolically embedded collection of subgroups* introduced by Dahmani, Guirardel, and Osin [2017]. In particular, this notion provides a suitable framework for developing a group theoretic version of Thurston's theory of hyperbolic Dehn filling in 3-manifolds. Group theoretic Dehn filling was originally studied in the context of relatively hyperbolic groups by Groves and Manning [2008] and Osin [2007]. Recently it was used to obtain several deep results (most notably, it was employed in the proof of the virtual Haken conjecture by Agol [2013]). Yet another powerful tool is *small cancellation theory*, which can be used to prove various embedding theorems and to construct groups with unusual properties, see Hull [2016] and Osin [2010].

The main purpose of this paper is to survey the recent progress in the study of acylindrically hyperbolic groups and their hyperbolically embedded subgroups. In the next section we briefly discuss equivalent definitions, main examples, and basic properties of acylindrically hyperbolic groups. Hyperbolically embedded subgroups are discussed in Section 3. Section 4 is devoted to group theoretic Dehn filling. An informal discussion of small cancellation theory and a survey of some application is given in Section 5.

2 Acylindrically hyperbolic groups

2.1. Hyperbolic spaces and group actions. We begin by recalling basic definitions and general results about groups acting on hyperbolic spaces. Our main reference is Gromov [1987]; additional details can be found in Bridson and Haefliger [1999] and Ghys and de la Harpe [1990]. All group actions on metric spaces discussed in this paper are assumed to be isometric by default.

Definition 2.1. A metric space S is *hyperbolic* if it is geodesic and there exists $\delta \geq 0$ such that for any geodesic triangle Δ in S, every side of Δ is contained in the union of the δ-neighborhoods of the other two sides.

Example 2.2. Every bounded space S is hyperbolic with $\delta = \operatorname{diam}(S)$. Every tree is hyperbolic with $\delta = 0$. $\mathbb{H}^n$ is hyperbolic for every $n \in \mathbb{N}$. On the other hand, $\mathbb{R}^n$ is not hyperbolic for $n \geq 2$.

Given a hyperbolic space S, we denote by ∂S its *Gromov boundary*. We do not assume that the space is proper and therefore the boundary is defined as the set of equivalence classes of sequences of points convergent at infinity; for details we refer to Gromov [1987, Section 1.8]. The union $\widehat{S} = S \cup \partial S$ is a completely metrizable Hausdorff topological space containing S as a dense subset.

Example 2.3. The Gromov boundary of a bounded space is empty. $\partial(\mathbb{H}^n) = \mathbb{S}^{n-1}$. The boundary of an n-regular tree is the Cantor set if $n \geq 3$ and consists of two points if $n = 2$.

Let G be a group acting (isometrically) on a hyperbolic space S. This action extends to an action on $\widehat{S}$ by homeomorphisms. We denote by $\Lambda(G)$ the *limit set* of G, that is, the set of accumulation points of a G-orbit on ∂S. Thus

$$\Lambda(G) = \overline{Gs} \cap \partial S,$$

where $s \in S$ and $\overline{Gs}$ is the closure of the corresponding orbit. In fact, this definition is independent of the choice of $s \in S$. Given an element $g \in G$, we denote $\Lambda(\langle g \rangle)$ simply by $\Lambda(g)$ and call it the *limit set* of g.

Similarly to the classification of elements of $PSL(2, \mathbb{R}) = \operatorname{Isom} \mathbb{H}^2$, we have the following classification of isometries of abstract hyperbolic spaces.

Definition 2.4. An element $g \in G$ is called *elliptic* if $\Lambda(g) = \varnothing$ (equivalently, all orbits of $\langle g \rangle$ are bounded), *parabolic* if $|\Lambda(g)| = 1$; and *loxodromic* if $|\Lambda(g)| = 2$. Equivalently, an element $g \in G$ is loxodromic if the map $\mathbb{Z} \to S$ defined by $n \mapsto g^n s$ is a quasi-isometric embedding for every $s \in S$; in turn, this is equivalent to the existence of $c > 0$ such that $\mathrm{d}_S(s, g^n s) \geq c|n|$ for all $n \in \mathbb{Z}$. Two loxodromic elements $g, h \in G$ are called *independent* if $\Lambda(g) \cap \Lambda(h) = \varnothing$.

We recall the standard classification of groups acting on hyperbolic spaces, which goes back to Gromov [ibid., Section 8.2].

Theorem 2.5 (Gromov)**.** *For every group G acting on a hyperbolic space S, exactly one of the following conditions holds.*

1) $|\Lambda(G)| = 0$*. Equivalently, G has bounded orbits. In this case the action of G is called* elliptic.

2) $|\Lambda(G)| = 1$*. Equivalently, G has unbounded orbits and contains no loxodromic elements. In this case the action of G is called* parabolic.

3) $|\Lambda(G)| = 2$*. Equivalently, G contains loxodromic elements and any two loxodromic elements have the same limit points. In this case the action of G is called* lineal.

4) $|\Lambda(G)| = \infty$*. Then G always contains loxodromic elements. In turn, this case breaks into two subcases.*

a) *G fixes a point* $\xi \in \partial S$*. In this case* ξ *is the common limit point of all loxodromic elements of* G*. Such an action is called* quasi-parabolic.

b) *G has no fixed points on* ∂S*. Equivalently,* G *contains independent loxodromic elements. In this case the action is said to be of* general type.

Definition 2.6. The action of G is called *elementary* in cases 1)–3) and *non-elementary* in case 4).

An action of a group G on a metric space S is called (metrically) *proper* if the set $\{g \in G \mid \mathrm{d}_S(s, gs) \le r\}$ is finite for all $s \in S$ and $r \in \mathbb{R}_+$. Further, the action of G is *cobounded* if there exists a bounded subset $B \subseteq S$ such that $S = \bigcup_{g \in G} gB$. Finally, the action is *geometric* if it is proper and cobounded. (We work in the category of metric spaces here, so compactness gets replaced by boundedness.)

For geometric actions, we have the following, see Gromov [1987].

Theorem 2.7 (Gromov)**.** *Let* G *be a group acting geometrically on a hyperbolic space. Then exactly one of the following three conditions hold.*

(a) G *acts elliptically. In this case* G *is finite.*

(b) G *acts lineally. In this case* G *is virtually cyclic.*

(c) The action of G *is of general type.*

To every group G generated by a set X one can associate a natural metric space, namely the Cayley graph $\Gamma(G, X)$, on which G acts geometrically. The vertex set of $\Gamma(G, X)$ is G itself and two elements g, h are connected by an edge if $g = hx$ for some $x \in X^{\pm 1}$. This graph is endowed with the *combinatorial metric* induced by identification of edges with $[0, 1]$.

Definition 2.8. A group G is *hyperbolic* if it admits a geometric action on a hyperbolic space.

Equivalently, a group G generated by a finite set X is hyperbolic if the Cayley graph $\Gamma(G, X)$ is a hyperbolic metric space. The equivalence of these two definitions follows from the well-known Svarc-Milnor Lemma and quasi-isometry invariance of hyperbolicity of geodesic spaces, see Bridson and Haefliger [1999] and Gromov [1987] for details.

2.2. Equivalent definitions of acylindrical hyperbolicity. Recall that the action of a group G on a metric space S is *acylindrical* if for every $\varepsilon > 0$ there exist $R, N > 0$ such that for every two points x, y with $\mathrm{d}(x, y) \ge R$, there are at most N elements $g \in G$ satisfying

$$\mathrm{d}(x, gx) \le \varepsilon \quad \text{and} \quad \mathrm{d}(y, gy) \le \varepsilon.$$

The notion of acylindricity goes back to paper Sela [1997], where it was considered for groups acting on trees. In the context of general metric spaces, the above definition is due to Bowditch [2008]. Informally, one can think of this condition as a kind of properness of the action on $S \times S$ minus a "thick diagonal".

Example 2.9. (a) If S is a bounded space, then every action $G \curvearrowright S$ is acylindrical. Indeed it suffices to take $R > \operatorname{diam}(S)$.

(b) It is easy to see that every geometric action is acylindrical. On the other hand, proper actions need not be acylindrical in general.

We begin with a classification of groups acting acylindrically on hyperbolic spaces. The following theorem is proved by Osin [2016] and should be compared to compared to Theorems 2.5 and 2.7.

Theorem 2.10. *Let G be a group acting acylindrically on a hyperbolic space. Then exactly one of the following three conditions holds.*

(a) G acts elliptically, i.e., G has bounded orbits.

(b) G acts lineally. In this case G is virtually cyclic.

(c) The action of G is of general type.

Compared to the general classification of groups acting on hyperbolic spaces, Theorem 2.10 rules out parabolic and quasi-parabolic actions and characterizes groups acting lineally. On the other hand, compared to Theorem 2.7, finiteness of elliptic groups is lacking. This part of Theorem 2.10 cannot be improved, see Example 2.9 (a).

Applying the theorem to cyclic groups, we obtain the following result first proved by Bowditch [2008].

Corollary 2.11. *Every element of a group acting acylindrically on a hyperbolic space is either elliptic or loxodromic.*

Definition 2.12. We call a group G *acylindrically hyperbolic* if it admits a non-elementary acylindrical action on a hyperbolic space. By Theorem 2.10, this is equivalent to the requirement that G is not virtually cyclic and admits an acylindrical action on a hyperbolic space with unbounded orbits.

Unfortunately, Definition 2.12 is hard to verify in practice. Instead, one often first proves that the group satisfies a seemingly weaker condition, which turns out to be equivalent to acylindrical hyperbolicity. To formulate this condition we need a notion introduced by Bestvina and Fujiwara [2002].

Definition 2.13. Let G be a group acting on a hyperbolic space S, g an element of G. One says that g satisfies the *weak proper discontinuity* condition (or g is a *WPD element*) if for every $\varepsilon > 0$ and every $s \in S$, there exists $M \in \mathbb{N}$ such that

$$(1) \qquad \left|\{a \in G \mid \mathrm{d}_S(s, as) < \varepsilon,\ \mathrm{d}(g^M s, ag^M s) < \varepsilon\}\right| < \infty.$$

Obviously this condition holds for any $g \in G$ if the action of G is proper and for every loxodromic $g \in G$ if G acts on S acylindrically.

Theorem 2.14 (Osin [2016, Theorem 1.2]). *For any group G, the following conditions are equivalent.*

(a) G is acylindrically hyperbolic.

(b) G is not virtually cyclic and admits an action on a hyperbolic space such that at least one element of G is loxodromic and satisfies the WPD condition.

(c) There exists a generating set X of G such that the corresponding Cayley graph $\Gamma(G, X)$ is hyperbolic, $|\partial\Gamma(G, X)| > 2$, and the natural action of G on $\Gamma(G, X)$ is acylindrical.

Part (c) of this theorem is especially useful for studying properties of acylindrically hyperbolic groups since it allows to pass from a (possibly non-cobounded) action of G on a general hyperbolic space to the more familiar action on the Cayley graph. It was recently proved by Balasubramanya [2017] that one can ensure even a stronger condition, namely that $\Gamma(G, X)$ is quasi-isometric to a tree.

2.3. Examples. Obviously every geometric action is acylindrical. In particular, this applies to the action of any finitely generated group on its Cayley graph with respect to a finite generating set. Thus every hyperbolic group is virtually cyclic or acylindrically hyperbolic. More generally, non-virtually-cyclic relatively hyperbolic groups with proper peripheral subgroups are acylindrically hyperbolic. In the latter case the action on the relative Cayley graph is non-elementary and acylindrical, see Osin [2016]. Below we discuss some less obvious examples.

(a) *Mapping class groups.* The mapping class group $MCG(\Sigma_{g,p})$ of a closed surface of genus g with p punctures is acylindrically hyperbolic unless $g = 0$ and $p \le 3$ (in these exceptional cases, $MCG(\Sigma_{g,p})$ is finite). For $(g, p) \in \{(0, 4), (1, 0), (1, 1)\}$ this follows from the fact that $MCG(\Sigma_{g,p})$ is non-elementary hyperbolic. For all other values of (g, p) this follows from hyperbolicity of the curve complex $\mathcal{C}(\Sigma_{g,p})$ of $\Sigma_{g,p}$ first proved by Masur and Minsky [1999] and acylindricity of the action of $MCG(\Sigma_{g,p})$ on $\mathcal{C}(\Sigma_{g,p})$, which is due to Bowditch [2008].

(b) $Out(F_n)$. Let $n \geq 2$ and let F_n be the free group of rank n. Bestvina and Feighn [2010] proved that for every fully irreducible automorphism $f \in Out(F_n)$ there exists a hyperbolic graph such that $Out(F_n)$ acts on it and the action of f satisfies the weak proper discontinuity condition. Thus $Out(F_n)$ is acylindrically hyperbolic by Theorem 2.14.

(c) *Groups acting on $CAT(0)$ spaces.* Sisto [2011] showed that if a group G acts properly on a proper $CAT(0)$ space and contains a rank one element, then G is either virtually cyclic or acylindrically hyperbolic. Together with the work of Caprace and Sageev [2011], this implies the following alternative for right angled Artin groups: every right angled Artin group is either cyclic, decomposes as a direct product of two non-trivial groups, or acylindrically hyperbolic. An alternative proof of the later result was found by Kim and Koberda [2014]. A similar theorem holds for graph products of groups and, even more generally, subgroups of graph products, see Minasyan and Osin [2015]. For a survey of examples of acylindrically hyperbolic groups arising from actions on $CAT(0)$ cubical complexes we refer to Genevois [2017].

(d) *Fundamental groups of graphs of groups.* The following theorem was proved by Minasyan and Osin [2015].

Theorem 2.15. *Let G be a group acting minimally on a simplicial tree T. Suppose that G does not fix any point of ∂T and there exist vertices u, v of T such that the pointwise stabilizer of $\{u, v\}$ is finite. Then G is either virtually cyclic or acylindrically hyperbolic.*

If G is the fundamental group of a graph of groups $\mathcal{G}$, then one can apply Theorem 2.15 to the action of G on the associated Bass-Serre tree. In this case the minimality of the action and the absence of fixed points on ∂T can be recognized from the local structure of $\mathcal{G}$. We mention here two particular cases. We say that a subgroup C of a group G is *weakly malnormal* if there exists $g \in G$ such that $|C^g \cap C| < \infty$.

Corollary 2.16. *Let G split as a free product of groups A and B with an amalgamated subgroup C. Suppose $A \neq C \neq B$ and C is weakly malnormal in G. Then G is either virtually cyclic or acylindrically hyperbolic.*

Note that the virtually cyclic case cannot be excluded from this corollary. Indeed it realizes if C is finite and has index 2 in both factors.

Corollary 2.17. *Let G be an HNN-extension of a group A with associated subgroups C and D. Suppose that $C \neq A \neq D$ and C is weakly malnormal in G. Then G is acylindrically hyperbolic.*

These results were used by Minasyan and Osin [ibid.] to prove acylindrical hyperbolicity of a number of groups. E.g., it implies that for every field k, the automorphism group $Aut\, k[x, y]$ of the polynomial algebra $k[x, y]$ is acylindrically hyperbolic. Some other applications are discussed below.

(e) 3*-manifold groups.* Minasyan and Osin [2015] (see also Minasyan and Osin [2017]) proved that for every compact orientable irreducible 3-manifold M, the fundamental group $\pi_1(M)$ is either virtually polycyclic, or acylindrically hyperbolic, or M is Seifert fibered. In the latter case, $\pi_1(M)$ contains a normal subgroup $N \cong \mathbb{Z}$ such that $\pi_1(M)/N$ is acylindrically hyperbolic.

(f) *Groups of deficiency at least* 2*.* In Osin [2015], the author proved that every group which admits a finite presentation with at least 2 more generators than relations is acylindrically hyperbolic. (The original proof contained a gap which is fixed in Minasyan and Osin [2017].) Interestingly, the proof essentially uses results about ℓ^2-Betti numbers of groups.

(g) *Miscellaneous examples.* Other examples include central quotients of Artin-Tits groups of spherical type (see Calvez and Wiest [2017]) and of FC type with underlying Coxeter graph of diameter at least 3 (see Chatterji and Martin [2016]), small cancellation groups, including infinitely presented ones, (see Gruber and Sisto [2014]), orthogonal forms of Kac–Moody groups over arbitrary fields (see Caprace and Hume [2015]), the Cremona group (see Dahmani, Guirardel, and Osin [2017] and references therein; the main contribution towards this result is due to Cantat and Lamy [2013]), and non-elementary convergence groups (see Sun [2017]).

2.4. Some algebraic and analytic properties. Our next goal is to survey some algebraic and analytic properties of acylindrically hyperbolic groups.

(a) *Finite radical.* Every acylindrically hyperbolic group G contains a unique maximal finite normal subgroup denoted $K(G)$ and called the *finite radical* of G, see Dahmani, Guirardel, and Osin [2017]. It also coincides with the amenable radical of G. In particular, G has no infinite amenable normal subgroups.

(b) *SQ-univerality.* Recall that a group G is *SQ-universal* if every countable group can be embedded into a quotient of G. Informally, this property can be considered as an indication of algebraic "largeness" of G. Dahmani, Guirardel, and Osin [ibid.] proved the following result by using group theoretic Dehn filling.

Theorem 2.18. *Every acylindrically hyperbolic group is SQ-universal.*

One consequence of this, also obtained by Dahmani, Guirardel, and Osin [ibid.], is that every subgroup of the mapping class group $MCG(\Sigma)$ of a punctured closed surface Σ is either virtually abelian or SQ-universal. It is easy to show using cardinality arguments that every finitely generated SQ-universal group has uncountably many non-isomorphic quotients. This observation allows one to reprove various (well-known) non-embedding theorems for higher rank lattices in mapping class groups since these lattices have countably many normal subgroups by the Margulis normal subgroup theorem. For instance, we immediately obtain that every homomorphism from an irreducible lattice in a connected semisimple Lie group of $\mathbb{R}$-rank at least 2 with finite center to $MCG(\Sigma)$ has finite image (compare to the main result of Farb and Masur [1998]).

(c) *Mixed identities.* A group G satisfies a *mixed identity* $w = 1$ for some $w \in G * F_n$, where F_n denotes the free group of rank n, if every homomorphism $G * F_n \to G$ that is identical on G sends w to 1. A mixed identity $w = 1$ is non-trivial if $w \neq 1$ as an element of $G * F_n$. We say that G is *mixed identity free* (or *MIF* for brevity) if it does not satisfy any non-trivial mixed identity.

The property of being MIF is much stronger than being identity free and imposes strong restrictions on the algebraic structure of G. For example, if G has a non-trivial center, then it satisfies the non-trivial mixed identity $[a, x] = 1$, where $a \in Z(G) \setminus \{1\}$. Similarly, it is easy to show (see Hull and Osin [2016b]) that a MIF group has no finite normal subgroups, is directly indecomposable, has infinite girth, etc. By constructing highly transitive permutation representations of acylindrically hyperbolic groups, Hull and the author proved that every acylindrically hyperbolic group with trivial finite radical is MIF.

(d) *Quasi-cocycles and bounded cohomology.* The following theorem was proved in several papers under various assumptions (see Bestvina, Bromberg, and Fujiwara [2016], Bestvina and Fujiwara [2002], Hamenstädt [2008], and Hull and Osin [2013] and references therein), which later turned out to be equivalent to acylindrical hyperbolicity.

Theorem 2.19. *Suppose that a group G is acylindrically hyperbolic. Let $V = \mathbb{R}$ or $V = \ell^p(G)$ for some $p \in [1, +\infty)$. Then the kernel of the natural map $H^2_b(G, V) \to H^2(G, V)$ is infinite dimensional. In particular,* $\dim H^2_b(G, V) = \infty$.

This result opens the door for Monod and Shalom [2006] rigidity theory for group actions on spaces with measure. It also implies that acylindrically hyperbolic groups are not boundedly generated, i.e., are not products of finitely many cyclic subgroups.

(e) *Stability properties.* It is not difficult to show that the class of acylindrically hyperbolic groups is stable under taking extensions with finite kernel and quotients modulo finite normal subgroups. It is also stable under taking finite index subgroups and, more generally, s-normal subgroups Osin [2016]. Recall that a subgroup N of a group G is s-normal if $g^{-1}Ng \cap N$ is infinite for all $g \in G$.

On the other hand, it is not known if acylindrical hyperbolicity is stable under finite extensions (see Minasyan and Osin [2017]). More generally, we propose the following.

Question 2.20. *(a) Is acylindrical hyperbolicity of finitely generated groups a quasi-isometry invariant?*

(b) Is acylindrical hyperbolicity a measure equivalence invariant?

The last question is partially motivated by the fact that the property $H^2_b(G, \ell^2(G)) \neq 0$ enjoyed by all acylyndrically hyperbolic groups by Theorem 2.19 is a measure equivalence invariant. For details we refer to Monod and Shalom [2006].

3 Hyperbolically embedded subgroups

3.1. Definition and basic examples. Hyperbolically embedded collections of subgroups were introduced by Dahmani, Guirardel, and Osin [2017] as generalizations of peripheral subgroups of relatively hyperbolic groups. To simplify our exposition we restrict here to the case of a single subgroup; the general case only differs by notation.

Let G be a group, H a subgroup of G. Suppose that X is a relative generating set of G with respect to H, i.e., $G = \langle X \cup H \rangle$. We denote by $\Gamma(G, X \sqcup H)$ the Cayley graph of G whose edges are labeled by letters from the alphabet $X \sqcup H$. That is, two vertices $f, g \in G$ are connected by an edge going from f to g and labeled by $a \in X \sqcup H$ iff $fa = g$ in G. Disjointness of the union in this definition means that if a letter $h \in H$ and a letter $x \in X$ represent the same element $a \in G$, then for every $g \in G$, the Cayley graph $\Gamma(G, X \sqcup H)$ will have two edges connecting g and ga: one labelled by h and the other labelled by x.

We naturally think of the Cayley graph $\Gamma_H = \Gamma(H, H)$ of H with respect to the generating set H as a (complete) subgraph of $\Gamma(G, X \sqcup H)$.

Definition 3.1. Let G be a group, $H \leq G$, and X a (possibly infinite) subset of G. We say that H is *hyperbolically embedded in G with respect to X* (we write $H \hookrightarrow_h (G, X)$) if $G = \langle X \cup H \rangle$ and the following conditions hold.

(a) The Cayley graph $\Gamma(G, X \sqcup H)$ is hyperbolic.

(b) For every $n \in \mathbb{N}$, there are only finitely many elements $h \in H$ such that the vertices h and 1 can be connected in $\Gamma(G, X \sqcup H)$ by a path of length at most n that avoids edges of Γ_H.

Further we say that H is hyperbolically embedded in G and write $H \hookrightarrow_h G$ if $H \hookrightarrow_h (G, X)$ for some $X \subseteq G$.

Note that for any group G we have $G \hookrightarrow_h G$. Indeed we can take $X = \varnothing$ in this case. Further, if H is a finite subgroup of a group G, then $H \hookrightarrow_h G$. Indeed $H \hookrightarrow_h (G, X)$ for $X = G$. These cases are referred to as *degenerate*. We consider two additional examples borrowed from Dahmani, Guirardel, and Osin [ibid.].

Example 3.2. (a) Let $G = H \times \mathbb{Z}$, $X = \{x\}$, where x is a generator of $\mathbb{Z}$. Then $\Gamma(G, X \sqcup H)$ is quasi-isometric to a line and hence it is hyperbolic. However, every two elements $h_1, h_2 \in H$ can be connected by a path of length at most 3 in $\Gamma(G, X \sqcup H)$ that avoids edges of Γ_H (see Figure 1). Thus $H \not\hookrightarrow_h (G, X)$ whenever H is infinite.

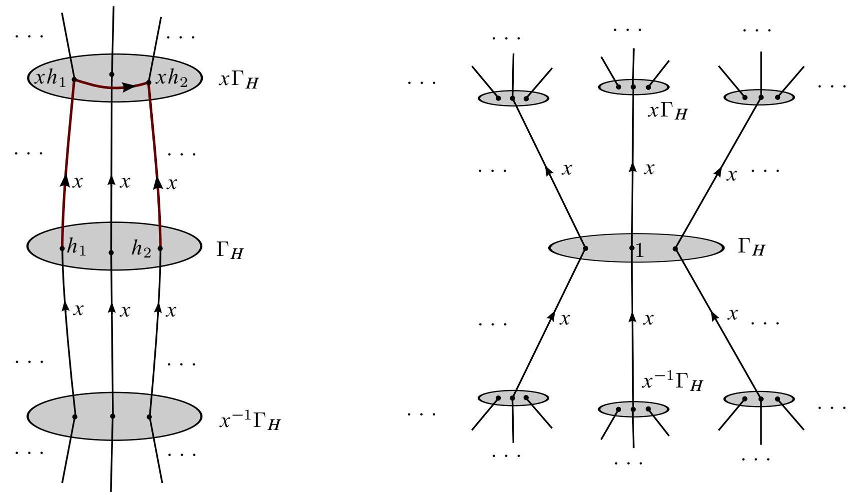

Figure 1: Cayley graphs $\Gamma(G, X \sqcup H)$ for $G = H \times \mathbb{Z}$ and $G = H * \mathbb{Z}$.

(b) Let $G = H * \mathbb{Z}$, $X = \{x\}$, where x is a generator of $\mathbb{Z}$. In this case $\Gamma(G, X \sqcup H)$ is quasi-isometric to a tree and no path connecting $h_1, h_2 \in H$ and avoiding edges of Γ_H exists unless $h_1 = h_2$. Thus $H \hookrightarrow_h (G, X)$.

It is worth noting that a version of the argument from Example 3.2 (a) can be used to show that every hyperbolically embedded subgroup $H \hookrightarrow_h G$ is *almost malnormal*, i.e., satisfies $|g^{-1}Hg \cap H| < \infty$ for all $g \in G$.

The following result is proved by Dahmani, Guirardel, and Osin [ibid.] and can be regarded as a definition of relatively hyperbolic groups.

Theorem 3.3. *Let G be a group, H a subgroup of G. Then G is hyperbolic relative to H if and only if $H \hookrightarrow_h (G, X)$ for some finite subset $X \subseteq G$.*

3.2. Hyperbolically embedded subgroups in acylindrically hyperbolic groups. It turns out that acylindrical hyperbolicity of a group can be characterized by the existence of hyperbolically embedded subgroups. More precisely, we have the following.

Theorem 3.4 (Osin [2016]). *A group G is acylindrically hyperbolic if and only if it contains non-degenerate hyperbolically embedded subgroups.*

Moreover, in every acylindrically hyperbolic group one can find hyperbolically embedded subgroups of certain special types. We mention two results of this sort proved by Dahmani, Guirardel, and Osin [2017]. The first one plays an important role in applications of group theoretic Dehn filling and small cancellation theory discussed below.

Theorem 3.5. *Let G be a group acting on a hyperbolic space and let $g \in G$ be a loxodromic WPD element. Then g is contained in a unique maximal virtually cyclic subgroup $E(g)$ of G and $E(g) \hookrightarrow_h G$.*

Recall that $K(G)$ denotes the final radical of an acylindrically hyperbolic group G and F_n denotes the free group of rank n.

Theorem 3.6. *Let G be an acylindrically hyperbolic group. Then for every $n \in \mathbb{N}$, there exists a subgroup $H \hookrightarrow_h G$ isomorphic to $F_n \times K(G)$.*

The latter theorem is especially useful in conjunction with various "extension" results proved by Abbott, Hume, and Osin [2017], Frigerio, Pozzetti, and Sisto [2015], and Hull and Osin [2013]. Roughly speaking, these results claim that various things (e.g., group actions on metric spaces or quasi-cocycles) can be "extended" from a hyperbolically embedded subgroup to the whole group.

4 Group theoretic Dehn filling

4.1. Dehn surgery in 3-manifolds. Dehn surgery on a 3-dimensional manifold consists of cutting of a solid torus from the manifold, which may be thought of as "drilling" along an embedded knot, and then gluing it back in a different way. The study of these "elementary transformations" of 3-manifolds is partially motivated by the Lickorish-Wallace theorem, which states that every closed orientable connected 3-manifold can be obtained by performing finitely many surgeries on the 3-dimensional sphere.

The second part of the surgery, called *Dehn filling*, can be formalized as follows. Let M be a compact orientable 3-manifold with toric boundary. Topologically distinct ways to attach a solid torus to ∂M are parameterized by free homotopy classes of unoriented essential simple closed curves in ∂M, called *slopes*. For a slope s, the corresponding Dehn filling $M(s)$ of M is the manifold obtained from M by attaching a solid torus $\mathbb{D}^2 \times \mathbb{S}^1$ to ∂M so that the meridian $\partial \mathbb{D}^2$ goes to a simple closed curve of the slope s.

The following fundamental theorem is due to Thurston [1982, Theorem 1.6].

Theorem 4.1 (Thurston's hyperbolic Dehn surgery theorem)**.** *Let M be a compact orientable 3-manifold with toric boundary. Suppose that $M \setminus \partial M$ admits a complete finite volume hyperbolic structure. Then $M(s)$ is hyperbolic for all but finitely many slopes s.*

4.2. Filling in hyperbolically embedded subgroups. Dehn filling can be generalized in the context of abstract group theory as follows. Let G be a group and let H be a subgroup of G. One can think of G and H as the analogues of $\pi_1(M)$ and $\pi_1(\partial M)$, respectively. Associated to any $\sigma \in H$, is the quotient group $G/\langle\langle s \rangle\rangle$, where $\langle\langle s \rangle\rangle$ denotes the normal closure of s in G.

If $G = \pi_1(M)$ and $H = \pi_1(\partial M) \cong \mathbb{Z} \oplus \mathbb{Z}$, where M is as in Thurston's theorem, then H is indeed a subgroup of G and for every slope s, which we think of as an element of H, we have

$$\pi_1(M(s)) = \pi_1(M)/\langle\langle s\rangle\rangle \tag{2}$$

by the Seifert-van Kampen theorem. Thus $G/\langle\langle s\rangle\rangle$ is the algebraic counterpart of the filling $M(s)$.

It turns out that the analogue of Thurston's theorem holds if we start with a pair $H \leq G$ such that H is hyperbolically embedded in G. The vocabulary translating geometric terms to algebraic ones can be summarized as follows (we abbreviate "complete finite volume" as CFV).

3-MANIFOLDS	**GROUPS**
a compact orientable 3-manifold M	a group G
∂M	$H \leq G$
$M \setminus \partial M$ admits a finite volume hyperbolic structure	H is hyperbolically embedded in G
a slope s	an element $h \in H$
$M(s)$	$G/\langle\langle h\rangle\rangle$

In these settings, the analogue of Thurston's theorem was proved by Dahmani, Guirardel, and Osin [2017]. Note that instead of considering single elements of H, we allow normal subgroups generated by arbitrary sets of elements. A number of additional properties can be added to the main statements (a)–(c); we mention just one of them, which is necessary for the applications considered in the next section.

Theorem 4.2. *Let G be a group, H a subgroup of G. Suppose that $H \hookrightarrow_h (G, X)$ for some $X \subseteq G$. Then there exists a finite subset $\mathfrak{F}$ of nontrivial elements of H such that for every subgroup $N \lhd H$ that does not contain elements of $\mathfrak{F}$, the following hold.*

(a) If G is acylindrically hyperbolic, then so is $G/\langle\langle N\rangle\rangle$, where $\langle\langle N\rangle\rangle$ denotes the normal closure of N in G.

(b) The natural map from H/N to $G/\langle\langle N\rangle\rangle$ is injective (equivalently, $H \cap \langle\langle N\rangle\rangle = N$).

(c) $H/N \hookrightarrow_h (G/\langle\langle N\rangle\rangle, \overline{X})$*, where* $\overline{X}$ *is the natural image of* X *in* $G/\langle\langle N\rangle\rangle$*.*

(d) $\langle\langle N\rangle\rangle$ *is the free product of conjugates of* N *in* G *and every element of* $\langle\langle N\rangle\rangle$ *is either conjugate to an element of* N *or acts loxodromically on* $\Gamma(G, X \sqcup H)$*.*

Note that if $H \hookrightarrow_h G$ is non-degenerate, then G is always acylindrically hyperbolic. However the theorem holds (trivially) for degenerate hyperbolically embedded subgroups as well.

Combining this theorem with Theorem 3.3 and some basic properties of relatively hyperbolic groups, we obtain the following result, which was first proved by Osin [2007]. It was also independently proved by Groves and Manning [2008] under the additional assumptions that the group G is torsion free and finitely generated.

Corollary 4.3. *Suppose that a group* G *is hyperbolic relative to a subgroup* $H \neq G$*. Then for any subgroup* $N \lhd H$ *avoiding a fixed finite set of nontrivial elements, the natural map from* H/N *to* $G/\langle\langle N\rangle\rangle$ *is injective and* $G/\langle\langle N\rangle\rangle$ *is hyperbolic relative to* H/N*. In particular, if* H/N *is hyperbolic, then so is* $G/\langle\langle N\rangle\rangle$*; if, in addition,* G *is non-virtually-cyclic, then so is* $G/\langle\langle N\rangle\rangle$*.*

Under the assumptions of Thurston's theorem, we have $H = \pi_1(\partial M) = \mathbb{Z} \oplus \mathbb{Z}$. Slopes in ∂M correspond to non-trivial primitive elements $s \in H$; for every such s, we have $H/\langle s\rangle \cong \mathbb{Z}$. Applying Corollary 4.3 to $N = \langle s\rangle \lhd H$, we obtain that $G/\langle\langle N\rangle\rangle$ is not virtually cyclic and hyperbolic. Modulo the geometrization conjecture this algebraic statement is equivalent to hyperbolicity of $M(s)$. Thus parts (a)–(c) of Theorem 4.2 indeed provide a group theoretic generalization of Thurston's theorem.

4.3. Applications. It is not feasible to discuss all applications of group theoretic Dehn surgery in a short survey. Here we list some of the results which make use of Theorem 4.2 or its relatively hyperbolic analogue, Corollary 4.3, and provide references for further reading. Then we pick one application and discuss it in more detail.

(a) *The virtual Haken conjecture.* Group theoretic Dehn filling in relatively hyperbolic groups, along with Wise's machinery of virtually special groups, was used in Agol's proof of the virtual Haken conjecture Agol [2013]. Additional results on Dehn filling necessary for the proof were obtained by Agol, Groves, and Manning in the appendix to Agol [ibid.]. One piece of Wise's work used by Agol [ibid.] is the malnormal special quotient theorem; Agol, Groves, and Manning [2016] also found an alternative proof of this result based on Dehn filling technique.

(b)*The isomorphism problem for relatively hyperbolic groups.* Dahmani and Guirardel [2015] and Dahmani and Touikan [2013] used Dehn filling to solve the isomorphism problem for relatively hyperbolic groups with residually finite parabolic subgroups under certain additional assumptions. The main idea is to apply (an elaborated version of) Corollary 4.3 to finite index normal subgroups in parabolic groups. This yields an approximation of relatively hyperbolic groups by hyperbolic ones, which in turn allows the authors make use of the solution of the isomorphism problem for hyperbolic groups obtained by Dahmani and Guirardel [2011].

(c) *Residual finiteness of outer automorphism groups.* Minasyan and Osin [2010] used Dehn filling in relatively hyperbolic groups to prove that $Out(G)$ is residually finite for every residually finite group G with infinitely many ends; in general, this result fails for one ended groups. This result was recently generalized to conjugacy separable acylindrically hyperbolic groups by Antolin, Minasyan, and Sisto. In particular, they proved residual finiteness of mapping class groups of certain Haken 3-manifolds. Acylindrical hyperbolicity of 3-manifold groups plays a crucial role in the proof.

(d) *Primeness of von Neumann algebras.* Chifan, Kida, and Pant [2016] used Dehn filling to prove primeness of von Neumann algebras of certain relatively hyperbolic groups. This means that these von Neumann algebras cannot be decomposed as a tensor product of diffuse von Neumann algebras.

(e) *Farell-Jones conjecture for relatively hyperbolic groups.* Bartels [2017] proved that the class of groups satisfying the Farell-Jones conjecture is stable under relative hyperbolicity. In the particular case when peripheral subgroups are residually finite, an alternative proof based on Dehn filling was found by Antolín, Coulon, and Gandini [2015].

(f) *SQ-universality of acylindrically hyperbolic groups.* One simple application of Theorem 4.2 is the proof of Theorem 2.18. It follows easily from SQ-universality of free groups of rank 2, Theorem 3.6, and part (b) of Theorem 4.2. For details, see Dahmani, Guirardel, and Osin [2017].

4.4. Purely pseudo-Anosov subgroups of mapping class groups. We illustrate Theorem 4.2 by considering an application to mapping class groups. Recall that a subgroup of a mapping class group is called *purely pseudo-Anosov*, if all its non-trivial elements are pseudo-Anosov. The following question is Problem 2.12(A) in Kirby's list: *Does the mapping class group of any closed orientable surface of genus* $g \geq 1$ *contain a non-trivial purely pseudo-Anosov normal subgroup?* It was asked in the early 1980s and is often attributed to Penner, Long, and McCarthy. It is also recorded by Ivanov [2006, Problems 3], and Farb [2006] refers to it as a "well known open question".

The abundance of finitely generated non-normal purely pseudo-Anosov free subgroups of mapping class groups is well known, and follows from an easy ping-pong argument.

However, this method does not allow one to construct normal subgroups, which are usually infinitely generated. For a surface of genus 2 the question was answered by Whittlesey [2000] who proposed an example based on Brunnian braids. Unfortunately the methods of Whittlesey [ibid.] do not generalize even to closed surfaces of higher genus.

Another question was probably first asked by Ivanov (see Ivanov [2006, Problem 11]): *Is the normal closure of a certain nontrivial power of a pseudo-Anosov element of $MCG(S_g)$ free?* Farb [2006, Problem 2.9] also described this problem as a "basic test question" for understanding normal subgroups of mapping class groups.

The next theorem answers both questions positively in more general settings.

Theorem 4.4 (Theorem 2.30, Dahmani, Guirardel, and Osin [2017]). *Let G be a group acting on a hyperbolic space S, $g \in G$ a WPD loxodromic element. Then there exists $n \in \mathbb{N}$ such that the normal closure $\langle\langle g^n \rangle\rangle$ in G is free and purely loxodromic, i.e., every nontrivial element of $\langle\langle g^n \rangle\rangle$ acts loxodromically on S.*

This result can be viewed as a generalization of a theorem by Delzant [1996] stating that for a hyperbolic group G and every element of infinite order $g \in G$, there exists $n \in \mathbb{N}$ such that $\langle\langle g^n \rangle\rangle$ is free (see also Chaynikov [2011] for a clarification of certain aspects of Delzant's proof).

The idea of the proof is the following. By Theorem 3.5, g is contained in the maximal virtually cyclic subgroup $E(g)$ which is hyperbolically embedded in G. Since $\langle g \rangle$ has finite index in $E(g)$, we have $\langle g^n \rangle \lhd E(g)$. Passing to a multiple of n if necessary, we can ensure that $\langle g^n \rangle$ avoids any finite collection of non-trivial elements. Thus we can apply Theorem 4.2 to $H = E(g)$ and $N = \langle g^n \rangle$. Since $\langle g^n \rangle \cong \mathbb{Z}$, part (d) of the theorem implies that $\langle\langle g^n \rangle\rangle$ is free. That $\langle\langle g^n \rangle\rangle$ is purely loxodromic also follows from part (d) and some additional arguments relating $\Gamma(G, X \sqcup H)$ to S.

Applying Theorem 4.4 to mapping class groups acting on the curve complexes, we obtain the following.

Corollary 4.5. *Let Σ be a possibly punctured closed orientable surface. Then for any pseudo-Anosov element $a \in MCG(\Sigma)$, there exists $n \in \mathbb{N}$ such that the normal closure of a^n is free and purely pseudo-Anosov.*

5 Small cancellation theory and its applications

5.1. Generalizing classical small cancellation. The classical small cancellation theory deals with presentations

$$F(X)/\langle\langle \mathcal{R} \rangle\rangle = \langle X \mid \mathcal{R} \rangle,$$

where $F(X)$ is the free group with basis X, and common subwords of distinct relators are "small" in a certain precise sense. This property allows one to control cancellation in products of conjugates of relators in $\mathcal{R}$ (and their inverses); in turn, this leads to nice structural results for the normal closure $\langle\langle \mathcal{R} \rangle\rangle$ and the group $F(X)/\langle\langle \mathcal{R} \rangle\rangle$.

More generally, one can replace the free group $F(X)$ with a group G_0 enjoying some hyperbolic properties and add new relations to a presentation of G_0. If these new relations satisfy a suitable version of small cancellation, many results of the classical small cancellation theory can be reproved in these settings. On the other hand, the small cancellation assumptions are usually general enough to allow one to create interesting relations between elements.

The idea of generalizing classical small cancellation to groups acting on hyperbolic spaces is due to Gromov [1987], although some underlying ideas go back to the work of Olshanskii [1982, 1980]. In the case of hyperbolic groups, it was formalized by Delzant [1996], Olshanskii [1993], and others. Olshanskii's approach was generalized to relatively hyperbolic groups by Osin [2010] and further generalized to acylindrically hyperbolic groups by Hull [2016]. These generalizations employ isoperimetric characterizations of relatively hyperbolic groups and hyperbolically embedded subgroups obtained in Dahmani, Guirardel, and Osin [2017] and Osin [2006] and follow closely the classical theory. Yet another approach is based on Gromov's *rotating families* (see Coulon [2016] and references therein.)

Unfortunately, the ideas involved in this work are too technical for a short survey paper and we do not discuss them here. Instead we discuss few (indeed very few) applications of small cancellation theory in relatively hyperbolic groups to proving embedding theorems and studying conjugacy growth of groups.

5.2. Embedding theorems and conjugacy growth of groups. In 1949, Higman, B. H. Neumann, and H. Neumann [1949] proved that any countable group G can be embedded into a countable group B such that every two elements of the same order are conjugate in B. The group B constructed by Higman, B. H. Neumann, and H. Neumann [ibid.] is a union of infinite number of subsequent HNN–extensions and thus it is never finitely generated. Osin [2010] used small cancellation theory in relatively hyperbolic groups to prove the following stronger result. For a group G, let $\pi(G)$ denote the set of finite orders of elements of G.

Theorem 5.1. *Any countable group G can be embedded into a finitely generated group C such that any two elements of the same order are conjugate in C and $\pi(G) = \pi(C)$.*

We explain the idea of the proof in the particular case when C is torsion free. Let $G_0 = C * F(x, y)$, where $F(x, y)$ is the free group with basis $\{x, y\}$. Given any nontrivial lement $g \in G_0$, one first considers the HNN-extension

$$H = \langle G_0, t \mid t^{-1}gt = x\rangle.$$

Obviously x and g are conjugate in H. Then imposing an additional relation $t = w(x, y)$, where $w(x, y)$ is a suitable small cancellation word in the alphabet $\{x, y\}$, one ensures that this conjugation happens in a certain quotient group G_1 of G_0. Small cancellation theory is then used to show that the restriction of the natural homomorphism $G_0 \to G_1$ to C is injective and the image of $F(x, y)$ in G_1 is still "large enough". Here "large enough" means that the image of $F(x, y)$ in G_1 is non-elementary with respect to some acylindrical action of G_1 on a hyperbolic space. This allows us to iterate the process. Repeating it for all non-trivial elements we obtain a group with 2 conjugacy classes which is generated by 2 elements (the images of x and y) and contains C.

Applying the theorem to the group $G = \mathbb{Z}$, we obtain the following.

Corollary 5.2. *There exists a torsion free finitely generated group with* 2 *conjugacy classes.*

The existence of a finitely generated group with 2 conjugacy classes other than $\mathbb{Z}/2\mathbb{Z}$ was a long standing open problem, sometimes attributed to Maltsev. It is easy to see that such groups do not exist among finite (and residually finite) groups. It is also observed by Osin [2010] that such a group cannot be constructed as a limit of hyperbolic groups; this justifies the use of small cancellation theory in the more general settings.

Given a group G generated by a finite set X, the associated *conjugacy growth function* of G, denoted by $\xi_{G,X}$, is defined as follows: $\xi_{G,X}(n)$ is the number of conjugacy classes of elements that can be represented by words of length at most n is the alphabet $X \cup X^{-1}$. Given $f, g\colon \mathbb{N} \to \mathbb{N}$, we write $f \sim g$ if there exists $C \in \mathbb{N}$ such that $f(n) \le g(Cn)$ and $g(n) \le f(Cn)$ for all $n \in \mathbb{N}$. Obviously $\sim$ is an equivalence relation and $\xi_{G,X}(n)$ is independent of the choice of X up to this equivalence.

The conjugacy growth function was introduced by Babenko [1988] in order to study geodesic growth of Riemannian manifolds. For more details and a survey of some recent results about conjugacy growth we refer to Hull and Osin [2016a]. Based on ideas from the paper Osin [2010], Hull and the author also obtained a complete description of functions that occur as conjugacy growth functions of finitely generated groups. It is worth noting that such a description for the usual growth function seems to be out of reach at this time.

Theorem 5.3. *Let G be a group generated by a finite set X, and let f denote the conjugacy growth function of G with respect to X. Then the following conditions hold.*

(a) f is non-decreasing.

(b) There exists $a \ge 1$ such that $f(n) \le a^n$ for every $n \in \mathbb{N}$.

Conversely, suppose that a function $f : \mathbb{N} \to \mathbb{N}$ satisfies the above conditions (a) and (b). Then there exists an group G generated by a finite set X such that $\xi_{G,X} \sim f$.

Of course, the non-trivial part of the theorem is the fact that every function satisfying (a) and (b) realizes as the conjugacy growth function.

Yet another result proved by Hull and Osin [2016a] is the following.

Theorem 5.4. *There exists a finitely generated group G and a finite index subgroup $H \leq G$ such that H has 2 conjugacy classes while G is of exponential conjugacy growth.*

In particular, unlike the usual growth function, conjugacy growth of a group is not a quasi-isometry invariant.

Readers interested in other applications of small cancellation technique to groups with hyperbolically embedded subgroups are referred to Hull [2016] and Minasyan and Osin [2018]; for a slightly different approach employing rotating families see Gromov's paper Gromov [2003], Coulon's survey Coulon [2016], and references therein.

GLOBAL SURFACES OF SECTION FOR REEB FLOWS IN DIMENSION THREE AND BEYOND

Pedro A. S. Salomão and Umberto L. Hryniewicz

Dedicated to the memory of Professor Kris Wysocki

Abstract

We survey some recent developments in the quest for global surfaces of section for Reeb flows in dimension three using methods from Symplectic Topology. We focus on applications to geometry, including existence of closed geodesics and sharp systolic inequalities. Applications to topology and celestial mechanics are also presented.

1 Introduction

The idea of a global surface of section goes back to Poincaré and the planar circular restricted three-body problem.

Definition 1.1. *Let ϕ^t be a smooth flow on a smooth closed 3-manifold M. An embedded surface $\Sigma \hookrightarrow M$ is a global surface of section for ϕ^t if:*

(i) Each component of $\partial\Sigma$ is a periodic orbit of ϕ^t.

(ii) ϕ^t is transverse to $\Sigma \setminus \partial\Sigma$.

(iii) For every $p \in M \setminus \partial\Sigma$ there exist $t_+ > 0$ and $t_- < 0$ such that $\phi^{t_+}(p)$ and $\phi^{t_-}(p)$ belong to $\Sigma \setminus \partial\Sigma$.

Every $p \in \Sigma \setminus \partial\Sigma$ has a first return time $\tau(p) = \inf\{t > 0 \mid \phi^t(p) \in \Sigma\}$ and the dynamics of the flow are encoded in the first return map

$$\psi : \Sigma \setminus \partial\Sigma \to \Sigma \setminus \partial\Sigma, \qquad \psi(p) = \phi^{\tau(p)}(p). \tag{1}$$

In Poincaré [1912] Poincaré described annulus-like global surfaces of section for the planar circular restricted three-body problem (PCR3BP) for certain values of the Jacobi

MSC2010: primary 37JXX; secondary 53DXX.

constant and mass ratio. Poincaré's global sections motivated his celebrated *last geometric theorem*. The associated first return map preserves an area form, extends up to boundary, and satisfies a twist condition in the range of parameters considered. The exciting discovery made by Poincaré was that the twist condition implies the existence of infinitely many periodic points, i.e., infinitely many periodic orbits for the PCR3BP. In one stroke Poincaré gave a strong push towards a qualitative point of view for studying differential equations, and stated a fixed point theorem intimately connected to the Arnold conjectures and the foundations of Floer Theory.

The recent success of Floer theory and other methods from Symplectic Geometry prompted Hofer to coin the term *Symplectic Dynamics* Bramham and Hofer [2012]. In this note we are concerned with the success of these methods to study Reeb flows in dimension three, with an eye towards applications to geometry.

Our first goal is to discuss existence results for global sections. This will be done in Section 2. After stating Birkhoff's theorem, we focus on Hofer's theory of pseudo-holomorphic curves Hofer [1993]. We survey some published and also some unpublished results, without giving proofs.

Section 3 is devoted to some applications to systolic geometry that were obtained in collaboration with Abbondandolo and Bramham. We will explain how global surfaces of section open the door for symplectic methods in the study of sharp systolic inequalities. We focus on Riemannian two-spheres and on a special case of a conjecture of Viterbo. In Section 4 we present the planar circular restricted three-body problem in more detail. A conjecture due to Birkhoff on the existence of disk-like global surfaces of section for retrograde orbits is discussed.

We intend to convince the reader that there are many positive results for global sections in large classes of flows. However, there are situations where it might be hard to decide whether they exist or not. In sections 5 and 6 we discuss results designed to handle some of these situations. In Section 5 we present deep results of Hofer, Wysocki, and Zehnder [2003] concerning the existence of transverse foliations, and its use in the study of Hamiltonian dynamics near critical levels. In Section 6 we present a Poincaré-Birkhoff theorem for tight Reeb flows on S^3 proved in Hryniewicz, Momin, and Salomão [2015]. It concerns Reeb flows with a pair of closed orbits exactly as those in the boundary of Poincaré's annulus, i.e. forming a Hopf link.

The appendix A discusses a new proof of the existence of infinitely many closed geodesics on any Riemannian two-sphere, which is alternative to the classical arguments of Bangert [1993] and Franks [1992]. It relies on the work of Hingston [1993].

2 Existence results for global surfaces of section

Poincaré constructed his annulus map for a specific family of systems close to integrable[1]. One of the first statements for a large family of systems which can be quite far from integrable is due to Birkhoff.

Theorem 2.1 (Birkhoff [1966]). *Let γ be a simple closed geodesic of a positively curved Riemannian two-sphere. Consider the set A_γ of unit vectors along γ pointing towards one of the hemispheres determined by γ. Then A_γ is a global surface of section for the geodesic flow.*

In other words, every geodesic ray not contained in γ visits both hemispheres infinitely often. We call the embedded annulus A_γ the *Birkhoff annulus*. The family of geodesic flows on positively curved two-spheres is large, making the above statement quite useful. The proof heavily relies on Riemannian geometry and sheds little light on the general existence problem.

A very general theory to attack the existence problem of global surfaces of section exists, and nowadays goes by the name of Schwartzman-Fried-Sullivan theory, see Ghys [2009] or the original works Fried [1982], Schwartzman [1957], and Sullivan [1976]. It produces beautiful theorems with strong conclusions for general flows in dimension three, or even in higher dimensions. The drawback is that these conclusions often require hypotheses which are hard to check, limiting the range of applications. This should not be a surprise because the set of all flows on a 3-manifold is just too wild.

Hofer's pseudo-holomoprhic curve theory deals with the more restrictive class of Reeb flows. However, the results obtained require more reasonable hypotheses which one can often check, as we intend to demonstrate in the next paragraphs. Sometimes results apply automatically for classes of Reeb flows that are large enough to provide applications in topology and geometry. Consider $\mathbb{R}^4$ with coordinates (x_1, y_1, x_2, y_2) and its standard symplectic form $\omega_0 = \sum_{j=1}^{2} dx_j \wedge dy_j$. Here are two examples of such *unconditional* theorems.

Theorem 2.2 (Hofer, Wysocki, and Zehnder [1998]). *The Hamiltonian flow on a smooth, compact and strictly convex energy level in $(\mathbb{R}^4, \omega_0)$ admits a disk-like global surface of section.*

We see Theorem 2.2 as one of the pinnacles of Symplectic Dynamics, it is the guiding application of this theory to the study of global surfaces of section. All results to be discussed in this section are proved using the methods from Hofer, Wysocki, and Zehnder [ibid.].

[1] Angular momentum is preserved in the rotating Kepler problem.

Theorem 2.3 (Hryniewicz [2012, 2014]). *A periodic orbit of the Hamiltonian flow on a smooth, compact and strictly convex energy level in* $(\mathbb{R}^4, \omega_0)$ *bounds a disk-like global surface of section if, and only if, it is unknotted and has self-linking number* -1.

To explain the connection between the above statements and Reeb flows, and to describe further results of this theory, we need first to review basic notions. A contact form λ on a 3-manifold M is a 1-form such that $\lambda \wedge d\lambda$ defines a volume form. Its Reeb vector field R_λ is implicitly defined by

$$d\lambda(R_\lambda, \cdot) = 0, \qquad \lambda(R_\lambda) = 1. \tag{2}$$

The distribution $\xi = \ker \lambda$ is a contact structure, the pair (M, ξ) is a contact manifold. More precisely, these are the co-orientable contact manifolds since λ orients TM/ξ. We only work here with co-orientable contact structures. By a Reeb flow on (M, ξ) we mean one associated to a contact form λ on M such that $\xi = \ker \lambda$. Contact manifolds are the main objects of study in contact topology. Our interest here is shifted towards dynamics.

A knot is called transverse if at every point its tangent space is transverse to the contact structure. A transverse knot with a Seifert surface has a self-linking number, which is invariant under transverse isotopies. It is defined as follows: choose a non-vanishing section of the contact structure along the Seifert surface, then use this section to push the knot off from itself, and finally count intersections with the Seifert surface. The vector bundle $(\xi, d\lambda)$ is symplectic and has a first Chern class $c_1(\xi) \in H^2(M; \mathbb{Z})$. If $c_1(\xi)$ vanishes on $H_2(M; \mathbb{Z})$ then the self-linking number does not depend on the Seifert surface. The book Geiges [2008] by Geiges is a nice reference for these concepts.

Finally, we describe the Conley-Zehnder index in low-dimensions following Hofer, Wysocki, and Zehnder [2003]. Let γ be a periodic trajectory of the flow ϕ^t of the Reeb vector field R_λ, and let $T > 0$ be a period of γ. Since $(\phi^t)^*\lambda = \lambda$, we get a path of $d\lambda$-symplectic linear maps $d\phi^t : \xi_{\gamma(0)} \to \xi_{\gamma(t)}$. The orbit γ is called degenerate in period T if 1 is an eigenvalue of $d\phi^T : \xi_{\gamma(0)} \to \xi_{\gamma(0)}$, otherwise it is called non-degenerate in period T. The contact form λ is called non-degenerate when every periodic trajectory is non-degenerate in every period. When T is the primitive period we may simply call γ degenerate or non-degenerate accordingly.

Since T is a period, we get a well-defined map $\gamma : \mathbb{R}/T\mathbb{Z} \to M$ still denoted by γ without fear of ambiguity. Choose a symplectic trivialization Φ of $\gamma^*\xi$. Then the linearized flow $d\phi^t : \xi_{\gamma(0)} \to \xi_{\gamma(t)}$ gets represented as a path of symplectic matrices $M : \mathbb{R} \to Sp(2)$ satisfying $M(0) = I$, $M(t+T) = M(t)M(T)\ \forall t$. For every non-zero $u \in \mathbb{R}^2$ we write $M(t)u = (r(t)\cos\theta(t), r(t)\sin\theta(t))$ in polar coordinates, for some continuous lift of argument $\theta : \mathbb{R} \to \mathbb{R}$, and define the rotation function $\Delta_M : \mathbb{R}^2 \setminus \{(0,0)\} \to \mathbb{R}$ by $\Delta_M(u) = \frac{\theta(T)-\theta(0)}{2\pi}$. The image of Δ_M is a compact interval of length strictly less than $1/2$. The rotation interval J_M is defined as the image of Δ_M.

Consider the following function $\tilde{\mu}(J)$ defined on closed intervals J of length less than $1/2$. If $\partial J \cap \mathbb{Z} = \varnothing$ then set $\tilde{\mu}(J) = 2k$ when $k \in J$, or $\tilde{\mu}(J) = 2k+1$ when $J \subset (k, k+1)$. If $\partial J \cap \mathbb{Z} \neq \varnothing$ then set $\tilde{\mu}(J) = \lim_{\epsilon \to 0^+} \tilde{\mu}(J - \epsilon)$. The Conley-Zehnder index can be finally defined as $\mathrm{CZ}^{\Phi}(\gamma, T) = \tilde{\mu}(J_M)$. We omit the period when it is taken to be the primitive period. If $c_1(\xi)$ vanishes on spheres and $\gamma : \mathbb{R}/T\mathbb{Z} \to M$ is contractible then we write $\mathrm{CZ}^{\mathrm{disk}}$ for the index computed with a trivialization that extends to a capping disk.

The Conley-Zehnder index is an extremely important tool. It is related to Fredholm indices of solutions of many of the elliptic equations from Symplectic Topology, in particular to dimensions of moduli spaces of holomorphic curves.

Definition 2.4 (Hofer, Wysocki and Zehnder)**.** *A contact form λ on a 3-manifold M is dynamically convex if $c_1(\ker \lambda)$ vanishes on spheres and contractible periodic Reeb orbits $\gamma : \mathbb{R}/T\mathbb{Z} \to M$ satisfy $\mathrm{CZ}^{\mathrm{disk}}(\gamma, T) \geq 3$.*

The terminology is justified as follows. The standard contact structure ξ_0 on the unit sphere $S^3 \subset \mathbb{R}^4$ is defined as the kernel of $\lambda_0 = \frac{1}{2}\sum_{j=1}^{2} x_j dy_j - y_j dx_j$ restricted to S^3. More generally, λ_0 restricts to a contact form on any smooth, compact hypersurface S in $(\mathbb{R}^4, \omega_0)$ that is (strictly) star-shaped with respect to the origin. The associated Reeb flow reparametrizes the Hamiltonian flow on S for any Hamiltonian realizing S as a regular energy level. Moreover, it is smoothly conjugated to a Reeb flow on (S^3, ξ_0). Conversely, every Reeb flow on (S^3, ξ_0) is smoothly conjugated to the Reeb flow of λ_0 restricted to some S. When S is strictly convex we get dynamical convexity in view of

Theorem 2.5 (Hofer, Wysocki, and Zehnder [1998])**.** *The Hamiltonian flow on a smooth, compact and strictly convex energy level in $(\mathbb{R}^4, \omega_0)$ is smoothly conjugated to a dynamically convex Reeb flow on (S^3, ξ_0).*

A Reeb flow will be called dynamically convex when it is induced by a dynamically convex contact form. The next result and Theorem 2.5 together imply Theorem 2.3.

Theorem 2.6 (Hryniewicz [2012, 2014])**.** *Let γ be a periodic orbit of a dynamically convex Reeb flow on (S^3, ξ_0). Then γ bounds a disk-like global surface of section if, and only if, it is unknotted and has self-linking number -1. Moreover, such an orbit binds an open book decomposition whose pages are disk-like global surfaces of section.*

These statements are powered by a non-trivial input.

Theorem 2.7 (Hofer, Wysocki, and Zehnder [1996b])**.** *Any Reeb flow on (S^3, ξ_0) has an unknotted periodic orbit with self-linking number -1.*

Putting together theorems 2.6 and 2.7 we obtain a more general version of Theorem 2.2.

Theorem 2.8 (Hofer, Wysocki, and Zehnder [1998]). *Any dynamically convex Reeb flow on (S^3, ξ_0) admits a disk-like global surface of section.*

Global sections open the door for tools in two-dimensional dynamics. Here is a strong application in this direction taken from Hofer, Wysocki, and Zehnder [ibid.]. The return map of the disk obtained from Theorem 2.8 preserves an area form with finite total area. Brouwer's translation theorem provides a periodic orbit simply linked to the boundary of the disk. If the fixed point corresponding to this orbit is removed then we end up with a return map on the open annulus. Results of John Franks [1992] complete the proof of the following statement.

Corollary 2.9 (Hofer, Wysocki, and Zehnder [1998]). *Dynamically convex Reeb flows on (S^3, ξ_0) admit either two or infinitely many periodic orbits.*

To push Theorem 2.6 beyond dynamical convexity one needs to introduce linking assumptions with certain periodic orbits. This is aligned to Schwartzman-Fried-Sullivan theory where one makes linking assumptions with invariant measures.

Theorem 2.10 (Hryniewicz, Licata, and Salomão [2015] and Hryniewicz and Salomão [2011]). *A periodic orbit γ of a Reeb flow on (S^3, ξ_0) binds an open book decomposition whose pages are disk-like global surfaces of section if it matches the following conditions:*

(a) γ is unknotted, has self-linking number -1 and satisfies $\mathrm{CZ}^{\mathrm{disk}}(\gamma) \geq 3$.

(b) γ is linked to all periodic orbits $\gamma' : \mathbb{R}/T\mathbb{Z} \to S^3 \backslash \gamma$ such that either $\mathrm{CZ}^{\mathrm{disk}}(\gamma', T) = 2$, or $\mathrm{CZ}^{\mathrm{disk}}(\gamma', T) = 1$ and γ' is degenerate in period T.

Conversely, if γ is non-degenerate (in its primitive period) then these assumptions are necessary for γ to bound a disk-like global surface of section.

After all these results on the 3-sphere we would like to discuss more general Reeb flows. Can we recover and generalize Birkhoff's Theorem 2.1? To make a statement in this direction we need to recall a few concepts.

The notion of fibered link has a contact topological analogue. If λ is a contact form and L is a transverse link then the right notion of fibered is that L binds an open book decomposition satisfying

(i) $d\lambda$ is an area form on each page, and

(ii) the boundary orientation induced on L by the pages oriented by $d\lambda$ coincides with the orientation induced on L by λ.

Such an open book is said to support the contact structure $\xi = \ker \lambda$. We may call them *Giroux open books* because of their fundamental role in the classification of contact structures due to Giroux [2002]. An open book decomposition is said to be *planar* if pages have no genus. A contact structure orients the underlying 3-manifold by $\lambda \wedge d\lambda$, where λ is any defining contact form. A global surface of section will be called *positive* if the orientation induced on it by the flow and the ambient orientation turns out to orient its boundary along the flow.

Theorem 2.11. *Let (M, ξ) be a closed, connected contact 3-manifold. Let the link $L \subset M$ bind a planar Giroux open book decomposition Θ of M. Denote by $f \in H_2(M, L; \mathbb{Z})$ the class of a page of Θ, and by $\gamma_1, \dots, \gamma_n$ the components of L. Let the contact form λ define ξ and realize L as periodic Reeb orbits, and consider the following assertions:*

- *(i) L bounds a positive genus zero global surface of section for the λ-Reeb flow representing the class f.*
- *(ii) L binds a planar Giroux open book whose pages are global surfaces of section for the λ-Reeb flow and represent the class f.*
- *(iii) The following hold:*
  - *(a) $\mathrm{CZ}^{\Theta}(\gamma_k) > 0$ for all k.*
  - *(b) Every periodic λ-Reeb orbit in $M \setminus L$ has non-zero intersection number with f.*

Then (iii) $\Rightarrow$ (ii) $\Rightarrow$ (i). Moreover, (i) $\Rightarrow$ (iii) provided a certain C^∞-generic condition holds.

In (iii-a) $\mathrm{CZ}^{\Theta}(\gamma_k)$ is the Conley-Zehnder index of γ_k in its primitive period computed with a trivialization aligned to the normal of a page of Θ. The genericity needed for (i) $\Rightarrow$ (iii) is implied by non-degeneracy of the contact form. Theorem 2.11 is fruit of joint work with Kris Wysocki and will be proved in Hryniewicz, Salomão, and Wysocki [n.d.]. It heavily relies on Siefring's intersection theory Siefring [2011].

As a first test note that Birkhoff's Theorem 2.1 follows as a consequence. Indeed, the unit sphere bundle of S^2 has a contact form induced by pulling back the tautological 1-from on T^*S^2 via Legendre transform. Reeb flow is geodesic flow. A simple closed geodesic lifts to two closed Reeb orbits, which form a link that binds a supporting open book. Pages are annuli that are isotopic to the Birkhoff annulus. Positivity of the curvature and the Gauss-Bonnet theorem imply that (iii-a) and (iii-b) hold. Birkhoff's theorem follows.

Theorem 2.11 has applications to Celestial Mechanics. The following statement is the abstract result needed for these applications. The standard primitive λ_0 of ω_0 is symmetric by the antipodal map. Identifying antipodal points we obtain $\mathbb{R}P^3 = S^3/\{\pm 1\}$. The restriction of λ_0 to S^3 descends to a contact form on $\mathbb{R}P^3$ defining its standard contact structure, still denoted ξ_0. The Hopf link

$$\widetilde{l}_0 = \{(x_1, y_1, x_2, y_2) \in S^3 \mid x_1 = y_1 = 0 \text{ or } x_2 = y_2 = 0\}$$

is antipodal symmetric and descends to a transverse link l_0 on $\mathbb{R}P^3$. Any transverse link in $(\mathbb{R}P^3, \xi_0)$ transversely isotopic to l_0 will be called a Hopf link. Any transverse knot in $(\mathbb{R}P^3, \xi_0)$ transversely isotopic to a component of l_0 will be called a Hopf fiber.

Theorem 2.12 (Hryniewicz and Salomão [2016], Hryniewicz, Salomão, and Wysocki [n.d.]). *Consider an arbitrary dynamically convex Reeb flow on* $(\mathbb{R}P^3, \xi_0)$. *Any periodic orbit which is a Hopf fiber binds an open book decomposition whose pages are rational disk-like global surfaces of section. Any pair of periodic orbits forming a Hopf link binds an open book decomposition whose pages are annulus-like global surfaces of section.*

These techniques have applications to existence of elliptic periodic orbits. A periodic orbit is elliptic if all Floquet multipliers lie in the unit circle.

Theorem 2.13 (Hryniewicz and Salomão [2016]). *Any Reeb flow on* $(\mathbb{R}P^3, \xi_0)$ *which is sufficiently* C^∞*-close to a dynamically convex Reeb flow admits an elliptic periodic orbit. This orbit binds a rational open book decomposition whose pages are disk-like global surfaces of section. Its double cover has Conley-Zehnder index equal to* 3.

When combined with a result of Harris and Paternain [2008] relating pinched flag curvatures to dynamical convexity, Theorem 2.13 refines the main result from Rademacher [2007].

Corollary 2.14. *Consider a Finsler metric on the two-sphere with reversibility* r. *If all flag curvatures lie in* $(r^2/(r+1)^2, 1]$ *then there exists an elliptic closed geodesic. Moreover, its velocity vector defines a periodic orbit of the geodesic flow that bounds a rational disk-like global surface of section. A fixed point of the return map gives a second closed geodesic.*

We end this section with a topological application. We look for characterizations of contact 3-manifolds in terms of Reeb dynamics, motivated by early fundamental results of Hofer, Wysocki, and Zehnder [1995a, 1999a].

Identify $\mathbb{R}^4 \simeq \mathbb{C}^2$ by $(x_1, y_1, x_2, y_2) \simeq (z_1 = x_1 + iy_1, z_2 = x_2 + iy_2)$ and fix relatively prime integers $p \geq q \geq 1$. The action of $\mathbb{Z}/p\mathbb{Z}$ generated by the map $(z_1, z_2) \mapsto (e^{i2\pi/p} z_1, e^{i2\pi q/p} z_2)$ is free on S^3, and the lens space $L(p,q)$ is defined as its orbit space. The 1-form $\lambda_0 = \frac{1}{2}\sum_{j=1}^2 x_j dy_j - y_j dx_j$ is invariant and descends to a contact form on $L(p,q)$. The induced contact structure is called standard, we still denote it by ξ_0 with no fear of ambiguity.

A knot K on a closed 3-manifold M is p-unknotted if there is an immersion $u : \mathbb{D} \to M$ such that $u|_{\mathbb{D}\setminus\partial\mathbb{D}}$ defines a proper embedding $\mathbb{D} \setminus \partial\mathbb{D} \to M \setminus K$, and $u|_{\partial\mathbb{D}}$ defines a p-covering map $\partial\mathbb{D} \to K$. The map u is called a p-disk for K. The Hopf fiber $S^1 \times 0 \subset S^3$ is $\mathbb{Z}/p\mathbb{Z}$ invariant and descends to the simplest example of a p-unknotted knot in $L(p,q)$. The case $p = 2$ has the following geometric meaning: if we identify $L(2,1)$ with the unit tangent bundle of the round two-sphere then the velocity vector of a great circle is 2-unknotted.

In the presence of a contact structure a transverse p-unknotted knot has a rational self linking number. In the examples given above the knots are transverse and their rational self-linking numbers are equal to $-1/p$. These notions play a role in the following dynamical characterization of standard lens spaces.

Theorem 2.15 (Hofer, Wysocki, and Zehnder [1995a, 1999a] and Hryniewicz, Licata, and Salomão [2015]). *Let (M,ξ) be a closed connected contact 3-manifold, and let $p \geq 1$ be an integer. Then (M,ξ) is contactomorphic to some $(L(p,q),\xi_0)$ if, and only if, it carries a dynamically convex Reeb flow with a p-unknotted self-linking number $-1/p$ periodic orbit.*

This is a special case of more general statements where linking assumptions with certain periodic orbits are used. The existence of a p-unknotted self-linking number $-1/p$ periodic orbit implies that $(M,\xi) = (L(p,q),\xi_0)\#(M',\xi')$ for some contact 3-manifold (M',ξ'). Dynamical convexity forces $(M',\xi') = (S^3,\xi_0)$.

Using that $(L(2,1),\xi_0)$ is contactomorphic to the unit sphere bundle of any Finsler metric on S^2 we get a geometric application. Consider the set $\mathfrak{I}$ of immersions $S^1 \to S^2$ with no positive self-tangencies. Two immersions are declared equivalent if they are homotopic through immersions in $\mathfrak{I}$. This defines an equivalence relation $\sim$ and an element of $\mathfrak{I}/\sim$ will be called a *weak flat knot type*. This notion is related to Arnold's J^+-theory of plane curves. Note that a closed geodesic on a Finsler two-sphere has a well-defined weak flat knot type. Let k_8 be the weak flat knot type of a curve with precisely one self-intersection which is transverse. Clearly there are curves representing k_8 with an arbitrarily large number of self-intersections.

Theorem 2.16 (Hryniewicz and Salomão [2013]). *If a Finsler two-sphere with reversibility r has flag curvatures in $(r^2/(r+1)^2, 1]$ then no closed geodesic represents k_8.*

This statement follows from Theorem 2.15. In fact, the pinching of the curvature forces dynamical convexity (Harris and Paternain [2008]), and the velocity vector of a closed geodesic of type k_8 is unknotted with self-linking number -1 in the unit sphere bundle. Since $\mathbb{R}P^3$ is not the 3-sphere we conclude that such a closed geodesic does not exist.

3 Global surfaces of section applied to systolic geometry

Our first goal in this section is to explain how Birkhoff's annulus-like global surfaces of section (Theorem 2.1) allow for the possibility that symplectic and Riemannian methods be combined to get sharp systolic inequalities on the two-sphere. Our second goal is to describe how disk-like global surfaces of section can be used to prove a special case of Viterbo's conjecture Viterbo [2000]. The results described here were obtained in collaboration with Alberto Abbondandolo and Barney Bramham Abbondandolo, Bramham, Hryniewicz, and Salomão [2017a, 2018, 2017b,c].

The 1-systole $\mathrm{sys}_1(X,g)$ of a closed non-simply connected Riemannian manifold (X,g) is defined as the length of the shortest non-contractible loop. Systolic geometry has its origins in the following results.

Theorem 3.1 (Löwner)**.** *The inequality* $(\mathrm{sys}_1)^2/\mathrm{Area} \leq 2/\sqrt{3}$ *holds for every Riemannian metric on the two-torus. Equality is achieved precisely for the flat torus defined by an hexagonal lattice.*

Theorem 3.2 (Pu)**.** *The inequality* $(\mathrm{sys}_1)^2/\mathrm{Area} \leq \pi/2$ *holds for every Riemannian metric on* $\mathbb{R}P^2$*. Equality is achieved precisely for the round geometry.*

Systolic geometry is a huge and active field, it developed quite a lot since the results of Löwner and Pu. We emphasize Gromov's celebrated paper Gromov [1983].

To include simply connected manifolds one considers the length $\ell_{\min}(X,g)$ of the shortest non-constant closed geodesic of a closed Riemannian manifold (X,g). The systolic ratio is defined by

$$\rho_{\mathrm{sys}}(X,g) = \frac{(\ell_{\min}(X,g))^n}{\mathrm{Vol}(X,g)} \qquad (n = \dim X) \tag{3}$$

The systolic ratio of two-spheres is far from being well understood. An important statement is due to Croke.

Theorem 3.3 (Croke [1988])**.** *The function* $g \mapsto \rho_{\mathrm{sys}}(S^2,g)$ *is bounded among all Riemannian metrics on* S^2*.*

In view of Pu's inequality it is tempting to hope that a round two-sphere (S^2,g_0) maximizes the systolic ratio. Its value is $\rho_{\mathrm{sys}}(S^2,g_0) = \pi$. However, the Calabi-Croke sphere shows that the supremum of $\rho_{\mathrm{sys}}(S^2,g)$ is at least $2\sqrt{3} > \pi$. This is a singular metric constructed by glueing two equilateral triangles along their sides to form a "flat" two-sphere. It can be approximated by smooth positively curved metrics with systolic ratio close to $2\sqrt{3}$.

Question 1. *What is the value of* $\sup_{(S^2,g)} \rho_{\rm sys}(S^2,g)$*? Are there restrictions on the kinds of geometry that approximate this supremum?*

It has been conjectured that the answer to Question 1 is $2\sqrt{3}$. In Balacheff [2010] Balacheff shows that the Calabi-Croke sphere can be seen as some kind of local maximum if non-smooth metrics with a certain type of singular behavior are included.

A *Zoll metric* is one such that all geodesic rays are closed and have the same length. It is interesting that all Zoll metrics on S^2 have conjugated geodesic flows, and have systolic ratio equal to π.

It becomes a natural problem that of understanding the geometry of the function $\rho_{\rm sys}$ near (S^2, g_0). This problem was considered by Babenko and studied by Balacheff. In Balacheff [2006] Balacheff shows that (S^2, g_0) can be seen as a critical point of $\rho_{\rm sys}$ and conjectured that it is a local maximum. We will refer to this conjecture as the Babenko-Balacheff conjecture.

Contact geometry is a natural set-up to study systolic inequalities. This point of view was advertised and used by Álvarez Paiva and Balacheff [2014]. Let α be a contact form on a closed manifold M of dimension $2n-1$ oriented by $\alpha \wedge (d\alpha)^{n-1}$. We denote by $T_{\min}(M,\alpha)$ the minimal period among closed orbits of the Reeb flow. Existence of closed orbits is taken for granted. The contact volume of (M,α) is defined as

$$\mathrm{Vol}(M,\alpha) := \int_M \alpha \wedge (d\alpha)^{n-1}$$

and the systolic ratio of (M,α) as

$$\rho_{\rm sys}(M,\alpha) := \frac{T_{\min}(M,\alpha)^n}{\mathrm{Vol}(M,\alpha)}$$

Note that $\rho_{\rm sys}(M,\alpha)$ is invariant under re-scalings of α.

To see the connection to systolic geometry, consider a Riemannian n-manifold (X,g). The pull-back of the tautological form on T^*X by Legendre transform restricts to a contact form α_g on the unit sphere bundle T^1X. Since the Reeb flow of α_g is the geodesic flow of g, we get $T_{\min}(T^1X,\alpha_g) = \ell_{\min}(X,g)$. It turns out that $\mathrm{Vol}(X,g)$ and $\mathrm{Vol}(T^1X,\alpha_g)$ are proportional by a constant depending only on n. Hence $\rho_{\rm sys}(T^1X,\alpha_g) = C_n\, \rho_{\rm sys}(X,g)$ for every Riemannian metric g on X, where C_n depends only on n.

A Zoll contact form is one such that all Reeb trajectories are periodic and have the same period. These are usually called regular in the literature, but we prefer the term Zoll in view of the above connection to the Riemannian case.

A convex body in $\mathbb{R}^{2n}$ is a compact convex set with non-empty interior. In Viterbo [2000] Viterbo conjectured that

$$\frac{c(K)^n}{n!\mathrm{Vol}(K)} \leq 1 \tag{4}$$

holds for every convex body $K \subset \mathbb{R}^{2n}$ and every symplectic capacity c, where $\mathrm{Vol}(K)$ denotes euclidean volume. We end by discussing a special case of the conjecture. Let K be a convex body in $(\mathbb{R}^{2n}, \omega_0)$ with smooth and strictly convex boundary, with the origin in its interior. Denote by $\iota : \partial K \to \mathbb{R}^{2n}$ the inclusion map, and by λ_0 the standard Liouville form $\lambda_0 = \frac{1}{2}\sum_{j=1}^n x_j dy_j - y_j dx_j$. Then $\iota^*\lambda_0$ is a contact form on ∂K. In Hofer and Zehnder [1994] it is claimed that the Hofer-Zehnder capacity of K is equal to $T_{\min}(\partial K, \iota^*\lambda_0)$. In this case (4) is restated as

$$\rho_{\mathrm{sys}}(\partial K, \iota^*\lambda_0) \leq 1 \tag{5}$$

which is supposed to be an equality if, and only if, $\iota^*\lambda_0$ is Zoll.

Having described our problems, we move on to state some results. Recall that for $\delta \in (0, 1]$, a positively curved closed Riemannian manifold is said to be δ-pinched if the minimal and maximal values $K_{\min}, K_{\max}$ of the sectional curvatures satisfy $K_{\min}/K_{\max} \geq \delta$. On a positively curved two-sphere we write $\ell_{\max}$ for the length of the longest closed geodesic without self-intersections. Note that $\ell_{\max}$ is finite.

Theorem 3.4 (Abbondandolo, Bramham, Hryniewicz, and Salomão [2017a])**.** *If (S^2, g) is δ-pinched for some $\delta > (4+\sqrt{7})/8 = 0.8307...$ then $\ell_{\min}(S^2, g)^2 \leq \pi \mathrm{Area}(S^2, g) \leq \ell_{\max}(S^2, g)^2$. Moreover, any of these inequalities is an equality if, and only if, the metric is Zoll.*

This first inequality confirms the Babenko-Balacheff conjecture on an explicit and somewhat large C^2-neighborhood of the round geometry. It seems that the upper bound involving $\ell_{\max}$ was not known before.

We discuss some related problems before explaining the role of global surfaces of section in the proof of Theorem 3.4. The pinching constant δ seems to be a helpful parameter. For instance, one could consider the non-increasing bounded (Theorem 3.3) function

$$\rho : (0, 1] \to \mathbb{R} \qquad \rho(\delta) = \sup\{\rho_{\mathrm{sys}}(S^2, g) \mid (S^2, g) \text{ is } \delta\text{-pinched}\}$$

to study the positively curved case.

Question 2. *Is it true that $\rho(1/4) = \pi$? What does the graph of $\rho(\delta)$ look like?*

The Calabi-Croke sphere shows that $\lim_{\delta \to 0^+} \rho(\delta) \geq 2\sqrt{3}$. Theorem 3.4 implies that $\rho(\delta) = \pi$ for all $\delta > (4+\sqrt{7})/8$. One must try to understand among which metrics does the round metric maximize systolic ratio. Assuming positive curvature it might be reasonable to expect that $\inf\{\delta \mid \rho(\delta) = \pi\} \leq 1/4$.

If curvature assumptions are dropped then the situation might be much harder. What about symmetry assumptions? Here is a result in this direction that answers a question by Álvarez-Paiva and Balacheff.

Theorem 3.5. *Inequality $\rho_{\mathrm{sys}} \leq \pi$ holds for every sphere of revolution, with equality precise when the metric is Zoll.*

Global surfaces of section show up in the proofs of theorems 3.4 and 3.5 to connect systolic inequalities to a quantitative fixed point theorem for symplectic maps of the annulus. We outline the proof to make this point precise.

Let (S^2, g) be δ-pinched. If $\delta > 1/4$ then $\ell_{\min}$ is only realized by simple closed geodesics. Let γ be a closed geodesic of length $\ell_{\min}$. By Theorem 2.1 the Birkhoff annulus A_γ is a global surface of section. Let λ be the 1-form on A_γ given by restricting the contact form α_g. Then $d\lambda$ is an area form on the interior of A_γ, and vanishes on ∂A_γ. The total $d\lambda$-area of A_γ is $2\ell_{\min}$.

The first return map ψ and the first return time τ are defined on the interior of A_γ, but it turns out that they extend smoothly to A_γ. Moreover, ψ preserves boundary components. Santaló's formula reads

(6) $$2\pi \operatorname{Area}(S^2, g) = \int_{T^1S^2} \alpha_g \wedge d\alpha_g = \int_{A_\gamma} \tau \, d\lambda$$

Since ψ preserves the 2-form $d\lambda$, it follows that $\psi^*\lambda - \lambda$ is closed.

We now need to consider lifts of ψ to the universal covering of A_γ. If ψ admits a lift in the kernel of the FLUX homomorphism then $\psi^*\lambda - \lambda$ is exact. The unique primitive σ of $\psi^*\lambda - \lambda$ satisfying

$$\sigma(p) = \int_p^{\psi(p)} \lambda \quad \forall p \in \partial A_\gamma$$

is called the *action of* ψ. Here the integral is taken along the boundary according to the lift with zero FLUX. The Calabi invariant is defined as

$$\operatorname{CAL}(\psi) = \frac{1}{\int_{A_\gamma} d\lambda} \int_{A_\gamma} \sigma \, d\lambda = \frac{1}{2\ell_{\min}} \int_{A_\gamma} \sigma \, d\lambda$$

Of course, we need to worry about whether ψ admits a lift of zero FLUX, but this follows from reversibility of the geodesic flow.

It is a very general fact that τ is also a primitive of $\psi^*\lambda - \lambda$. Toponogov's theorem proves that if $\delta > 1/4$ then

(7) $$\tau = \sigma + \ell_{\min}$$

Combining (7) with (6) we finally get

$$2\pi \,\mathrm{Area}(S^2, g) = 2(\ell_{\min})^2 + 2\ell_{\min}\mathrm{CAL}(\psi) \tag{8}$$

Equations (7) and (8) should be seen as some kind of dictionary between geometry and dynamics: action corresponds to length, Calabi invariant corresponds to area.

We are now in position to make the link to the quantitative fixed point theorem and conclude the argument. Roughly speaking, the theorem states:

If ψ admits a generating function (of a specific kind), $\mathrm{CAL}(\psi) \le 0$ and $\psi \neq id$, then there exists a fixed point p_0 satisfying $\sigma(p_0) < 0$.

Arguing indirectly, suppose that either $\pi\,\mathrm{Area} < (\ell_{\min})^2$, or $\pi\,\mathrm{Area} = (\ell_{\min})^2$ and g is not Zoll. It follows from (8) and a little more work that either $\mathrm{CAL}(\psi) < 0$, or $\mathrm{CAL}(\psi) = 0$ and ψ is not the identity. Toponogov's theorem comes into play again to show that ψ admits the required generating function provided $\delta > (4+\sqrt{7})/8$. The fixed point theorem applies to give a fixed point of negative action. By (7) this fixed point corresponds to a closed geodesic of length strictly smaller than $\ell_{\min}$. This contradiction finishes the proof.

The above argument reveals how global surfaces of section can serve as bridge between systolic geometry and symplectic dynamics. The same strategy proves a special case of Viterbo's conjecture in dimension 4.

Theorem 3.6 (Abbondandolo, Bramham, Hryniewicz, and Salomão [2018]). *There exists a C^3-neighborhood $\mathcal{U}$ of the space of Zoll contact forms on S^3 such that $\alpha \in \mathcal{U} \Rightarrow \rho_{\mathrm{sys}}(S^3, \alpha) \le 1$ with equality if, only if, α is Zoll.*

The proof again strongly relies on global surfaces of sections. Namely, if a contact form is C^3-close to the standard contact form λ_0 then its Reeb flow admits a disk-like global surface of section whose first return map extends up to the boundary and is C^1-close to the identity. We have a dictionary between maps and flows just as in the proof of Theorem 3.4: contact volume corresponds to Calabi invariant, return time corresponds to action. The quantitative fixed point theorem applies to give the desired conclusion.

One could see the constants in sharp systolic inequalities for Riemannian surfaces as invariants. Similarly, one could hope to construct contact invariants from sharp systolic inequalities for contact forms. The following statement shows that this is not possible in dimension three: systolic inequalities are not purely contact topological phenomena. For example, inequalities such as (5) must depend on the convexity assumption.

Theorem 3.7 (Abbondandolo, Bramham, Hryniewicz, and Salomão [2018, 2017b]). *For every co-orientable contact 3-manifold (M, ξ) and every $c > 0$ there exists a contact form α on M satisfying $\xi = \ker\alpha$ and $\rho_{\mathrm{sys}}(M, \alpha) > c$.*

Hofer, Wysocki, and Zehnder [1999a, 1998] introduced the notion of dynamically convex contact forms, see Section 2 for a detailed discussion. It plays a crucial role in the construction of global surfaces of section (theorems 2.6, 2.8). Dynamical convexity is automatically satisfied on the boundary of a smooth convex body with strictly convex boundary. It becomes relevant to decide whether (5) holds for dynamically convex contact forms on S^3.

Theorem 3.8 (Abbondandolo, Bramham, Hryniewicz, and Salomão [2017c])**.** *Given any* $\epsilon > 0$ *there is a dynamically convex contact form* α *on* S^3 *such that* $\rho_{\text{sys}}(S^3, \alpha) > 2 - \epsilon$.

A narrow connection between high systolic ratios and negativity of Conley-Zehnder indices is quantified in Abbondandolo, Bramham, Hryniewicz, and Salomão [ibid.].

Observe that Theorem 3.8 implies that either Viterbo's conjecture is not true, or there exists a dynamically convex contact form on S^3 whose Reeb flow is not conjugated to the Reeb flow on a strictly convex hypersurface of $(\mathbb{R}^4, \omega_0)$. Unfortunately we can not decide which alternative holds. It also proves that there are smooth compact star-shaped domains U in $(\mathbb{R}^4, \omega_0)$ with the following property: the value $c(U)$ of any capacity realized as the action of some closed characteristic on ∂U is strictly larger than the Gromov width of U.

Global surfaces of section continue to play essential role in the proofs of Theorem 3.7 and Theorem 3.8. Both start by constructing global sections for certain Reeb flows with well-controlled return maps. Then the Reeb flows are modified by carefully changing the return maps in order to make the systolic ratio increase.

4 The planar circular restricted three-body problem

The three-body problem is that of understanding the motion of three massive particles which attract each other according to Newton's law of gravitation. Some simplifying assumptions turn this problem into a two-degree-of-freedom Hamiltonian system:

- The three particles move in a fixed plane.
- The mass of the third body (satellite) is neglected and so the first two particles (primaries) move according to the two-body problem.
- The primaries move on circular trajectories about their center of mass.

In inertial coordinates where the center of mass of the primaries rests at the origin one gets $z_1 = r_1 e^{i\omega t}$ and $z_2 = -r_2 e^{i\omega t}$ for some ω, where $r_1, r_2 > 0$ satisfy $m_1 r_1 - m_2 r_2 = 0$ and $(r_1 + r_2)^3 \omega^2 = m_1 + m_2$. It is harmless to assume that $\omega = r_1 + r_2 = m_1 + m_2 = 1$ which makes the mass ratio $\mu := m_1 = r_2 \in (0, 1)$ the unique parameter of the system.

In rotating (non-inertial) coordinates the position $q(t) \in \mathbb{C}$ of the satellite relative to the second primary is given by $z_3(t) = (q(t) - \mu)e^{it}$, from where it follows that

$$\ddot{q} + 2i\dot{q} - (q - \mu) = -\mu \frac{q-1}{|q-1|^3} - (1-\mu)\frac{q}{|q|^3}. \tag{9}$$

As is well known, if we set $p = \dot{q} + i(q - \mu)$ and consider

$$H_\mu(q,p) = \frac{1}{2}|p|^2 + \langle q - \mu, ip\rangle - \frac{\mu}{|q-1|} - \frac{1-\mu}{|q|}, \tag{10}$$

then (9) becomes Hamilton's equations

$$\dot{q} = \nabla_p H_\mu, \qquad \dot{p} = -\nabla_q H_\mu. \tag{11}$$

The function H_μ has five critical points. A sublevel set below its lowest critical value defines three *Hill regions* in the configuration plane, two of which are bounded while the third is a neighborhood of ∞. Each bounded Hill region is topologically a punctured disk and contains a primary, namely, one of them is a punctured neighborhood of the origin and the other is a punctured neighborhood of 1. The boundaries of the Hill regions are called *ovals of zero velocity*, since there we have $(q - \mu) = -ip \Leftrightarrow \dot{q} = 0$. From now on we restrict to *subcritical cases*, i.e. energy levels $H_\mu = -c$ where $-c$ is below the lowest critical value of H_μ. We focus on the bounded Hill region near the origin.

Following Poincaré, mathematicians first tried to understand the limiting behavior as $\mu \to 0^+$ or as $\mu \to 1^-$. The limit as $\mu \to 0^+$ is in some ways better behaved than the limit $\mu \to 1^-$, but sometimes it is just the other way around. In the limit $\mu = 0$ the system describes the so-called rotating Kepler problem, where all mass is concentrated at the origin. The boundary of the bounded Hill region about the origin converges to a circle of definite radius. As $\mu \to 1^-$ the bounded Hill region about the origin collapses, and we face a somewhat more singular situation.

Definition 4.1. *A retrograde orbit is a periodic orbit $t \mapsto (q(t), p(t))$ such that $q(t)$ is in the Hill region about the origin, and describes a curve without self-intersections with winding number -1 around the origin. Analogously, a direct orbit is a periodic orbit $t \mapsto (q(t), p(t))$ such that $q(t)$ is in the Hill region about the origin, and describes a curve without self-intersections with winding number $+1$ around the origin.*

The difficulty in finding direct orbits led Birkhoff to consider the following strategy in Birkhoff [1914, section 19]. Firstly one should try to find a disk-like global surface of section bounded by a (doubly covered) retrograde orbit. For this to make sense collision orbits need to be regularized. Secondly, due to preservation of an area form with finite total area, one can apply Brouwer's translation theorem to the first return map and find a fixed point that should correspond to a direct orbit. Two main difficulties are: (1) for an arbitrary mass ratio it is hard to find global surfaces of section, and (2) it might be hard to check that the fixed point corresponds to a direct orbit. The following is extracted from Birkhoff [ibid., section 19]:

"This state of affairs seems to me to make it probable that the restricted problem of three bodies admit of reduction to the transformation of a discoid into itself as long as there is a closed oval of zero velocity about J, and that in consequence there always exists at least one direct periodic orbit of simple type."

More recently this has been called a conjecture, which perhaps should be read as following: For any value of μ and any subcritical energy value, there must be a way of finding a disk-like global surface of section in order to understand the movement of the satellite inside the Hill region about the origin. To implement the strategy of Birkhoff this disk should be spanned by the retrograde orbit, in particular fixed points could be good candidates for direct orbits. Again, all this only makes sense if collision orbits are regularized.

Note that the smallest critical value of H_μ converges to $-\frac{3}{2}$ both when $\mu \to 0^+$ or $\mu \to 1^-$. Here is a good point to state and discuss our result concerning Birkhoff's conjecture.

Theorem 4.2. *For every $c > \frac{3}{2}$ there exists $\epsilon > 0$ such that the following holds.*

(a) If $1 - \mu < \epsilon$ and collisions are regularized via Levi-Civita regularization, then the double cover of every retrograde orbit inside the Hill region about the origin bounds a disk-like global surface of section. Moreover, if we quotient by antipodal symmetry then this disk descends to a rational disk-like global surface of section.

(b) If $\mu < \epsilon$ and collisions are regularized via Moser regularization, then every retrograde orbit inside the Hill region about the origin bounds a rational disk-like global surface of section.

Results of Albers, Fish, Frauenfelder, Hofer and van Koert from Albers, Fish, Frauenfelder, Hofer, and van Koert [2012] imply that if $1 - \mu$ is small enough then Levi-Civita regularization lifts the Hamiltonian flow on the corresponding component of $H_\mu^{-1}(-c)$ to the characteristic flow on a strictly convex hypersurface $\widetilde{\Sigma}_{\mu,c}$, up to time reparametrization. Moreover, $\widetilde{\Sigma}_{\mu,c}$ is antipodal symmetric and each state is represented twice as a pair of antipodal points. Results from Hofer, Wysocki, and Zehnder [1998] apply and give disk-like global surfaces of section in $\widetilde{\Sigma}_{\mu,c}$. Statement (a) above says that there is such a global section in $\widetilde{\Sigma}_{\mu,c}$ spanned by the lift of every doubly covered retrograde orbit, and that it descends to a global section in the quotient $\Sigma_{\mu,c} = \widetilde{\Sigma}_{\mu,c}/\{\pm 1\}$. If $\mu = 0$ then Moser regularization applies to the rotating Kepler problem to compactify the Hamiltonian flow on $H_\mu^{-1}(-c)$ to the characteristic flow on a fiberwise starshaped hypersurface $\Sigma_{\mu,c}$ inside TS^2, up to time reparametrization. A proof of this statement can be found in the paper Albers, Frauenfelder, van Koert, and Paternain [2012] where the contact-type property of energy levels of the PCR3BP is studied. Again we have $\Sigma_{\mu,c} \simeq \mathbb{R}P^3$. Statement (b) above says that every retrograde orbit bounds a rational disk-like global surface of section in $\Sigma_{\mu,c}$. A proof in this case would rely on the dynamical convexity obtained in Albers, Fish, Frauenfelder, and van Koert [2013] for $\mu = 0$. Hence, for μ close to 0 or 1 we can always apply Theorem 2.13 and obtain a pair of periodic orbits which are 2-unknotted and have self-linking number $-1/2$. These orbits are transversely isotopic to (a quotient of) a Hopf link. Theorem 2.12 can also be applied and an annulus-like global surface of section is obtained.

We end with a sketch of proof of (a) in Theorem 4.2. Fix $c > 3/2$. The component $\dot{\Sigma}_{\mu,c} \subset H_\mu^{-1}(-c)$ which projects to the Hill region surrounding $0 \in \mathbb{C}$ contains collision orbits. These orbits are regularized with the aid of Levi-Civita coordinates $(v,u) \in \mathbb{C}\times\mathbb{C}$ given by $q = 2v^2$ and $p = -\frac{u}{\bar{v}}$, which are symplectic up to a constant factor. The regularized Hamiltonian is

$$\begin{aligned} K_{\mu,c}(v,u) &:= |v|^2(H_\mu(p,q)+c) \\ &= \frac{1}{2}|u|^2 + 2|v|^2\langle u, iv\rangle - \mu\Im(uv) - \frac{1-\mu}{2} - \mu\frac{|v|^2}{|2v^2-1|} + c|v|^2, \end{aligned} \tag{12}$$

and there is a two-to-one correspondence between a centrally symmetric sphere-like component $\widetilde{\Sigma}_{\mu,c} \subset K_{\mu,c}^{-1}(0)$ and $\dot{\Sigma}_{\mu,c}$, up to collisions.

Now we consider the re-scaled coordinates $v = \hat{v}\sqrt{1-\mu}$ and $u = \hat{u}\sqrt{1-\mu}$, with Hamiltonian

$$\begin{aligned} \hat{K}_{\mu,c}(\hat{v},\hat{u}) &:= \frac{1}{1-\mu}K_{\mu,c}(v,u) \\ &= \frac{1}{2}|\hat{u}|^2 + 2(1-\mu)|\hat{v}|^2\langle \hat{u}, i\hat{v}\rangle - \mu\Im(\hat{u}\hat{v}) - \frac{1}{2} - \mu\frac{|\hat{v}|^2}{|2(1-\mu)\hat{v}^2-1|} + c|\hat{v}|^2. \end{aligned} \tag{13}$$

The component $\widetilde{\Sigma}_{\mu,c} \subset K_{\mu,c}^{-1}(0)$ gets re-scaled and we denote it by $\hat{\Sigma}_{\mu,c} \subset \hat{K}_{\mu,c}^{-1}(0)$.

Taking $\mu \to 1^-$ we see from (13) that $\hat{\Sigma}_{\mu,c}$ converges in the C^∞ topology to a hypersurface satisfying

$$\frac{1}{2}|\hat{u}|^2 - \Im(\hat{u}\hat{v}) + (c-1)|\hat{v}|^2 = \frac{1}{2}. \tag{14}$$

In order to have a better picture of the hypersurface in (14), we denote, for simplicity, $\hat{v} = \hat{v}_1 + i\,\hat{v}_2$ and $\hat{u} = \hat{u}_1 + i\,\hat{u}_2$. Then (14) is equivalent to

$$(\hat{u}_1 - \hat{v}_2)^2 + (\hat{u}_2 - \hat{v}_1)^2 + 2\left(c - \frac{3}{2}\right)(\hat{v}_1^2 + \hat{v}_2^2) = 1. \tag{15}$$

Taking new coordinates $(w = w_1 + i w_2, z = z_1 + i z_2) \in \mathbb{C} \times \mathbb{C}$ with $w_1 = \hat{u}_1 - \hat{v}_2$, $w_2 = \hat{u}_2 - \hat{v}_1$ and $z = \hat{v}\sqrt{2c-3}$, which are symplectic up to a constant factor, we see that (15) is equivalent to $w_1^2 + w_2^2 + z_1^2 + z_2^2 = 1$.

We conclude that the regularized Hamiltonian flow on $\hat{\Sigma}_{\mu,c}$ converges smoothly to the standard Reeb flow on (S^3, ξ_0) as $\mu \to 1^-$ up to reparametrizations. Its orbits are the Hopf fibers. Since the projection of the retrograde orbit winds once around $0 \in \mathbb{C}$ in q-coordinates, it is doubly covered by a simple closed orbit $P_{\mu,c} \subset \widetilde{\Sigma}_{\mu,c}$, which in z-coordinates winds once around $0 \in \mathbb{C}$. Hence, $P_{\mu,c}$ converges smoothly to a Hopf fiber in (w, z) and, in particular, it is unknotted and has self-linking number -1. The dynamical convexity of the Hamiltonian flow on $\hat{\Sigma}_{\mu,c}$ and Theorem 2.6 imply that it is the boundary of a disk-like global surface of section. In view of Theorem 2.12, we may assume that this global section descends to a rational disk-like global section on $\Sigma_{\mu,c} = \widetilde{\Sigma}_{\mu,c}/\{\pm 1\}$.

5 Transverse foliations

We discuss the idea of transverse foliations adapted to a 3-dimensional flow based on the concepts introduced by Hofer, Wysocki and Zehnder in Hofer, Wysocki, and Zehnder [2003]. This generalizes the notion of open books and global sections.

Definition 5.1. *Let ϕ^t be a smooth flow on an oriented closed 3-manifold M. A transverse foliation for ϕ^t is formed by:*

(i) A finite set $\mathcal{P}$ of primitive periodic orbits of ϕ^t, called binding orbits.

(ii) A smooth foliation of $M \setminus \cup_{P \in \mathcal{P}} P$ by properly embedded surfaces. Every leaf $\dot{\Sigma}$ is transverse to ϕ^t, has an orientation induced by ϕ^t and M, and there exists a compact embedded surface $\Sigma \hookrightarrow M$ so that $\dot{\Sigma} = \Sigma \setminus \partial\Sigma$ and $\partial\Sigma$ is a union of components of $\cup_{P \in \mathcal{P}} P$. An end z of $\dot{\Sigma}$ is called a puncture. To each puncture z there is an associated component $P_z \in \mathcal{P}$ of $\partial\Sigma$ called the asymptotic limit of $\dot{\Sigma}$ at z. A puncture z of $\dot{\Sigma}$ is called positive if the orientation on P_z induced by $\dot{\Sigma}$ coincides with the orientation induced by ϕ^t. Otherwise z is called negative.

The following theorem is a seminal result on the existence of transverse foliations for Reeb flows on the tight 3-sphere. It is based on pseudo-holomorphic curve theory in symplectic cobordisms.

Theorem 5.2 (Hofer, Wysocki, and Zehnder [2003]). *Let ϕ^t be a nondegenerate Reeb flow on (S^3, ξ_0). Then ϕ^t admits a transverse foliation. The binding orbits have self-linking number -1 and their Conley–Zehnder indices are 1, 2 or 3. Every leaf $\dot\Sigma$ is a punctured sphere and has precisely one positive puncture. One of the following conditions holds:*

- *The asymptotic limit of $\dot\Sigma$ at its positive puncture has Conley-Zehnder index 3 and the asymptotic limit of $\dot\Sigma$ at any negative puncture has Conley-Zehnder index 1 or 2. There exists at most one negative puncture whose asymptotic limit has Conley-Zehnder index 2.*
- *The asymptotic limit of $\dot\Sigma$ at its positive puncture has Conley-Zehnder index 2 and the asymptotic limit of $\dot\Sigma$ at any negative puncture has Conley-Zehnder index 1.*

The open books with disk-like pages constructed in Hofer, Wysocki, and Zehnder [1995a, 1999a, 1998], Hryniewicz [2012, 2014], Hryniewicz, Licata, and Salomão [2015], and Hryniewicz and Salomão [2011] for Reeb flows on (S^3, ξ_0) are particular cases of transverse foliations with a single binding orbit. The main obstruction for the existence of such an open book with a prescribed binding orbit P is the presence of closed orbits with Conley-Zehnder index 2 which are unlinked to P. One particular transverse foliation of interest which deals with such situations is the so called 3-2-3 foliation.

Definition 5.3. *A 3-2-3 foliation for a Reeb flow ϕ^t on (S^3, ξ_0) is a transverse foliation for ϕ^t with precisely three binding orbits P_3, P_2 and P_3'. They are unknotted, mutually unlinked and their respective Conley-Zehnder indices are 3, 2 and 3. The leaves are punctured spheres and consist of*

- *A pair of planes U_1 and U_2, both asymptotic to P_2 at their positive punctures.*
- *A cylinder V asymptotic to P_3 at its positive puncture and to P_2 at its negative puncture; a cylinder V' asymptotic to P_3' at its positive puncture and to P_2 at its negative puncture.*
- *A one parameter family of planes asymptotic to P_3 at their positive punctures; a one parameter family of planes asymptotic to P_3' at their positive punctures.*

The 3-2-3 foliations are the natural objects to consider if one studies Hamiltonian dynamics near certain critical energy levels.

Take a Hamiltonian H on $\mathbb{R}^4$ which has a critical point $p \in H^{-1}(0)$ with Morse index 1 and of saddle-center type. Its center manifold is foliated by the so called Lyapunoff orbits $P_{2,E} \subset H^{-1}(E)$, $E > 0$ small. Each one of them is unknotted, hyperbolic inside its energy level and has Conley-Zehnder index 2.

Assume that for every $E < 0$ the energy level $H^{-1}(E)$ contains two sphere-like components S_E and S_E' which develop a common singularity at p as $E \to 0^-$. This means that S_E converges in the Hausdorff topology to $S_0 \subset H^{-1}(0)$ as $E \to 0^-$, where S_0 is homeomorphic to the 3-sphere and contains p as its unique singularity. The analog holds for S'_E. Therefore, $S_0 \cap S'_0 = \{p\}$ and, for $E > 0$ small, $H^{-1}(E)$ contains a sphere-like component W_E close to $S_0 \cup S'_0$. We observe that W_E contains the Lyapunoff orbit $P_{2,E}$ and is in correspondence with the connected sum of S_E and S'_E.

Definition 5.4. *We say that S_0 is strictly convex if S_0 bounds a convex domain in $\mathbb{R}^4$ and all the sectional curvatures of $S_0 \setminus \{p\}$ are positive. We say that S'_0 is strictly convex if analogous conditions hold.*

The following theorem is inspired by results in Hofer, Wysocki, and Zehnder [2003].

Theorem 5.5 (de Paulo and Salomão [2018, n.d.])**.** *If H is real analytic and both S_0 and S'_0 are strictly convex then, for every $E > 0$ small, the Hamiltonian flow on the sphere-like component $W_E \subset H^{-1}(E)$ admits a 3-2-3 foliation. The Lyapunoff orbit $P_{2,E}$ is one of the binding orbits and there exist infinitely many periodic orbits and infinitely many homoclinics to $P_{2,E}$ in W_E.*

One difficulty in proving Theorem 5.5 is that there are no non-degeneracy assumptions of any kind. A criterium for checking strict convexity of the subsets S_0 and S'_0 is found in Salomão [2003].

The notion of 3-2-3 foliation is naturally extended to Reeb flows on connected sums $\mathbb{R}P^3\#\mathbb{R}P^3$. In this case the binding orbits P_3 and P'_3 are non-contractible and the families of planes are asymptotic to their respective double covers. The existence of 3-2-3 foliations for Reeb flows on $\mathbb{R}P^3\#\mathbb{R}P^3$ is still an object of study and it is conjectured that they exist for some Hamiltonians in celestial mechanics such as the Euler's problem of two centers in the plane and the planar circular restricted three body problem for energies slightly above the first Lagrange value.

A more general theory of transverse foliations for Reeb flows still needs to be developed. If one wishes to use holomorphic curves then one step is implemented by Fish and Siefring [2013], who showed persistence under connected sums. Transverse foliations on mapping tori of disk-maps were constructed by Bramham [2015a,b] to study questions about rigidity of pseudo-rotations.

6 A Poincaré-Birkhoff theorem for tight Reeb flows on S^3

Poincaré's last geometric theorem is nowadays known as the Poincaré-Birkhoff theorem. In its simplest form it is a statement about fixed points of area-preserving annulus homeomorphisms $f : \mathbb{R}/\mathbb{Z} \times [0, 1] \to \mathbb{R}/\mathbb{Z} \times [0, 1]$ preserving orientation and boundary components. The map f can be lifted to the universal covering $\mathbb{R} \times [0, 1]$. Let us denote projection onto the first coordinate by $p : \mathbb{R} \times [0,1] \to \mathbb{R}$. Then f is said to satisfy a *twist condition* on the boundary if it admits a lift to the universal covering $F : \mathbb{R} \times [0,1] \to \mathbb{R} \times [0,1]$ such that the rotation numbers

$$\lim_{n\to\infty} \frac{p \circ F^n(x,0)}{n} \qquad \lim_{n\to\infty} \frac{p \circ F^n(x,1)}{n}$$

differ. We call the open interval I bounded by these numbers the twist interval.

Theorem 6.1 (Poincaré-Birkhoff Birkhoff [1913] and Poincaré [1912]). *If $I \cap \mathbb{Z} \neq \varnothing$ then f has at least two fixed points.*

Poincaré [1912] found annulus-like global surfaces of section for the PCR3BP for energies below the lowest critical value of the Hamiltonian, and when the mass is almost all concentrated in the primary around which the satellite moves. The boundary orbits form a Hopf link in the three-sphere. For generic values of the parameters, the Poincaré-Birkhoff theorem applies to the associated return map and proves the existence of infinitely many periodic orbits.

One also finds such pair of orbits for the Hamiltonian flow on a smooth, compact and strictly convex energy level inside $(\mathbb{R}^4, \omega_0)$. In fact, the fundamental result of Hofer, Wysocki, and Zehnder [1998] provides an unknotted periodic orbit P_0 that bounds a disk-like global surface of section. Brouwer's translation theorem yields a second periodic orbit P_1 simply linked to P_0, but much more can be said. The orbit P_0 is the binding of an open book decomposition whose pages are disk-like global surfaces of section. It turns out that the following statement follows: the flow is smoothly conjugated to a Reeb flow on (S^3, ξ_0) in such a way that $P_0 \cup P_1$ corresponds to a link transversely isotopic to the standard Hopf link

$$\widetilde{l}_0 = \{(x_1, y_1, x_2, y_2) \in S^3 \mid x_1 = y_1 = 0 \text{ or } x_2 = y_2 = 0\}$$

If the fixed point corresponding to P_1 is removed from the disk-like global section spanned by P_0, then we obtain a diffeomorphism of the open annulus that preserves a standard area-form and can be continuously extended to the boundary. It is interesting to study the twist condition for this map. We need to consider the transverse rotation numbers θ_0 and θ_1 of P_0 and P_1 with respect to Seifert surfaces (disks). In terms of Conley-Zehnder indices, these can be read as follows:

$$1 + \theta_0 = \lim_{n\to\infty} \frac{\mathrm{CZ}(P_0^n)}{2n} \qquad 1 + \theta_1 = \lim_{n\to\infty} \frac{\mathrm{CZ}(P_1^n)}{2n} \tag{16}$$

Here $\mathrm{CZ}(P_i^n)$ denotes the Conley-Zehnder index of the n-iterated orbit P_i computed with respect to a global trivialization of ξ_0. The open book singles out a lift of the map to the strip such that the rotation numbers on the boundary are precisely $1/\theta_0$ and θ_1. The Poincaré-Birkhoff theorem proves the following non-trivial statement: *If $\theta_1 \neq 1/\theta_0$ then there are infinitely many periodic orbits in the complement of $P_0 \cup P_1$. These orbits are distinguished by their homotopy classes in the complement of $P_0 \cup P_1$.*

One motivation for the main result of this section is to study the possibility of extending the above discussion to situations where neither P_0 nor P_1 bound global sections. Before the statement we need some notation. The term *Hopf link* will be referred to any transverse link in (S^3, ξ_0) that is transversely isotopic to the standard Hopf link $\widetilde{l}_0$. Given non-zero vectors $u, v \in \mathbb{R}^2$ in the complement of the third quadrant, we write $u > v$ (or $v < u$) if the argument of u is larger than that of v in the counter-clockwise sense.

Theorem 6.2 (Hryniewicz, Momin, and Salomão [2015]). *Consider a Reeb flow on (S^3, ξ_0) that admits a pair of periodic orbits P_0, P_1 forming a Hopf link. Denote by θ_0, θ_1 their transverse rotation numbers computed with respect to Seifert surfaces. If (p, q) is a pair of relatively prime integers satisfying*

$$(\theta_0, 1) < (p, q) < (1, \theta_1) \qquad \text{or} \qquad (1, \theta_1) < (p, q) < (\theta_0, 1)$$

then there is a periodic orbit $P \subset S^3 \setminus (P_0 \cup P_1)$ such that $p = \operatorname{link}(P, P_0)$ and $q = \operatorname{link}(P, P_1)$.

The main tools in the proof are the contact homology theory introduced by Momin [2011] and the intersection theory of punctured holomorphic curves in dimension four developed by Siefring [2011].

Another source of motivation for Theorem 6.2 is a result due to Angenent [2005] which we now recall. It concerns geodesic flows on Riemannian two-spheres. Let g be a Riemannian metric on S^2, and let $\gamma : \mathbb{R} \to S^2$ be a closed geodesic of length L parametrized with unit speed. In particular $\gamma(t)$ is L-periodic. Jacobi fields along γ are characterized by the second order ODE $y''(t) = -K(\gamma(t))y(t)$ where K denotes the Gaussian curvature. Given a (non-trivial) solution $y(t)$ we can write $y'(t) + iy(t) = r(t)e^{i\theta(t)}$ in polar coordinates. The Poincaré inverse rotation number of γ is defined as

$$\rho(\gamma) = \frac{L}{2\pi} \lim_{t \to +\infty} \frac{\theta(t)}{t} \tag{17}$$

The special case of the results from Angenent [ibid.] that we would like to emphasize concerns the case when γ is simple, that is, $\gamma|_{[0,L)}$ is injective. Denote by $n(t)$ a normal vector along $\gamma(t)$. Given relatively prime integers $p, q \neq 0$ and $\epsilon > 0$ small, a (p, q)-satellite about γ is the equivalence class of the immersion $\alpha_\epsilon : \mathbb{R}/\mathbb{Z} \to S^2$

$$\alpha_\epsilon(t) = \exp_{\gamma(qtL)}\left(\epsilon \sin(2\pi pt)\, n(qtL)\right). \tag{18}$$

Two immersions are equivalent if they are homotopic through immersions, but self-tangencies and tangencies with γ are not allowed.

Theorem 6.3 (Angenent [2005]). *If a rational number p'/q' strictly between $\rho(\gamma)$ and 1 is written in lowest terms then there exists a closed geodesic which is a (p',q')-satellite about γ.*

Let us explain the connection between theorems 6.2 and 6.3. The unit tangent bundle $T^1S^2 = \{v \in TS^2 \mid g(v,v) = 1\}$ admits a contact form λ_g whose Reeb flow coincides with the geodesic flow. It is given by the restriction to T^1S^2 of the pull-back of the tautological 1-form on T^*S^2 by the associated Legendre transform. The L-periodic orbits $\dot\gamma(t)$ and $-\dot\gamma(-t)$ form a link l_γ on T^1S^2 transverse to the contact structure $\ker\lambda_g$. There exists a double cover $S^3 \to T^1S^2$ that pulls back the Reeb flow of λ_g to a Reeb flow on (S^3,ξ_0). Moreover, it pulls back the link l_γ to a Hopf link consisting of periodic orbits $P_0 \cup P_1$ just like in the statement of Theorem 6.2. Note that $\rho(\gamma) \neq 1$ forces the vectors $(\theta_0 = 2\rho(\gamma)-1, 1)$ and $(1, \theta_1 = 2\rho(\gamma)-1)$ to span a non-empty sector. Then Theorem 6.2 captures the contractible (p',q')-satellites of Theorem 6.3 up to homotopy, and a refinement for Reeb flows on the standard $\mathbb{R}P^3$ (Hryniewicz, Momin, and Salomão [2015, Theorem 1.9]) captures all the (p',q')-satellites of Theorem 6.3 up to homotopy. Of course, we do not hope to capture geodesics up to equivalence of satellites because Theorem 6.2 deals with more general flows than those dealt by Theorem 6.3. For instance, it handles non-reversible Finsler geodesic flows with a pair of closed geodesics homotopic to a pair of embedded loops through immersions without positive tangencies. In particular, it covers reversible Finsler metrics with a simple closed geodesic.

Finally, a pair of closed Reeb orbits forming a Hopf link is not known to exist in general for a Reeb flow on (S^3,ξ_0). Each of its components is unknotted, transverse to ξ_0 and has self-linking number -1; we refer to such a closed curve as a Hopf fiber. The existence of at least one closed Reeb orbit on (S^3,ξ_0) which is a Hopf fiber is proved in Hofer, Wysocki, and Zehnder [1996b]; this is a difficult result. If P is a nondegenerate closed orbit which bounds a disk-like global surface of section then P is a Hopf fiber and its rotation number is > 1. Moreover, a fixed point of the first return map, assured by Brouwer's translation theorem, determines a closed orbit P' which forms a Hopf link with P. One may ask whether every closed orbit which is a Hopf fiber and has rotation number > 1 admits another closed orbit forming together a Hopf link. In that direction we have the following result which may be seen as a version of Brouwer's translation theorem for Reeb flows on (S^3,ξ_0).

Theorem 6.4 (Hryniewicz, Momin, and Salomão [n.d.]). *Assume that a Reeb flow on (S^3,ξ_0) admits a closed Reeb orbit P which is a Hopf fiber. If the transverse rotation number $\rho(P)$ belongs to $(1,+\infty) \setminus \left\{1+\frac{1}{k} : k \in \mathbb{N}\right\}$ then there exists a closed orbit P' simply linked to P.*

The closed orbit P' in Theorem 6.4 is not even known to be unknotted.

A Closed geodesics on a Riemannian two-sphere

The purpose of this appendix is to describe the steps of a new proof of the existence of infinitely many closed geodesics on any Riemannian two-sphere. The argument is based on a combination of Angenent's theorem (Theorem 6.3) and the work of Hingston [1993], it serves as an alternative to the classical proof that combines results of Victor Bangert and John Franks. We recommend Oancea [2015] for an account of the closed geodesic problem on Riemannian manifolds.

Theorem A.1 (Bangert [1993] and Franks [1992])**.** *Every Riemannian metric on S^2 admits infinitely many closed geodesics.*

We start with a remark from Hingston [1993]. The space of embedded loops in the two-sphere carries a 3-dimensional homology class modulo short loops. One can use Grayson's curve shortening flow to run a min-max argument over this class and obtain a special simple closed geodesic γ_*. The crucial fact here is that Grayson's curve shortening flow preserves the property of being embedded. The sum of the Morse index and the nullity of γ_* is larger than or equal to 3, in particular $\rho(\gamma_*) \geq 1$.

If $\rho(\gamma_*) = 1$ (Hingston's non-rotating case) then γ_* is a very special critical point of the energy functional. The growth of Morse indices under iterations of γ_* follows a specific pattern. Index plus nullity of γ_* is equal to 3, and if γ_* is isolated then its local homology is non-trivial in degree 3. If every iterate of γ_* is isolated then the analysis of Hingston [ibid.] shows that there are infinitely many closed geodesics. If some iterate γ_* is not isolated then already there are infinitely many closed geodesics. Hence we are left with the case $\rho(\gamma_*) > 1$, which is covered by Theorem 6.3. Theorem A.1 is proved. The case $\rho(\gamma_*) > 1$ is handled independently by Theorem 6.2.

The work of Hingston [ibid.] triggered many developments, including a proof of the Conley conjecture for standard symplectic tori in Hingston [2009]. In Ginzburg [2010] used Floer homology and Hingston's methods to prove the Conley conjecture for aespherical symplectic manifolds.

STABILITY CONDITIONS IN SYMPLECTIC TOPOLOGY

Ivan Smith

Abstract

We discuss potential (largely speculative) applications of Bridgeland's theory of stability conditions to symplectic mapping class groups.

1 Introduction

A symplectic manifold (X, ω) which is closed or convex at infinity has a Fukaya category $\mathcal{F}(X, \omega)$, which packages the algebraic information held by moduli spaces of holomorphic discs in X with Lagrangian boundary conditions Seidel [2008] and Fukaya, Oh, Ohta, and Ono [2009]. The associated category of perfect modules $D^\pi \mathcal{F}(X, \omega) = \mathcal{F}(X, \omega)^{perf}$ is a triangulated category, linear over the Novikov field Λ. The category is $\mathbb{Z}$-graded whenever $2c_1(X) = 0$.

Any $\mathbb{Z}$-graded triangulated category $\mathcal{C}$ has an associated complex manifold $\mathrm{Stab}(\mathcal{C})$ of stability conditions Bridgeland [2007], which carries an action of the group $\mathrm{Auteq}(\mathcal{C})$ of triangulated autoequivalences of $\mathcal{C}$. Computation of the space of stability conditions remains challenging, but a number of instructive examples are now available, and it is reasonable to wonder what the theory of stability conditions might say about symplectic topology. One direction in which one can hope for non-trivial applications concerns global structural features of the symplectic mapping class group. The existing theory will need substantial development for this to bear fruit, so a survey risks being quixotic, but it provides a vantage-point from which to interpret some recent activity Bridgeland and Smith [2015], Smith [2015], and Sheridan and Smith [2017b].

Partially funded by a Fellowship from EPSRC. Thanks to friends and colleagues at Cambridge for a decade and a half of moral support, intellectual stimulation and company lifting spirits.

Acknowledgments. These notes draw on discussions or joint work with all of Denis Auroux, Arend Bayer, Tom Bridgeland, Jonny Evans, Daniel Huybrechts, Oscar Randal-Williams, Tony Scholl, Paul Seidel, Nick Sheridan and Michael Wemyss. More generally, I am extremely indebted to all my collaborators, who have taught me more than I (and probably they) would have thought possible.

2 Mapping class groups

2.1 Surfaces. Consider a closed oriented surface Σ_g of genus g. The mapping class group $\Gamma_g = \pi_0 \mathrm{Diff}(\Sigma_g)$ has been the focus of an enormous amount of attention, from many viewpoints. Here are a few of its salient features, see Farb and Margalit [2012], Calegari [2009], and Morita [2007] for detailed references.

1. Γ_g is finitely presented. The action on homology defines a natural surjection $\Gamma_g \to Sp_{2g}(\mathbb{Z})$ with kernel the Torelli group I_g; the latter is torsion-free, infinitely generated when $g = 2$, finitely generated (but not known to be finitely presented) when $g > 2$.

2. Γ_g has finite rational cohomological dimension. It has finitely many conjugacy classes of finite subgroups; is generated by finitely many torsion elements; satisfies the Tits alternative; and is residually finite, in particular contains no non-trivial divisible element.

3. There is a dynamical classification of mapping classes: given simple closed curves α, β on Σ, the geometric intersection numbers $\iota(\alpha, \phi^n(\beta))$ are either periodic, grow linearly or grow exponentially. A random walk on the mapping class group will almost surely end on the last case. Γ_g has non-trivial quasi-morphisms (and scl), hence does not obey a law.

Here scl denotes stable commutator length. Recall that a group G *obeys a law* if there is a word w in a free group $\mathbb{F}$ for which every homomorphism $\mathbb{F} \to G$ sends $w \mapsto \mathrm{id}$. (Abelian, nilpotent and solvable groups obey laws; groups with non-vanishing scl do not.) It is worth pointing out that plenty of elementary things remain unknown: must a subgroup of I_g generated by two elements be commutative or free?

Broadly speaking, the above results might be divided into three categories: results (finite presentability, non-existence of non-trivial divisible elements, etc) which underscore the similarities between the mapping class group and arithmetic groups; results of a general group-theoretic or finiteness nature, in the vein of geometric group theory; and results (scl, behaviour of random walks) of a more dynamical flavour, in some cases connecting via geometric intersection numbers rather directly to Floer theory. These three directions suggest broad classes of question one might ask about the (symplectic) mapping class groups of higher-dimensional manifolds.

Much of what we know about Γ_g comes from the fact that, although not a hyperbolic group when $g > 1$ (it contains free abelian subgroups of rank $2g - 1 > 1$), it acts on geometrically meaningful spaces which are non-positively-curved in a suitable sense: Teichmüller space, on the one hand, and the complex of curves on another (the latter is δ-hyperbolic Masur and Minsky [1999]). Indeed, Γ_g can be characterised via these actions, as the isometry group of the former for the Teichmüller metric (when $g > 2$; for $g = 2$ one should quotient by the hyperelliptic involution) Royden [1970], or as the simplicial isometry group of the latter Ivanov [1997].

2.2 Higher-dimensional smooth manifolds. There is no simply-connected manifold of dimension > 3 for which the homotopy type of the diffeomorphism group $\mathrm{Diff}(M)$ is known completely. Nonetheless, there are many broad structural results concerning diffeomorphism groups and mapping class groups in high dimensions. Deep results in surgery theory Sullivan [1977] imply that if M is a simply-connected manifold of dimension at least five, then $\pi_0\mathrm{Diff}(M)$ is commensurable with an arithmetic group, hence is finitely presented and contains no non-trivial divisible elements. The arithmetic group arises from automorphisms of the Sullivan minimal model; the forgetful map from $\pi_0\mathrm{Diff}(M)$ to the group of tangential self-homotopy equivalences of M has finite kernel up to conjugacy Browder [1967]. Arithmetic groups cannot contain non-trivial divisible elements. Indeed, their eigenvalues, in a fixed matrix representation, are algebraic integers of bounded degree. Therefore a divisible subgroup is composed of unipotent elements, and has Zariski closure a unipotent subgroup; but commutative unipotent groups only have free abelian arithmetic subgroups Kambayashi, Miyanishi, and Takeuchi [1974]. (Note that general finitely presented groups *can* contain non-trivial divisible elements: indeed, every finitely presented group is a subgroup of some finitely presented group G whose commutator subgroup $[G, G]$ has only divisible elements and with $G/[G, G] \cong \mathbb{Z}$, cf. Baumslag and Miller [1988].) The same conclusions, in particular finite presentability, also apply to the Torelli group.

Away from the simply connected case, much less is known. For $n \geqslant 6$, the mapping class group $\pi_0\mathrm{Diff}(T^n)$ has a split subgroup $(\mathbb{Z}/2)^\infty$ arising from the Whitehead group Wh_2 of the fundamental group Hatcher [1978] and Hsiang and Sharpe [1976], so finite generation can fail. (This is in fact a phenomenon about homeomorphisms, rather distinct from questions of exotic smooth structures.) The group of homotopy self-equivalences $hAut(M)$ when $\pi_1(M)$ is general also seems mysterious: can $hAut(M)$, or $\pi_0\mathrm{Diff}(M)$, ever contain a divisible group, for instance the rationals, as a subgroup? Given the lack of complete computations, nothing seems to be known about the realisability problem, i.e.

which groups occur as smooth mapping class groups: is there an M for which $\pi_0\mathrm{Diff}(M)$ is a rank 2 free group?

2.3 Symplectic manifolds. Fix a symplectic $2n$-manifold (X,ω), closed or convex at infinity. Let $\mathrm{Symp}(X,\omega)$ denote the group of diffeomorphisms of X preserving ω, equipped with the C^∞-topology.

1. If $H^1(X;\mathbb{R}) = 0$ then the connected component of the identity $\mathrm{Symp}_0(X) = \mathrm{Symp}(X,\omega)\cap\mathrm{Diff}_0(X)$ is exactly the subgroup $\mathrm{Ham}(X)$ of Hamiltonian symplectomorphisms, and the symplectic mapping class group is the quotient $\pi_0\mathrm{Symp}(X) = \mathrm{Symp}(X,\omega)/\mathrm{Ham}(X)$.
2. If $H^1(X;\mathbb{R}) \neq 0$ then there is a flux homomorphism (defined on the universal cover)
$$\Phi : \widetilde{\mathrm{Symp}}(X,\omega) \to H^1(X;\mathbb{R})$$
whose kernel is the universal cover of the Hamiltonian group. The image Γ of Φ viewed as a homomorphism on $\pi_1\mathrm{Symp}(X,\omega)$ is a discrete group Ono [2006], and $\mathrm{Symp}_0(X)/\mathrm{Ham}(X) \cong H^1(X;\mathbb{R})/\Gamma$. $\mathrm{Symp}_0(X,\omega)$ carries a foliation by copies of $\mathrm{Ham}(X)$, whose leaf space is locally isomorphic to $H^1(X;\mathbb{R})$. Since Floer theory is Hamiltonian invariant, it is sometimes useful to equip $\mathrm{Symp}(X,\omega)$ with the weaker "Hamiltonian topology", in which (by definition) only isotopies along the leaves are continuous.

There is a forgetful map
$$q : \pi_0\mathrm{Symp}(X,\omega) \to \pi_0\mathrm{Diff}(X)$$
which is typically neither injective nor surjective. For non-injectivity, one has Seidel's results on squared Dehn twists and their inheritors Seidel [1999] and Tonkonog [2015]: if $L \subset X$ is a Lagrangian sphere, there is an associated twist τ_L, which has finite order smoothly if $n = \dim_{\mathbb{R}}(L)$ is even, but typically has infinite order symplectically, for instance for smooth hypersurfaces of degree > 2 in projective space. If $n = 2$, the smooth finiteness can be seen rather explicitly. The cotangent bundle $T^*S^2 = \{x^2+y^2+z^2 = 1\} \subset \mathbb{C}^3$ is an affine quadric; the Dehn twist τ_L in the zero-section L is the monodromy of the Lefschetz degeneration $\{x^2+y^2+z^2 = t\}$ of that quadric around the unit circle in the t-plane; that family base-changes to give a family with a 3-fold node $\{x^2+y^2+z^2 = t^2\}$; and the node admits a small resolution, so the base-change family has trivial smooth monodromy and $\tau_L^2 = \mathrm{id}$ in (compactly supported) C^∞.

For non-surjectivity, a diffeomorphism cannot be isotopic to a symplectic diffeomorphism unless it preserves $[\omega]$ and $c_i(X) \in H^{2i}(X;\mathbb{Z})$, and furthermore permutes the classes with non-trivial Gromov-Witten invariants Ruan [1993]. There are also diffeomorphisms acting trivially on cohomology which do not preserve the homotopy class of any almost complex structure Randal-Williams [2015], so q is not onto the Torelli subgroup for many projective hypersurfaces.

There should be further, less homotopy-theoretic constraints on Torelli symplectomorphisms. A diffeomorphism $\phi : X \to X$ induces an automorphism of the A_∞-algebra $H^*(X;\mathbb{C})$ (where the A_∞-structure is the classical one on cohomology) which may have non-trivial higher-order terms even when the linear action is trivial. If X is Fano, its quantum cohomology

$$QH^*(X;\mathbb{C}) \cong \oplus_\lambda QH^*(X;\lambda) \qquad \lambda \in \mathrm{Spec}(*c_1(X)) \tag{2-1}$$

splits into generalised eigenspaces for quantum product by $c_1(X)$, and the higher-order terms of any symplectomorphism should preserve this decomposition, i.e. be compatible with the quantum-corrected A_∞-structure, a non-linear constraint.

2.4 Monodromy. If X admits a Kähler metric g with positive-dimensional isometry group $K \subset \mathrm{Isom}(X,g)$, then the map $K \to \mathrm{Symp}(X,\omega)$ is often rather interesting, at least for higher homotopy groups. Gromov [1985] proved that $\mathbb{P}U(3) \simeq \mathrm{Symp}(\mathbb{P}^2)$ and inferred that the group of compactly supported symplectomorphisms $\mathrm{Symp}_{ct}(\mathbb{C}^2)$ is contractible; for $n > 2$ we don't know anything about $\pi_0\mathrm{Symp}_{ct}(\mathbb{C}^n,\omega_{\mathrm{st}})$. It follows that fully computing $\pi_0\mathrm{Symp}(X,\omega)$ will not be feasible in essentially any higher-dimensional case, and replacing it with an algebraic avatar makes sense.

The most obvious source of information regarding $\pi_0\mathrm{Symp}(X,\omega)$ comes from algebraic geometry: if X is a smooth projective variety and varies in a moduli space $\mathcal{M}$ (of complex structures, or complete intersections, with fixed polarisation), parallel transport yields a map

$$\rho : \pi_1(\mathcal{M}) \to \pi_0\mathrm{Symp}(X,\omega); \tag{2-2}$$

most known constructions of non-trivial symplectic mapping classes arise this way. Even in simple cases, classical topology struggles to say much about (2-2). Let p be a degree m polynomial with distinct roots. Let X be the Milnor fibre $\{x^2+y^2+p(z)=0\} \subset \mathbb{C}^3$ of the A_{m-1}-singularity $\mathbb{C}^2/(\mathbb{Z}/m)$. Parallel transport for the family over configuration space varying p, and simultaneous resolution of 3-fold nodes, now yields a diagram

$$\begin{array}{ccc} Br_m & \xrightarrow{\ \rho\ } & \pi_0\mathrm{Symp}_{ct}(X) \\ \downarrow & & \downarrow \\ \mathrm{Sym}_m & \xrightarrow{\ \mu\ } & \pi_0\mathrm{Diff}_{ct}(X) \end{array} \tag{2-3}$$

but ρ is actually injective Khovanov and Seidel [2002]. For Milnor fibres of most singularities, the kernel

$$\pi_0\mathrm{Symp}_{ct}(X,\omega) \to \pi_0\mathrm{Diff}_{ct}(X)$$

is large Keating [2014]. In another direction, let $\mathcal{M}_{d,n} = Z_{d,n}/\mathbb{P}\,\mathrm{GL}_{n+2}(\mathbb{C})$ denote the moduli space of degree d hypersurfaces in $\mathbb{P}^{n+1}$, with $Z_{d,n} \subset H^0(\mathbb{P}^{n+1}, \mathcal{O}(d))$ the discriminant complement. Tommasi [2014] proved that $\tilde{H}^*(\mathcal{M}_{d,n};\mathbb{Q}) = 0$ for $d \geqslant 3$ and $* < (d+1)/2$, so the natural map $\mathcal{M}_{d,n} \to B\mathrm{Diff}(X_{d,n})$ cannot be probed using the rather rich cohomology of the image Galatius and O. Randal-Williams [2017]. It seems unclear when (2-2) induces an interesting map on rational cohomology.

Whilst (the possible failure of) *injectivity* of ρ can be probed using Floer-theoretic methods, these seem much less well-adapted to understanding the possible *surjectivity* of ρ; for questions of finite generation, or residual finiteness, one needs maps out of $\pi_0\mathrm{Symp}(X,\omega)$, i.e. one needs to have it act on something. Whilst one can formally write down analogues of the complex of curves, the lack of classification results for Lagrangian submanifolds makes it hard to extract useful information. Spaces of stability conditions on the Fukaya category emerge as another contender, simply because they have been effective in some situations on the other side of the mirror.

Obviously, since $\pi_0\mathrm{Symp}(X,\omega)$ acts on spaces associated to the Fukaya category through the action of the quotient $\mathrm{Auteq}(\mathcal{F}(X,\omega))/\langle[2]\rangle$ (dividing by twice the shift functor), one can only hope to extract information about the latter; this is somewhat similar to first steps in surgery theory, in which one obtains information about $\pi_0\mathrm{Diff}(M)$ from the quotient group $hAut(M)$ of homotopy self-equivalences on the one-hand, as probed by surgery theory and L-theory, and separately (and with separate techniques) from pseudo-isotopy theory and algebraic K-theory. In classical surgery theory, $B\mathrm{Diff}(M)$ is more accessible to study (e.g. cohomologically) than $\pi_0\mathrm{Diff}(M)$, and working at the space level is crucial for many applications. One can upgrade autoequivalences of an A_∞-category to a simplicial space, but there are no compelling computations, and we will not pursue that direction. We should at least mention the Seidel representation Seidel [1997] $\pi_1\mathrm{Ham}(X,\omega) \to QH^*(X)^\times$ (to the group of invertibles) as indication that the higher homotopy groups may carry interesting information away from the Calabi-Yau setting; when $c_1(X) = 0$ the situation is less clear-cut.

We will say that a symplectic manifold (X,ω) is *homologically mirror* to an algebraic variety X° over Λ if there is a Λ-linear equivalence $D^\pi\mathcal{F}(X,\omega) \simeq D^b(X^\circ)$. The following result, whilst narrow in scope, gives a first indication that knowing that something is a homological mirror might sometimes be leveraged to extract new information.

Proposition 2.1. *Let (X,ω) be a $K3$ surface which is homologically mirror to an algebraic $K3$ surface X°. Then a symplectomorphism f of X which preserves the Lagrangian* *isotopy class of each Lagrangian sphere in X acts on $D^\pi\mathcal{F}(X)$ with finite order. If f acts on $D^\pi\mathcal{F}(X)$ non-trivially then it acts on $H^*(X;\mathbb{C})$ non-trivially.*

Proof. An autoequivalence of $D^b(X^\circ)$ acting trivially on the set of spherical objects in $D^b(X^\circ)$ arises from a transcendental automorphism of X°, cf. Huybrechts [2012, Appendix A]. The group of such is a finite cyclic group Huybrechts [2016a, Ch.3 Corollary 3.4] acting faithfully on cohomology. Finally, all spherical objects in $D^\pi\mathcal{F}(X)$ are quasi-isomorphic to Lagrangian sphere vanishing cycles Sheridan and Smith [2017b] (the proof given in *op. cit.*, relying on constraining lattice self-embeddings via discriminant considerations, can be generalised away from the case when X° has Picard rank one). □

One could view this as a weak version of the fact that Γ_g acts faithfully on the complex of curves. Note that for a double plane $X \to \mathbb{P}^2$ branched over a sextic one expects that every Lagrangian sphere arises from a degeneration of the branch locus, and the covering involution reverses orientation but preserves its (unoriented) Lagrangian isotopy class, suggesting the conclusion may be optimal.

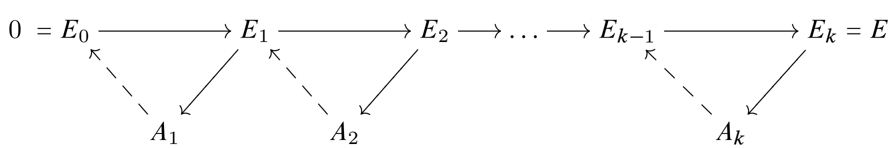
3 Stability conditions

3.1 Definitions. Let $\mathcal{C}$ be a proper, i.e. cohomologically finite, triangulated category, linear over a field k. We will assume that the numerical Grothendieck group $K(\mathcal{C})$, i.e. the quotient of the Grothendieck group $K^0(\mathcal{C})$ by the kernel of the Euler form, is free and of finite rank d. The space of (locally finite numerical) stability conditions will then be a d-dimensional complex manifold.

A *stability condition* $\sigma = (Z, \mathcal{P})$ on $\mathcal{C}$ consists of a group homomorphism $Z\colon K(\mathcal{C}) \to \mathbb{C}$ called the *central charge*, and full additive subcategories $\mathcal{P}(\phi) \subset \mathcal{C}$ of *σ-semistable objects of phase* ϕ for each $\phi \in \mathbb{R}$, which together satisfy a collection of axioms, the most important being:

(a) if $E \in \mathcal{P}(\phi)$ then $Z(E) \in \mathbb{R}_{>0} \cdot e^{i\pi\phi} \subset \mathbb{C}$;

(b) for each nonzero object $E \in \mathcal{C}$ there is a finite sequence of real numbers $\phi_1 > \phi_2 > \cdots > \phi_k$ and a collection of triangles



with $A_j \in \mathcal{P}(\phi_j)$ for all j.

We will always furthermore impose the "support property": for a norm $\|\cdot\|$ on $K(\mathcal{C})\otimes\mathbb{R}$ there is a constant $C > 0$ such that $\|\gamma\| < C\cdot|Z(\gamma)|$ for all $\gamma\in K(\mathcal{C})$ represented by σ-semistable objects in $\mathcal{C}$. (This in particular means all our stability conditions are "full", cf. Bayer and Macrì [2011, Proposition B.4].) The semistable objects A_j appearing in the filtration of axiom (b) are unique up to isomorphism, and are called the *semistable factors* of E. We set

$$\phi^+(E)=\phi_1,\quad \phi^-(E)=\phi_k,\quad m(E)=\sum_i |Z(A_i)|\in\mathbb{R}_{>0}.$$

A simple object E of $\mathcal{P}(\phi)$ is said to be stable of phase ϕ and mass $|Z(E)|$. Let $\mathrm{Stab}(\mathcal{C})$ denote the set of all stability conditions on $\mathcal{C}$. It carries a natural topology, induced by the metric

(3-1)
$$d(\sigma_1,\sigma_2)=\sup_{0\neq E\in\mathcal{C}}\left\{|\phi^-_{\sigma_2}(E)-\phi^-_{\sigma_1}(E)|,\ |\phi^+_{\sigma_2}(E)-\phi^+_{\sigma_1}(E)|,\ \left|\log\frac{m_{\sigma_2}(E)}{m_{\sigma_1}(E)}\right|\right\}\in[0,\infty].$$

Theorem 3.1 (Bridgeland [2007]). *The space* $\mathrm{Stab}(\mathcal{C})$ *has the structure of a complex manifold, such that the forgetful map* $\pi:\ \mathrm{Stab}(\mathcal{C})\longrightarrow\mathrm{Hom}_{\mathbb{Z}}(K(\mathcal{C}),\mathbb{C})$ *taking a stability condition to its central charge is a local isomorphism.*

The group of triangulated autoequivalences $\mathrm{Auteq}(\mathcal{C})$ acts on $\mathrm{Stab}(\mathcal{C})$ by holomorphic automorphisms which preserve the metric. There is a commuting (continuous, non-holomorphic) action of the universal cover of the group $\mathrm{GL}^+(2,\mathbb{R})$, not changing the subcategories $\mathcal{P}$, but acting by post-composition on the central charge viewed as a map to $\mathbb{C}=\mathbb{R}^2$ (and correspondingly adjusting the ϕ-labelling of $\mathcal{P}$). A subgroup $\mathbb{C}\subset\widetilde{\mathrm{GL}}^+(2,\mathbb{R})$ acts freely, by

$$\mathbb{C}\ni t:(Z,P)\mapsto(Z',\mathcal{P}'),\quad Z'(E)=e^{-i\pi t}\cdot Z(E),\quad \mathcal{P}'(\phi)=\mathcal{P}(\phi+\mathrm{Re}(t)).$$

For any integer n, the action of the shift $[n]$ coincides with the action of $n\in\mathbb{C}$. Of particular relevance is the quotient $\mathrm{Stab}(\mathcal{C})/\langle[2]\rangle$, on which the $\widetilde{\mathrm{GL}}^+(2,\mathbb{R})$-action descends to a $\mathrm{GL}^+(2,\mathbb{R})$-action; in the symplectic setting, this will amount to focussing attention on symplectomorphisms rather than graded symplectomorphisms. We will write $\mathrm{Stab}(\mathcal{F}(X))$ for $\mathrm{Stab}(D^\pi\mathcal{F}(X,\omega))$.

Remark 3.2. *If a power of the shift functor of* $\mathcal{C}$ *is isomorphic to the identity,* $\mathrm{Stab}(\mathcal{C})=\varnothing$, *so* $\mathrm{Stab}(\mathcal{F}(X))$ *is only non-trivial when* $2c_1(X)=0$. *Phantom subcategories of derived categories of coherent sheaves Gorchinskiy and Orlov [2013] have trivial K-theory so also cannot admit any stability condition.*

The definition was motivated by ideas in string theory which in turn connect closely to symplectic topology: if (X,ω) is a symplectic manifold with $c_1(X)=0$, there is conjecturally an injection from the Teichmüller space $\mathfrak{M}_X(J,\Omega)$ of marked pairs (J,Ω) comprising a compatible integrable complex structure J and J-holomorphic volume form $\Omega \in \Omega^{n,0}(X;J)$ into $\mathrm{Stab}(\mathcal{F}(X))$. In this scenario, given (J,Ω), then $Z(L) = \int_L \Omega$, the categories $\mathcal{P}(\phi)$ contain the special Lagrangians of phase ϕ, and the Harder-Narasimhan filtration should be the output of some version of mean curvature flow with surgeries at finite-time singularities, cf. Joyce [2015].

An important point is that even if one can build a map $\mathfrak{M}_X(J,\Omega) \to \mathrm{Stab}(\mathcal{F}(X))$, simply for dimension reasons it often can't be onto an open subset; one expects it to have image a complicated transcendental submanifold of high codimension. There is rarely a predicted geometric interpretation of the "general" stability condition. (Completeness of (3-1) was proven in Woolf [2012]; contrast with the Weil-Petersson metric on moduli spaces of Calabi-Yau's, which frequently has the boundary at finite distance Wang [1997] and is incomplete.) More positively, since the vanishing cycle of any nodal degeneration can be realised by a special Lagrangian Hein and Sun [2017], one expects any Lagrangian sphere which is such a vanishing cycle to be stable for some stability condition, and to define an "end" to the space of stability conditions, where the mass of this stable object tends to zero. Thus one might hope that the global topology of $\mathrm{Stab}(\mathcal{F}(X))/\mathrm{Auteq}(\mathcal{F}(X))$ carries information about Lagrangian spheres.

3.2 Properties. $\mathrm{Stab}(\mathcal{C})$ is a complex manifold. But it inherits additional structure: it is modelled on a fixed vector space such that the transition maps between charts are locally the identity, and it has a global étale map to $\mathrm{Hom}_{\mathbb{Z}}(K(\mathcal{C}),\mathbb{C}) \cong \mathbb{C}^d$.

Fix a connected component $\mathrm{Stab}_\dagger(\mathcal{C})$ of $\mathrm{Stab}(\mathcal{C})$. Let $\mathrm{Auteq}_\dagger(\mathcal{C})$ denote the quotient of the subgroup of $\mathrm{Auteq}(\mathcal{C})$ which preserves $\mathrm{Stab}_\dagger(\mathcal{C})$ by the subgroup of "negligible" autoequivalences, i.e. those which act trivially on $\mathrm{Stab}_\dagger(\mathcal{C})$. Negligible autoequivalences can exist, for instance coming from automorphisms of projective surfaces which act trivially on the algebraic cohomology (these need not be trivial on the transcendental cohomology).

Lemma 3.3. $\mathrm{Stab}_\dagger(\mathcal{C})$ *has a well-defined integral affine structure and a canonical measure. The quotient* $\mathcal{Q} = \mathrm{Stab}_\dagger(\mathcal{C})/\mathrm{Auteq}_\dagger(\mathcal{C})$ *is a complex orbifold, with* $2c_i(\mathcal{Q}) = 0$ *for* i *odd.*

Proof. The affine structure comes from the integral lattice in $K(\mathcal{C})$. The measure is obtained from Lebesgue measure in $\mathrm{Hom}_{\mathbb{Z}}(K(\mathcal{C}),\mathbb{C})$, normalised so that the quotient torus $\mathrm{Hom}_{\mathbb{Z}}(K(\mathcal{C}),\mathbb{C}/(\mathbb{Z}\oplus i\mathbb{Z}))$ has volume one. We claim that, having killed the generic stabiliser, $\mathrm{Auteq}_\dagger(\mathcal{C})$ acts with finite stabilisers. The argument is due to Bridgeland, and applies to the space of stability conditions satisfying the support condition whenever the central charge is required to factor through a finite rank lattice N (see also Huybrechts [2016b]). Given any stability condition σ and $R \in \mathbb{R}_{>0}$, there are only finitely many classes $n \in N$ which are represented by a σ-semistable object E with $|Z_\sigma(E)| < R$. For

$R \gg 0$ sufficiently large, these classes will span the lattice (fix a set of objects of $\mathcal{C}$ whose classes give a basis of N, and consider the classes represented by the semistable factors in the HN-filtrations of those objects). Any autoequivalence ϕ fixing σ must permute this finite set, so some fixed power σ^k fixes all these elements pointwise. Then σ^k acts trivially on $\mathrm{Hom}_{\mathbb{Z}}(N, \mathbb{C})$, hence by Theorem 3.1 on a neighbourhood of $\sigma \in \mathrm{Stab}_{\dagger}(\mathcal{C})$, and hence acts trivially globally (since it's a holomorphic automorphism). This shows that for any $\sigma \in \mathrm{Stab}_{\dagger}(\mathcal{C})$, the stabiliser of σ acts faithfully on a finite set. The proof also shows that the stabiliser of a point $\sigma \in \mathrm{Stab}_{\dagger}(\mathcal{C})$ injects into $\mathrm{GL}(d; \mathbb{Z})$ via the action on the central charge, so the torsion orders of stabilisers are bounded only in terms of d.

To deduce that the quotient is an orbifold, it remains to see that the action of $\mathrm{Auteq}_{\dagger}(\mathcal{C})$ is properly discontinuous, so admits slices. Bridgeland [2007, Lemma 6.4] proves that if two stability conditions σ, τ have the same central charge, then they co-incide or are at distance $d(\sigma, \tau) \geqslant 1$. Therefore, if the action was not properly discontinuous, there would be a stability condition σ and an infinite sequence of elements in $\mathrm{GL}(d, \mathbb{Z})$ which failed to displace a small ball around Z_σ. This easily yields a contradiction. Since autoequivalences act on $\mathrm{Hom}_{\mathbb{Z}}(K(\mathcal{C}), \mathbb{C})$ via the complexifications of integral linear maps, they preserve the real and imaginary subbundles of the tangent bundle. Thus, $\mathrm{Stab}_{\dagger}(\mathcal{C})$ has holomorphically trivial tangent bundle, and the tangent bundle of $\mathrm{Stab}_{\dagger}(\mathcal{C})/\mathrm{Auteq}_{\dagger}(\mathcal{C})$ is the complexification of a real bundle, so the odd Chern classes of the quotient orbifold are 2-torsion. □

The diagonal group $\mathrm{diag}(e^t, e^{-t}) \subset \mathrm{SL}(2, \mathbb{R})$ acts on $\mathrm{Stab}(\mathcal{C})$ by expanding and contracting the real and imaginary directions in $\mathrm{Hom}_{\mathbb{Z}}(K(\mathcal{C}), \mathbb{C})$, which are tangent to smooth Lagrangian subbundles of the tangent bundle (for the flat Kähler form on $\mathbb{C}^d$), somewhat reminiscent of an Anosov flow. If this flow on $\mathrm{Stab}(\mathcal{C})$ was the geodesic flow of a complete Riemannian metric, then classical results (non-existence of conjugate points) would imply that $\mathrm{Stab}(\mathcal{C})$ was a $K(\pi, 1)$. Despite the naivety of such reasoning, in known cases, the connected components of $\mathrm{Stab}(\mathcal{C})$ are contractible, or diffeomorphic to spaces independently conjectured to be contractible in the literature Allcock [2013], Kontsevich and Zorich [1997], and Qiu and Woolf [2014].

Corollary 3.4. *If* $\mathrm{Stab}_{\dagger}(\mathcal{C})$ *is contractible,* $\mathrm{Auteq}_{\dagger}(\mathcal{C})$ *has finite rational cohomological dimension.*

Proof. This is true for any discrete group Γ acting on a contractible finite-dimensional manifold Q with finite stabilisers, provided the action admits slices. (To prove the result, apply the Leray-Hirsch theorem to the projection $(Q \times E\Gamma) \to Q \times_{\Gamma} E\Gamma$, and note that the stalks of the pushforward of the constant sheaf $\mathbb{Q}$ vanish.) The existence of slices for the action follows from proper discontinuity. □

If a finitely generated countable group G has an embedding $G \times G \hookrightarrow G$ (e.g. the finitely presented "Thompson's group F") then it has infinite rational cohomological dimension Gandini [2012], so the contractibility hypothesis already excludes some "reasonable" countable groups from being autoequivalence groups.

It is tempting to believe contractibility holds, when it does, for some intrinsic geometric reason, e.g. that the canonical metric (3-1) is non-positively curved, making $\mathrm{Stab}(\mathcal{C})$ a complete CAT(0) space. (If the phases of σ-semistable objects are dense in S^1, then the $\mathrm{GL}^+(2,\mathbb{R})$-orbit of σ is free, and the metric on the quotient $\mathrm{GL}^+(2,\mathbb{R})/\mathbb{C}$ is the standard hyperbolic metric on the upper half-plane up to scale Woolf [2012].) This would be of dynamical relevance. Groups acting on weakly hyperbolic spaces with rank one elements (which typically exist) admit infinite-dimensional families of quasimorphisms, for instance the "counting" quasimorphisms of Epstein and Fujiwara [1997], see also Calegari [2009]. On the other hand, Malyutin [2011] shows that if $\Phi : G \to \mathbb{R}^3$ is defined by a triple of unbounded quasimorphisms, and if $S \subset G$ has bounded Φ-image, then S is transient, meaning that a random walk on G (defined with respect to any non-degenerate probability measure, i.e. one whose support generates G as a semigroup) will visit S only finitely many times almost surely. A prototypical example is that the reducible or periodic surface diffeomorphisms – those for which $\iota(\alpha, \phi^n(\beta))$ is not exponential for all α, β in (Section 2.1, (3)) – are transient in Γ_g, and random mapping classes of surfaces are pseudo-Anosov.

Corollary 3.5. *If* $\mathrm{Stab}_\dagger(\mathcal{C})$ *is complete CAT(0) and* $\mathrm{Auteq}_\dagger(\mathcal{C})$ *acts with rank one elements, then scl of the kth element of a random walk tends to infinity as k tends to infinity almost surely.*

One can analogously look for quantitative "unbounded generation" results. Borel and Harish-Chandra [1962] proved the isometry group of an arithmetic lattice acts on elements of fixed square with finitely many orbits. Suppose this homological statement lifts, and that $\mathcal{C}$ has only finitely many conjugacy classes of spherical object under autoequivalence. Quasimorphisms can be averaged to be homogeneous, hence constant on conjugacy classes, so then all spherical twists have uniformly bounded image under any Φ as above. If $S \subset G$ is transient and $N \subset G$ is finite, then $(S \cup S^{-1} \cup N)^k$ is transient for any fixed k. For $\mathcal{C} = \mathcal{F}(X)$ we have noted that one hopes a Lagrangian sphere defines an end to (a component meeting $\mathfrak{M}_X(J,\Omega)$ of) $\mathrm{Stab}(\mathcal{F}(X))$ corresponding to a nodal degeneration. Suppose that there is a partial compactification of $\mathcal{Q} = \mathrm{Stab}_\dagger(\mathcal{F}(X))/\mathrm{Auteq}_\dagger(X)$, or of $\mathfrak{M}_X(J,\Omega)$, with an irreducible primitive analytic divisor D parametrizing nodal degenerations of X. A choice of a closed oriented surface S transverse to D at one point exhibits, via the usual presentation for $\pi_1(S)$, the corresponding spherical twist as a product of commutators, and hence all conjugate spherical twists as products of the same number of commutators. Then Corollary 3.5 would imply that, for any fixed k, a random element of $\mathrm{Auteq}_{\dagger}(\mathcal{F}(X))$ would almost surely not be a product of fewer than k spherical twists.

This raises the question: how does one find *Floer-theoretic* conditions for sets of symplectomorphisms to lie in a bounded set under the image of a quasimorphism on $\pi_0\mathrm{Symp}(X)$?

3.3 Classification of objects. Consider some concrete computations. Since the space of stability conditions is expected to be contractible, the object of interest is the orbifold covering map

$$\pi : \mathrm{Stab}_{\dagger}(\mathcal{C}) \to \mathrm{Stab}_{\dagger}(\mathcal{C})/\mathrm{Auteq}_{\dagger}(\mathcal{C}) = \mathcal{Q}. \tag{3-2}$$

- (X, ω) is $(T^2, \omega_{\mathrm{st}})$. Then $\mathcal{Q}$ is a $\mathbb{C}^*$-bundle over $\mathfrak{h}/SL(2,\mathbb{Z})$, and $\mathrm{Auteq}(\mathcal{F}(X))$ is an extension of $SL(2;\mathbb{Z})$ by $\mathbb{Z} \oplus X \times X^{\vee}$ (acting by shift, translation and tensoring by flat bundles); Bridgeland [2007] and Polishchuk and Zaslow [1998].

- (X, ω) is $\{x^2 + y^2 + z^k = 1\} \subset (\mathbb{C}^3, \omega_{\mathbb{C}^3})$ and we consider the compact Fukaya category. Then $\mathcal{Q} = \mathrm{Conf}_k(\mathbb{C})$ parametrises polynomials with k distinct roots, cf. the monodromy discussion of (2-3); $\mathrm{Auteq}(\mathcal{F}(X))/[2] = Br_k$ is the braid group Thomas [2006] and Ishii, Ueda, and Uehara [2010].

- (X, ω) is (Σ, M), a surface with non-empty boundary containing a non-empty set of boundary marked points $M \subset \partial\Sigma$, and we consider the partially wrapped[1] Fukaya category $\mathcal{F}(\Sigma; M)$ stopped at M Sylvan [2015], whose objects include arcs ending on $\partial\Sigma \backslash M$. Then $\mathcal{Q}$ is a space of marked flat structures (meromorphic quadratic differentials) on Σ, up to diffeomorphism Haiden, Katzarkov, and Kontsevich [2017].

The computation of $\mathrm{Stab}(\mathcal{C})$, when feasible, often goes hand-in-hand with a classification for some class of objects of the category $\mathcal{C}$, which is of independent interest. (Whilst the objects of $\mathcal{F}(X)$ are *a priori* geometric, the objects of $\mathcal{F}(X)^{perf}$ are not, and a concrete interpretation of an arbitrary perfect module is rarely available.) In the cases above, one uses:

- Atiyah's classification of bundles on elliptic curves, which implies that a twisted complex on objects in $\mathcal{F}(T^2)$ is again quasi-represented by a simple closed curve with local system;

- Ishii-Uehara's proof Ishii and Uehara [2005] that all spherical objects in $\mathrm{Tw}\,\mathcal{F}(X_p)$ are in the braid group orbit of a fixed Lagrangian sphere;

[1] The compact Fukaya category $\mathcal{F}$ is proper but not smooth; the wrapped category $\mathcal{W}$ is smooth but not proper; the partially wrapped category, which depends on additional data – here, the set M – has both properties. It determines $\mathcal{W}$ as a localization, and (conjecturally, in nice cases) $\mathcal{F}$ as a subcategory of compact objects of $\mathcal{W}$.

- Haiden-Katzarkov-Kontsevich's proof that every indecomposable twisted complex of objects of $\mathcal{F}(\Sigma; M)$ is represented by an immersed curve with local system.

By appealing to either sheaf-theoretic properties of wrapped categories Lee [2015] or equivariant arguments Seidel [2012], one can deduce from the last example above that on a closed surface Σ_g, every spherical object is geometric, i.e. quasi-isomorphic to an immersed curve with local system. It is tempting to speculate that, starting from that point, one can recover the complex of curves and hence the classical mapping class group from the derived Fukaya category $D^\pi \mathcal{F}(\Sigma_g)$.

3.4 Measure and growth. Recall that $\mathrm{Stab}_\dagger(\mathcal{C})$ has a canonical measure $d\nu$ inherited from Lebesgue measure in $\mathrm{Hom}_{\mathbb{Z}}(K(\mathcal{C}), \mathbb{C})$. Since autoequivalences act linearly and integrally on $K(\mathcal{C})$, the measure is $\mathrm{Auteq}_\dagger(\mathcal{C})$-invariant, so descends to the quotient orbifold. This will essentially always have infinite measure, since there is a free $\mathbb{R}$-action on $\mathrm{Stab}(\mathcal{C})$, rescaling the central charge.

Hypothesis 3.6. *There is a submanifold* $\mathrm{Stab}_{=1,\dagger}(\mathcal{C})$ *which is a slice to the* $\mathbb{R}$*-action, which is invariant under the universal cover of* $SL(2,\mathbb{R})$*, and for which*

$$\mathrm{Stab}_{=1,\dagger}(\mathcal{C})/\mathrm{Auteq}_\dagger(\mathcal{C})$$

has finite measure.

Existence of a slice is usually not difficult, but the finite measure hypothesis is probably much more severe. Let S be a Riemann surface and $\phi \in H^0(2K_S)$ a quadratic differential with distinct zeroes. There is a local CY Kähler threefold

$$Y_\phi = \{(q_1, q_2, q_3) \in K_S \oplus K_S \oplus K_S \mid q_1^2 + q_2^2 + q_3^2 = \phi\} \tag{3-3}$$

which depends up to deformation only on the genus $g(S)$. The space of stability conditions modulo autoequivalences on $\mathcal{F}(Y_\phi)$ is conjecturally the moduli space $\mathcal{M}(S,\phi)$ of quadratic differentials with simple zeroes, and the normalisation $\int_S \phi \wedge \bar{\phi} = 1$ to surfaces of flat area 1 defines a slice to the $\mathbb{R}$-action. This has finite measure by deep results of Veech [1993]. For a K3 surface X°, $Z(E) = (\Omega, ch(E))$ for a period vector $\Omega \in \mathbb{N}(X^\circ) \otimes \mathbb{C}$, where $\mathbb{N}(X^\circ)$ is the extended Neron-Severi group $H^0 \oplus \mathrm{Pic} \oplus H^4$, and the condition $(\Omega, \bar{\Omega}) = 1$ defines a slice.

Given Hypothesis 3.6, one can play the following game (a well-known trope in the flat surfaces community; we follow Zorich [2006]). Fix a stability condition σ; the support property means that the central charges $Z(E)$ of σ-semistable objects are discrete in $\mathbb{C}$. For a compactly supported function $f \in C_{ct}(\mathbb{R}^2)$ we can then define $\hat{f}(\sigma) = \sum_{Z(E)} f(Z(E))$, summing over central charges represented by semistable E. A stronger version of Hypothesis 3.6 asks that the function $\sigma \mapsto \hat{f}(\sigma)$ be $d\nu$-integrable, yielding a linear function

$$f \mapsto \int_{\mathrm{Stab}_{=1,\dagger}(\mathcal{C})/\mathrm{Auteq}_{\dagger}(\mathcal{C})} \hat{f}\, d\nu$$

which is $SL_2(\mathbb{R})$-invariant. The only such functionals on $C_{ct}(\mathbb{R}^2)$ are given by the total area and the value at zero; the latter is irrelevant here since $Z(E) \neq 0$ for any semistable E, so one finds that

$$\text{For every } f \in C_{ct}(\mathbb{R}^2), \quad \int_{\mathrm{Stab}_{=1,\dagger}(\mathcal{C})/\mathrm{Auteq}_{\dagger}(\mathcal{C})} \hat{f}\, d\nu = \tau(\mathcal{C}) \int_{\mathbb{R}^2} f\, dxdy$$

where $\tau(\mathcal{C})$ is an invariant of the category and the choice of component / slice. Taking f to be the indicator function of a disc of increasing radius R, one sees that $\tau(\mathcal{C})$ measures the growth rate of K-theory classes represented by semi-stable objects as their mass increases. For $\mathcal{M}(S,\phi)$ above, $\tau(\mathcal{C})$ is a Siegel-Veech number, and controls the quadratic growth rate of special Lagrangian 3-spheres by volume in the 3-fold (3-3) (in that case, the special Lagrangian 3-sphere representative of the homology class is expected to be unique).

4 Three more extended examples

4.1 K3 surfaces. Let Y be an algebraic K3 surface of Picard rank $\rho \geqslant 1$. Bridgeland [2008] has given a conjectural description of a distinguished component of $\mathrm{Stab}(D^b(Y))$ as the universal cover of a period domain. Recall $\mathbb{N}(Y) = H^0(Y) \oplus \mathrm{Pic}(Y) \oplus H^4(Y)$, which carries the Mukai pairing $\langle (a,b,c),(a',b',c')\rangle = ac' + ca' - b\cdot b'$. Let

$$\Omega = \{u \in \mathbb{N}(Y)\otimes\mathbb{C} \mid \mathrm{Re}(u), \mathrm{Im}(u) \text{ span a positive definite } 2\text{–plane}\}.$$

Fix one of the two connected components of Ω, and remove the locally finite union of hyperplanes $\delta^{\perp}$ indexed by -2-vectors $\delta \in \mathbb{N}(Y)$ (with its Mukai form), to obtain a period domain $\mathcal{P}_0^+(Y)$. Then Bridgeland [ibid.] constructs a connected component $\mathrm{Stab}_{\dagger} \subset \mathrm{Stab}(D^b(Y))$ and proves that there is a Galois covering

$$\mathrm{Stab}_{\dagger} \to \mathcal{P}_0^+(Y)$$

which identifies the Torelli autoequivalence group with the group of deck transformations. Bridgeland conjectures that $\mathrm{Stab}_{\dagger}$ is simply-connected and Auteq-invariant, which would yield the exact sequence

$$1 \to \pi_1(\mathcal{P}_0^+(Y)) \to \mathrm{Auteq}_{CY}(D^b(Y)) \to \mathrm{Aut}^+(H^*(Y)) \to 1$$

where the Calabi-Yau autoequivalences Auteq_{CY} are those acting trivially on the Hochschild homology group $HH_2(Y)$, and the final term is the index two subgroup of the full Hodge isometry group of automorphisms preserving the orientation of a maximal positive definite subspace. The generators of the first term would be mapped to squared spherical twists. Separately, a conjecture of Allcock [2013] on Coxeter arrangements would imply that, if Bridgeland's conjecture holds, then $\mathrm{Stab}_{\dagger}(D^b(Y))$ is indeed a CAT(0) space, in particular contractible. When $\rho(Y) = 1$, both conjectures are known, which yields a complete determination of both that component of the space of stability conditions and the autoequivalence group.

Proposition 4.1. *Let (X, ω) be a Kähler K3 surface which is homologically mirror to an algebraic K3 surface Y of Picard rank one. (Minimality of the Picard rank on the mirror corresponds to an irrationality hypothesis on the Kähler form ω on X.) Let $G\mathcal{F}(X) = \mathrm{Auteq}(D^\pi \mathcal{F}(X, \omega))$.*

1. *$G\mathcal{F}(X)$ is finitely presented.*
2. *The Torelli subgroup is infinitely generated and torsion-free.*
3. *$G\mathcal{F}(X)$ contains no divisible elements.*
4. *$G\mathcal{F}(X)$ cannot obey a law.*

Sketch comments. The first three statements are essentially immediate from Bayer and Bridgeland [2017]; in fact the categorical Torelli group in the (mirror to a) Picard rank one case is a countably generated free group. scl for free products of cyclic groups was computed in Walker [2013], e.g. there are examples for which $G\mathcal{F}(X) = \mathbb{Z}/p * \mathbb{Z}$, and for $\mathbb{Z}/p * \mathbb{Z}$ with generators a, b of the factors, $scl([a, b]) = 1/2 - 1/p$; as remarked previously, non-vanishing of scl rules out laws. See Sheridan and Smith [2017b] for related ideas and details. □

Proofs of the Bridgeland and Allcock conjectures would eliminate the Picard rank one hypothesis. Results for $G\mathcal{F}(X)$ do not immediately yield results for the symplectic mapping class group $\pi_0\mathrm{Symp}(X, \omega)$, but these can sometimes be extracted with more care. Let (X, ω) be the mirror quartic, a crepant resolution of $\{\sum_{j=0}^3 x_j^4 + \lambda \prod_j x_j = 0\}/\Gamma$ for $\Gamma \cong (\mathbb{Z}/4)^{\oplus 2}$, equipped with an "irrational" toric Kähler form (one induced from its embedding into a toric resolution of $[\mathbb{P}^3/\Gamma]$ such that the areas of the resolution curves and of a hyperplane section are rationally independent). Then (see Sheridan and Smith [ibid.]):

Theorem 4.2 (Sheridan, Smith)**.** *For the mirror quartic with an irrational toric Kähler form, the group $\ker(\pi_0\mathrm{Symp}(X) \to \pi_0\mathrm{Diff}(X))$ is infinitely generated.*

The map π of (3-2) is (modulo $GL(2,\mathbb{R})$) the universal cover of the orbifold $\mathfrak{h}/\Gamma_0(2)^+$, where $\Gamma_0(2)^+ = \mathbb{Z}/2 * \mathbb{Z}/4$, and $\mathrm{Auteq}_{CY}(\mathcal{F}(X))/[2] = \mathbb{Z} * \mathbb{Z}/4$ where again the CY autoequivalencs are those acting trivially on $HH_2(\mathcal{F}(X))$, cf. Bayer and Bridgeland [2017] and Sheridan and Smith [2017b]. One infers the Dehn twist τ_L in a Lagrangian sphere $L \subset X$ admits no non-trivial root in $\pi_0\mathrm{Symp}(X)$ (being a smooth involution, it is its own $(2p+1)$-st root in $\pi_0\mathrm{Diff}(X)$, for any $p \geqslant 1$); $\pi_0\mathrm{Symp}(X)$ is not generated by torsion elements (which all map to the same factor in the abelianization of $\mathrm{Auteq}(\mathcal{F}(X))$), in contrast to Γ_g, etc.

Remark 4.3. *It is interesting to compare the proof in Bayer and Bridgeland [2017] with the cartoon description of stability conditions in terms of special Lagrangians given at the end of Section 3.1. For a Picard rank one K3 surface X°, the central charge is given by $Z(E) = \langle \Omega, ch(E)\rangle$ for a vector $\Omega \in \mathbb{N}(X^\circ) \otimes \mathbb{C} \cong \mathbb{C}^3$ whose real and imaginary parts span a positive definite two-plane. There is a unique negative definite vector $\theta \in \mathbb{N}(X^\circ) \otimes \mathbb{R}$ orthogonal to $\{Re(\Omega), Im(\Omega)\}$. Fix $E = \mathcal{O}_x$ the skyscraper sheaf of a point, and a stability condition σ for which the largest and smallest semistable factors $A_\pm$ of E have phases $\phi_+ > \phi_-$ respectively. Then Bayer and Bridgeland [ibid.] studies the flow on* $\mathrm{Stab}(X^\circ)$ *defined by*

$$d\Omega/dt = \xi.\theta \qquad \xi = i\,\exp(i\pi/2(\phi_+ + \phi_-))$$

which locally pushes $A_\pm$ towards one another, decreasing $\phi_+ - \phi_-$. They prove such flows can be patched together and eventually contract $\mathrm{Stab}(X^\circ)$ *to the geometric chamber where E is semistable. Translating back to the A-side, the cartoon is now that instead of mean curvature flow, one fixes the Lagrangian torus, and flows in the space of holomorphic volume forms to try to make it special.*

4.2 Quiver threefolds. Let (Q,W) be a quiver with potential. This determines a 3-dimensional Calabi-Yau category $\mathcal{C}(Q,W)$ Ginzburg [2006]. If (Q,W) has no loops, there is a "mutation" operation which yields another (Q',W') and a (pair of) derived equivalence(s) $\mathcal{C}(Q,W) \simeq \mathcal{C}(Q',W')$. In a number of interesting cases, these categories are related to Fukaya categories of threefolds:

1. The zero-potential on the two-cycle quiver (arrows labelled e, f) is realised within the compact Fukaya category of the affine quartic $\{x^2+y^2+(zt)^2=1\} \subset \mathbb{C}^4$, which is a plumbing of two 3-spheres along a circle (plumbed so the Lagrange surgery is an $S^1 \times S^2$), see Evans, Smith, and Wemyss [n.d.].

2. The potential $(ef)^2$ on the same quiver is realised by the compact Fukaya category of the complement of a smooth hyperplane section in the variety of complete flags

in $\mathbb{C}^3$, which is again a plumbing of two 3-spheres along a circle (plumbed so the Lagrange surgery is an S^3); potentials $(ef)^p$ on the two-cycle quiver, for prime $p > 2$, may arise in characteristic p from the corresponding plumbings where the surgery is a Lens space $L(p,1)$, see Evans, Smith, and Wemyss [ibid.].

3. The potential associated Labardini-Fragoso [2009] to an ideal triangulation of a marked bordered surface (S, M) is realised by the Fukaya category of a threefold which is a conic fibration over S with special fibres at M Smith [2015] (this is a cousin of the space from (3-3), where $M = \varnothing$).

The category $\mathcal{C}(Q, W)$ has a distinguished heart, equivalent to the category of nilpotent representations of the Jacobi algebra $\mathrm{Jac}(Q, W)$, with d simple objects up to isomorphism if Q has d vertices. This implies that a large subset $\mathcal{U} \subset \mathrm{Stab}(\mathcal{C}(Q, W))$ with non-empty open interior is a union of cells $\overline{\mathfrak{h}}^d$ (where $\overline{\mathfrak{h}}$ is the union of the upper half-plane and the negative real axis excluding zero), indexed by t-structures having hearts with finite length, glued together along their boundaries by the combinatorics of tilting (quiver mutation). This provides one of the most direct routes to (partial) computations of spaces of stability conditions. Often, the image of $\mathcal{U}$ under the natural circle action on $\mathrm{Stab}(\mathcal{C})/\langle[2]\rangle$ covers a path-component.

Let ϕ be a meromorphic quadratic differential on a surface S with at least one pole of order $\geqslant 2$, with p double poles, and distinct zeroes. Let $M \subset S$ be the set of poles. There is a threefold $Y_\phi \to S$, a variant of that from (3-3), now with empty fibres over poles of order > 2 and reducible fibres (singular at infinity) over double poles; a choice of component of each reducible fibre defines a class $\eta \in H^2(Y_\phi; \mathbb{Z}/2)$. Let $\mathcal{F}(Y_\phi; \eta)$ denote the subcategory of the η-sign-twisted Fukaya category split-generated by Lagrangian spheres. Then (see Bridgeland and Smith [2015] and Smith [2015]):

Theorem 4.4 (Bridgeland, Smith)**.** *There is an equivalence $\mathcal{F}(Y_\phi; \eta) \simeq \mathcal{C}(Q, W)$ for (Q, W) the quiver with potential associated to any ideal triangulation of (S, M). Moreover,*

$$1 \to \mathrm{Sph}(S, M) \to \mathrm{Auteq}(\mathcal{C}(Q, W)) \to \Gamma^{\pm}(S, M) \to 1 \tag{4-1}$$

where $\Gamma^{\pm}$ is an extension of the mapping class group $\Gamma(S, M)$ by $(\mathbb{Z}/2)^p$.

The first factor in (4-1) acts through spherical twists and admits a natural representation to $\pi_0\mathrm{Symp}_{ct}(Y_\phi)$ whilst the quotient factor acts via non-compactly-supported elements of $\pi_0\mathrm{Symp}(Y_\phi)$. In particular, the natural map $\mathrm{Sph}(S, M) \to \pi_0\mathrm{Symp}_{ct}(Y_\phi)$ is actually split. Stable objects in Y_ϕ are all given by special Lagrangian 3-spheres or $S^1 \times S^2$'s, corresponding to open and closed saddle connections in the flat metric on (S, ϕ).

There are 3-folds $Y_{\phi,\psi}$ associated to a pair $(\phi,\psi) \in H^0(K_S^{\oplus 2}) \oplus H^0(K_S^{\oplus 3})$, fibred over S by A_2-Milnor fibres rather than A_1-Milnor fibres: given line bundles L_1, L_2 over S with $K_S = L_1 L_2$,

$$Y_{\phi,\psi} = \{(x,y,z) \in L_1^3 \oplus L_2^3 \oplus L_1 L_2 \,|\, xy = z^3 + \phi \cdot z + \psi\}.$$

In this case the conjectural embedding of a moduli space of pairs (ϕ,ψ) into $\mathrm{Stab}(\mathcal{F}(Y_{\phi,\psi}))$ cannot be onto an open set for dimension reasons (cf. Section 3.1). The DT-counting invariants for semistable objects in K-theory class $d\gamma$ can have exponential growth in d Galakhov, Longhi, Mainiero, Moore, and Neitzke [2013] and have interesting algebraic generating functions Mainiero [2016]. The 3-fold $Y_{\phi,\psi}$ now contains a special Lagrangian submanifold $L \cong (S^1 \times S^2)\#(S^1 \times S^2)$, obtained from surgery of two 3-spheres lying over tripods which meet at three end-points, and the wild representation theory of $\pi_1(L)$ may be responsible for the exponential growth of stable objects (flat bundles over L) on the symplectic side. It would be interesting to know if (3.6) is related to polynomial growth of DT-invariants.

4.3 Cubic four-folds. The derived category of a cubic four-fold $Y \subset \mathbb{P}^5$ admits a semi-orthogonal decomposition, the interesting piece of which is a CY2-category $\mathcal{A}_Y$ introduced by Kuznetsov [2010]. These categories are of symplectic nature, cf. Huybrechts [2017, Proposition 2.17] and Sheridan and Smith [2017a]. Let E be the (Fermat) elliptic curve with a non-trivial $\mathbb{Z}/3$-action, generated by ξ, and X be the K3 surface which is the crepant resolution of $(E \times E)/\langle(\xi,\xi^{-1})\rangle$. (This is sometimes called the "most algebraic" K3 surface; it has Picard rank 20 and, amongst such K3's, has smallest possible discriminant.) Then for certain toric Kähler forms ω on X which are "irrational" (again meaning the areas of the resolution curves and a hyperplane section are linearly independent over $\mathbb{Q}$), there is an equivalence Sheridan [2017] and Sheridan and Smith [2017a] (strictly, this requires incorporating certain immersed Lagrangian tori into $\mathcal{F}(X,\omega)$)

$$D^\pi \mathcal{F}(X,\omega) \simeq \mathcal{A}_{Y_{d(\omega)}} \subset D^b(Y_{d(\omega)})$$

where the valuations of the coefficients in the equation defining the cubic Y over Λ are determined by the choice of Kähler form. For sufficiently general Y, the space of stability conditions has been computed by Bayer, Lahoz, Macrì, and Stellari [2017], following a direct computation of autoequivalences due to Huybrechts [2017], and one finds (cf. Sheridan and Smith [2017a, n.d.]):

Theorem 4.5 (Sheridan, Smith)**.** *For the most algebraic K3 surface X with an irrational toric Kähler form, the map $\rho : \pi_0\mathrm{Symp}(X,\omega) \longrightarrow \mathrm{Auteq}(\mathcal{F}(X,\omega))/[2]$ has image $\mathbb{Z}/3$. If $Z(X,\omega) = \ker(\rho)$ then $\pi_0\mathrm{Symp}(X,\omega) = Z(X,\omega) \rtimes \mathbb{Z}/3$.*

The image of ρ is generated by the obvious residual diagonal action on $E \times E$, which lifts to X. Theorem 4.5 reduces the task of understanding the symplectic mapping class group of (X, ω) to that of understanding what Floer theory doesn't see, which is about as far as we could hope to come (one can draw similar conclusions in the setting of Theorem 4.2, see Sheridan and Smith [2017b]). More concretely, for such irrational Kähler forms one learns that $HF(\phi)$ can take only one of three possibilties for any symplectomorphism ϕ, and any ϕ has trivial Floer-theoretic entropy, etc. From the Künneth theorem, this has consequences for fixed points of symplectomorphisms of $X \times T^2$, say, which – in the same vein as the Arnol'd conjecture – go beyond information extractable from smooth topology (stabilising by taking product with T^2 serves to kill information from the Lefschetz theorem).

It is interesting to imagine turning around the direction of mirror symmetry in this case. Naively, one would predict some relation between the categories

$$D^{\pi}\mathcal{F}(Y;0) \qquad \text{and} \qquad D^b(X) = D(E \times E)^{\mathbb{Z}/3} \tag{4-2}$$

where $\mathcal{F}(Y;0)$ is the nilpotent summand of the Fukaya category (corresponding in (2-1) to the zero-eigenvalue). It seems far from obvious that these should be equivalent, and the actual relation, if any, might be more subtle. Nonetheless, although $\mathcal{F}(Y)$ is not $\mathbb{Z}$-graded as Y is Fano, the summand $\mathcal{F}(Y;0)$ *is* expected to admit a $\mathbb{Z}$-grading, whence one could talk about stability conditions. Let $\mathcal{M}_{3,d}$ denote the moduli space of cubic d-folds. These are well-studied spaces (and are famously CAT(0) for $d = 2, 3$ Allcock, Carlson, and Toledo [2002, 2011]). Starting from the lattice-theoretic co-incidence $H^2(X;\mathbb{Z}) \supset \mathrm{Pic}(X)^{\perp} = -A_2 = \langle h^2\rangle^{\perp} \subset H^4(Y;\mathbb{Z})$, where $h^2 \in H^4(Y;\mathbb{Z})$ is the class defined by a hyperplane, results of Laza [2010] yield an embedding (also observed by R. Potter)

$$\mathcal{M}_{3,4} \longrightarrow \mathrm{Auteq}_{CY}(X)\backslash \mathrm{Stab}_{\dagger}(D^b(X))/\widetilde{GL}^{+}(2,\mathbb{R})$$

onto the complement of an explicit divisor Δ (associated to the locally finite hyperplane arrangement defined by classes of square -6, or equivalently the complement in the period domain of the divisors associated to classes of square -2 and -6). Bridgeland's conjecture and some concrete relation in (4-2) might then give insight into the monodromy homomorphism

$$\pi_1(\mathcal{M}_{3,4}) \longrightarrow \pi_0\mathrm{Symp}(Y) \longrightarrow \mathrm{Auteq}(D^{\pi}\mathcal{F}(Y;0)).$$

In this way, one could hope to use stability conditions on $K3$ surfaces to attack classical problems related to the symplectic monodromy of hypersurfaces.

4.4 Clusters. Semantic sensitivities notwithstanding, we end with a digression. It may be useful to point out where much of the activity in the subject is concentrated. If (Q, W)

satisfies suitable non-degeneracy assumptions, one can associate to (Q, W) two spaces: $\mathrm{Stab}(\mathcal{C}(Q, W))$ and the cluster variety $\mathcal{X}(Q, W)$. The first is glued together out of chambers $\overline{\mathfrak{h}}^d$ indexed by the vertices of the tilting tree, and the second is glued from birational maps of algebraic tori $(\mathbb{C}^*)^d$ indexed by the same data. It is believed that there is a (complicated, transcendental) complex Lagrangian submanifold $B \subset \mathrm{Stab}(\mathcal{C})$ and an algebraic integrable system (with compact complex torus fibres) $\mathcal{T} \to B$ for which $\mathcal{T}$ and $\mathcal{X}$ are diffeomorphic, naturally equipped with different complex structures belonging to a single hyperkähler family Gaiotto, Moore, and Neitzke [2013] and Neitzke [2014]. The explicit diffeomorphism should be obtained from a Riemann-Hilbert problem, whose definition and solution involves the moduli stacks of stable objects and their Donaldson-Thomas theory Bridgeland [2016].

A genus d Lagrangian surface $\Sigma_d \subset X^4$ in a symplectic four-manifold defines a chart $(\mathbb{C}^*)^d$ in a tentative mirror to X, and one can use the complexity of cluster atlases to prove existence theorems for infinite families of Lagrangian surfaces Shende, Treumann, and Williams [2016]. This is a striking connection back to symplectic topology, but one that it seems hard to formulate on the space of stability conditions directly.

DEGENERATIONS AND MODULI SPACES IN KÄHLER GEOMETRY

Song Sun (孙崧)

Abstract

We report some recent progress on studying degenerations and moduli spaces of canonical metrics in Kähler geometry, and the connection with algebraic geometry, with a particular emphasis on the case of Kähler–Einstein metrics.

1 Introduction

One of the most intriguing features in Kähler geometry is the interaction between differential geometric and algebro-geometric aspects of the theory. In complex dimension one, the classical uniformization theorem provides a unique conformal metric of constant curvature -1 on any compact Riemann surface of genus bigger than 1. This analytic result turns out to be deeply connected to the algebraic fact that any such Riemann surface can be embedded in projective space as a *stable* algebraic curve in the sense of geometric invariant theory. It is also well-known that the moduli space of smooth algebraic curves of genus bigger than 1 can be compactified by adding certain singular curves with nodes, locally defined by the equation $xy = 0$, which gives rise to the *Deligne–Mumford compactification*. This is compatible with the differential geometric compactification using hyperbolic metrics, in the sense that whenever a node forms, locally the corresponding metric splits into the union of two hyperbolic cusps with infinite diameter. Intuitively, one can view the latter as a canonical differential geometric object associated to a nodal singularity.

On higher dimensional Kähler manifolds, a natural generalization of constant curvature metrics is the notion of a *canonical Kähler metric*, which is governed by some elliptic partial differential equation. In this article we will mainly focus on Calabi's *extremal Kähler metrics*. Let X be a compact Kähler manifold of dimension n, and let $\mathcal{H}$ be a

Partially supported by NSF grant DMS-1708420, the Alfred P. Sloan Fellowship, and a Simons Foundation grant (488633).

MSC2010: primary 53C55; secondary 53C21, 53C44, 14J10, 14J45.

Kähler class on X, i.e. the space of Kähler metrics on X in a given de Rham cohomology class (which we shall denote by $[\mathcal{H}] \in H^2(X;\mathbb{R})$). For example, any ample line bundle L gives rise to a Kähler class with $[\mathcal{H}] = 2\pi c_1(L)$. If we fix one Kähler metric $\omega \in \mathcal{H}$, then any other Kähler metric in $\mathcal{H}$ is of the form $\omega + i\partial\bar{\partial}\phi$ for some smooth function ϕ.

A Kähler metric ω is called *extremal* if it is the critical point of the Calabi functional $Ca(\omega) = \int_X S(\omega)^2\omega^n$ on $\mathcal{H}$, where $S(\omega)$ denotes the scalar curvature function of ω. Equivalently, by calculating the Euler–Lagrange equation, this means that the gradient vector field $\nabla_\omega S(\omega)$ is holomorphic. A special case is when the vector field vanishes, then ω is a *constant scalar curvature Kähler* metric. If moreover the first Chern class $c_1(X)$ is proportional to $[\mathcal{H}]$, say $2\pi c_1(X) = \lambda[\mathcal{H}]$, then this further reduces to the *Kähler–Einstein equation* $Ric(\omega) = \lambda\omega$.

There are several well-known fundamental questions that aim to build connections between the analytic theory of these metrics and algebraic geometry.

(1). **Existence**: When does $(X, \mathcal{H})$ contain an extremal Kähler metric?

To find an extremal Kähler metric amounts to solving a difficult non-linear elliptic PDE. The famous *Yau–Tian–Donaldson conjecture* states that the solvability of this PDE is equivalent to *K-stability* of $(X, \mathcal{H})$. K-stability is a complex/algebro-geometric notion; roughly speaking, it is tested by the positivity of certain numerical invariant, the *Donaldson–Futaki invariant*, associated to $\mathbb{C}^*$ equivariant *flat* degenerations of $(X, \mathcal{H})$. It is analogous to the Hilbert–Mumford criterion for stability in geometric invariant theory.

The Yau–Tian–Donaldson conjecture extends the *Calabi conjecture* on the existence of Kähler–Einstein metrics. In this special case we have a positive answer.

Theorem 1.1. *Let X be a compact Kähler manifold and $\mathcal{H}$ be a Kähler class with $2\pi c_1(X) = \lambda[\mathcal{H}]$.*

- *(Yau [1978]) If $\lambda = 0$, then there is a unique Kähler metric $\omega \in \mathcal{H}$ with $Ric(\omega) = 0$. This ω is usually referred to as a Calabi–Yau metric.*
- *(Yau [ibid.], Aubin [1976]) If $\lambda < 0$ (in which case X is of general type), then there is a unique Kähler metric $\omega \in \mathcal{H}$ with $Ric(\omega) = -\lambda\omega$.*
- *If $\lambda > 0$ (in which case X is a Fano manifold), then there is a Kähler metric $\omega \in \mathcal{H}$ with $Ric(\omega) = \lambda\omega$ if and only if X is K-stable. The "only if" direction is due to various authors in different generality including Tian [1997], Stoppa [2009], and R. J. Berman [2016], and the "if" direction is due to Chen–Donaldson–Sun (c.f. Chen, Donaldson, and Sun [2015a,b,c]), and later other proofs can be found in Datar and Székelyhidi [2016], Chen, Sun, and B. Wang [2015], and R. Berman, Boucksom, and Jonsson [2015].*

(2). **Compactification of moduli space and singularities**

It is known (c.f. Chen and Tian [2008] and R. J. Berman and Berndtsson [2017]) that extremal metric in a Kähler class $\mathcal{K}$, if exists, is unique up to holomorphic transformations of X, so it canonically represents the complex geometry of $(X, \mathcal{K})$. Locally one can deform either the Kähler class $\mathcal{K}$ or the complex structure on X, and the corresponding deformation theory of extremal Kähler metrics has been well-studied (c.f. LeBrun and Simanca [1994]). Globally to compactify the moduli space one needs to know how to take limits and what is the structure of the limits, especially near the singularities. This has interesting connection with the compactification from the algebro-geometric viewpoint, and is also intimately related to the existence question in (1).

(3). **Optimal degenerations**

There are two important geometric evolution equations, namely, the *Kähler–Ricci flow*, and the *Calabi flow*, that try to evolve an arbitrary Kähler metric towards a canonical metric. When $(X, \mathcal{K})$ is K-stable, then one expects the flow to exist for all time and converge to a canonical metric; when $(X, \mathcal{K})$ is not K-stable, then one expects the flow to generate a degeneration to some canonical geometric object associated to $(X, \mathcal{K})$, which is *optimal* in suitable sense.

We refer the readers to the article Donaldson [2018] in this proceeding for an overview on the existence question, and related discussion on K-stability. In this article we will report progress towards (2) and (3), mostly focusing on the case of Kähler–Einstein metrics.

Acknowledgments. I would like to thank Xiuxiong Chen, Simon Donaldson, Weiyong He, Hans-Joachim Hein, Chi Li, Yuji Odaka, Cristiano Spotti, Jingzhou Sun, Bing Wang, Yuanqi Wang, and Chengjian Yao for various fruitful discussions and collaborations on Kähler geometry. I am also grateful to Hans-Joachim Hein, Yuji Odaka, and Cristiano Spotti for helpful comments.

2 Gromov–Hausdorff limits

We consider a sequence of compact Kähler manifolds (X_i, ω_i) of dimension n. Throughout this section we will impose the following hypothesis

- $[\omega_i] = 2\pi c_1(L_i)$ for some ample line bundle L_i over X_i.

- $|Ric(\omega_i)| \leq \Lambda$ for some fixed $\Lambda > 0$.
- The diameter of (X_i, ω_i) is uniformly bounded above by $D > 0$.

These ensure the sequence of metrics to satisfy a *volume non-collapsing condition*, i.e. there exists $\kappa > 0$ such that for all i and all $p \in X_i$, $Vol(B(p,r)) \geq \kappa r^{2n}$ for all $r \in (0,1]$.

By the convergence theory of Riemannian manifolds one can pass to a subsequence and extract a *Gromov–Hausdorff limit* X_∞, which is a compact length space. This seems to be a very rough process at first sight but the important fact is that it is an intrinsic limit, which does not require a choice of coordinate systems on X_i. By the work of Cheeger, Colding, and Tian [2002], we know X_∞ can be written as the union of the regular part $\mathcal{R}$, which is a smooth open manifold endowed with a $C^{1,\alpha}$ Kähler structure $(J_\infty, \omega_\infty)$, and the singular set $\mathcal{S}$, which has Hausdorff codimension at least 4. In the case when $n = 2$ it has been known by Anderson [1989], Bando, Kasue, and Nakajima [1989], and Tian [1990b] that X_∞ has only isolated orbifold singularities. By possibly passing to a further subsequence, we may assume the Chern connection on L_i converges modulo gauge transformations to the Chern connection of a hermitian holomorphic line bundle $L_{\mathcal{R}}$ on $\mathcal{R}$. The following result establishes a basic connection with algebraic geometry

Theorem 2.1 (Donaldson and Sun [2014]). *(1) X_∞ is naturally homeomorphic to a normal projective variety in such a way that the algebraic singularities are a subset of the metric singularities, and, by passing to subsequence the convergence of X_i to X_∞ can be realized in a fixed Hilbert scheme.*

(2) If furthermore we assume ω_i is Kähler–Einstein, then the two singular sets are equal, and the algebraic singularities of X_∞ are log terminal in the sense of minimal model program. Moreover, ω_∞ extends to a global Kähler current that satisfies a singular Kähler–Einstein equation in the sense of pluripotential theory, c.f. Eyssidieux, Guedj, and Zeriahi [2009].

Remark 2.2.

- The projective algebraic structure on X_∞ is intrinsically determined by $(\mathcal{R}, L_{\mathcal{R}})$. Namely, denote by $\iota : \mathcal{R} \to X_\infty$ the natural inclusion map, and we can define $\mathcal{O}_{X_\infty} := \iota_*\mathcal{O}_{\mathcal{R}}$ and $L_\infty := \iota_* L_{\mathcal{R}}$. Then the precise meaning of (1) is that $(X_\infty, \mathcal{O}_{X_\infty})$ is a normal complex analytic space and L_∞ is an ample $\mathbb{Q}$-line bundle on X_∞. Moreover, by passing to a subsequence, (X_i, L_i) and (X_∞, L_∞) can be fit into a *flat* family.
- In the Kähler–Einstein case with $\lambda = 1$, the line bundle L_i is given by $K_{X_i}^{-1}$, and the diameter bound is automatically satisfied by Bonnet–Myers's theorem. In this case X_∞ is a smoothable $\mathbb{Q}$-*Fano variety*. Theorem 2.1 thus provides a *topological*

compactification of the moduli space of Kähler–Einstein Fano manifolds in each dimension, by adding all the possible Gromov–Hausdorff limits.

A key ingredient in the proof of Theorem 2.1 is to obtain the *partial C^0 estimate*, conjectured by G. Tian in ICM 1990 (c.f. Tian [1990a]). Recall, in general that if (X, L) is a polarized Kähler manifold and ω is a Kähler metric in $2\pi c_1(L)$, then ω determines a hermitian metric $|\cdot|$ on L, unique up to constant multiple. For all k we have an induced L^2 norm $\|\cdot\|$ on $H^0(X, L^k)$ (defined with respect to the volume form of $k\omega$). To compare these we define the *density of state function* (or the *Bergman function*)

$$\rho_{X,\omega,k}(x) = \sup_{s\in H^0(X,L^k),s\neq 0} \frac{|s(x)|^2}{\|s\|^2}.$$

By the Kodaira embedding theorem this is a positive function for k sufficiently large. It is easy to see for each $x \in X$, the supremum is achieved on a unique one dimension subspace $\mathbb{C}_x \subset H^0(X, L^k)$, and $\rho_{X,\omega,k}$ is a smooth function on X. Moreover, we have a C^∞ asymptotic expansion (c.f. Zelditch [1998])

$$\rho_{X,\omega,k} = 1 + \frac{S(\omega)}{2}k^{-1} + \cdots . \tag{2-1}$$

Its importance can be seen as follows

- Denote $N_k = \dim H^0(X, L^k)$, and choose an L^2 orthonormal basis $\{s_1, \cdots, s_{N_k}\}$ of $H^0(X, L^k)$, then there is an alternative expression

$$\rho_{X,\omega,k}(x) = \sum_{i=1}^{N_k} |s_i(x)|^2.$$

  So we get $N_k = \int_X \rho_{X,\omega,k}(k\omega)^n/n!$, and (2-1) can be viewed as a local version of the Riemann–Roch formula.

- Using an orthonormal basis of $H^0(X, L^k)$, for k large we get an embedding $\iota_k : X \to \mathbb{P}^{N_k-1}$, unique up to unitary transformations. Then we have

$$\iota_k^*\omega_k = k\omega + i\partial\bar\partial \log \rho_k. \tag{2-2}$$

  So by (2-1) we know $k^{-1}\iota_k^*\omega_k$ converges smoothly to ω as k tends to infinity. This is the *Kähler quantization* picture, which is essential in studying the relationship between constant scalar curvature Kähler metrics and algebraic stability (c.f. Donaldson [2001]).

Theorem 2.3 (Donaldson and Sun [2014]). *Under the hypothesis in the beginning of this section, there are k_0 and $\epsilon_0 > 0$ that depend only on n, Λ and D, such that $\rho_{X_i,\omega_i,k_0} \geq \epsilon_0$ for all i.*

Remark 2.4. (1). When $n = 2$ this is proved by Tian [1990b], using the fact that in this case the Gromov–Hausdorff limit is an orbifold; for general n this is conjectured by Tian [1990a]. Indeed Tian's original conjecture is stated under more general assumptions, and there has been substantial progress on this, see for example Theorem 1.9 in Chen and B. Wang [2014].

(2). One may ask if there is a uniform asymptotic behavior of the density of state function as k tends to infinity. In general the expansion (2-1) can not hold uniformly independent of i, but a weaker statement is plausible, see Conjecture 5.15 in Donaldson and Sun [2014].

(3). It follows from Theorem 2.3 and (2-2) that the embedding map ι_{k_0} has a uniform Lipschitz bound for all i, hence one can pass to limit and obtain a Lipschitz map from the Gromov–Hausdorff limit X_∞ to a fixed projective space. This is the starting point to prove Theorem 2.1.

The proof of Theorem 2.3 is based on Hörmander's construction of holomorphic sections on definite powers of L_i with control. The idea is to first find holomorphic sections of Gaussian type in a local model, then graft them to the manifolds X_i to get approximately holomorphic sections, and finally correct these to genuine holomorphic sections by solving a $\bar\partial$ equation. The solvability of $\bar\partial$ equation with uniform estimates only uses one global geometric assumption, namely the lower bound of Ricci curvature of ω_i.

Here we briefly describe the notion of model Gaussian sections. Suppose first we are at a *smooth* point $x \in X_i$ for some *fixed* i. If we dilate the metric ω_i to $k\omega_i$ based at x, then as k tends to infinity we get in the limit the standard flat metric on $\mathbb{C}^n$. The dilation has the effect of replacing the line bundle L_i by L_i^k and it is also important to notice that the corresponding limit line bundle is the trivial holomorphic bundle on $\mathbb{C}^n$ endowed with the non-trivial hermitian metric $e^{-|z|^2/2}$ whose curvature is exactly the flat metric. The obvious trivial section is then naturally a Gaussian section. Using this one can construct for k large a holomorphic section of L_i^k over X_i, whose L^2 norm has a definite upper bound and its pointwise norm at x has a definite positive lower bound. This implies $\rho_{X_i,\omega_i,k}(x) \geq \epsilon > 0$. The difficulty in the proof of Theorem 2.3 is then to obtain uniform estimate on both k and ϵ, which is not a priori clear since it is conceivable that when the metric ω_i starts to form singularities the region where the Gaussian model behaves well for a fixed k shrinks to one point. For this purpose we use the Gromov–Hausdorff limit X_∞ and consider a sequence of points $x_i \in X_i$ that tend to a point $x_\infty \in X_\infty$. If x_∞ is a smooth point then previous argument goes through with little change to yield $\rho_{X_i,\omega_i,k}(x_i) \geq \epsilon > 0$ for k and ϵ independent of i. If x_∞ is singular, then we can dilate the metric on X_∞ based at x_∞. By passing to a subsequence we can obtain a *pointed* Gromov–Hausdorff limit, called a *tangent cone*. It is a *metric cone* $C(Y)$ over a compact length space Y, which in particular admits a dilation action.

By Cheeger, Colding, and Tian [2002] we also know that $C(Y)$ is a $C^{1,\alpha}$ Kähler manifold outside a closed subset of Hausdorff codimension at least 4 which is invariant under dilation. On this smooth part, being a metric cone implies that the metric can be written as $g = \frac{1}{2}\mathrm{Hess}(r^2)$, where r is the distance to the cone vertex. Now the crucial point in our Kähler setting is that the Kähler form can correspondingly be written as $\omega = \frac{1}{2} i\partial\bar{\partial} r^2$, so in particular it is the curvature of the trivial holomorphic bundle with hermitian metric $e^{-r^2/2}$. This is exactly the generalization of the above local model on $\mathbb{C}^n$. Thus we also have the candidate Gaussian section in this case, but there are various technical difficulties that had to be overcome in Donaldson and Sun [2014], mainly due to the appearance of singularities on the tangent cones $C(Y)$. One point to notice is that the proof does *not* require the tangent cone at x_∞ to be unique, even though this turns out to be true and we will discuss more in the next section.

We mention that the extension of Theorem 2.1 and 2.3 to the case of Kähler–Einstein metrics with cone singularities plays a key role in the proof of the Yau–Tian–Donaldson conjecture for Fano manifolds (c.f. Chen, Donaldson, and Sun [2015a,b,c]). There are also other applications to the study of Gromov–Hausdorff limits of Kähler–Einstein metrics in the Calabi–Yau and general type case, c.f. Rong and Zhang [2011], Tosatti [2015], and Song [2017]. In both cases the diameter bound (hence the volume non-collapsing condition) is not automatically satisfied, and is essentially equivalent to the algebraic limit having at worst log terminal singularities.

There are a few interesting directions that require further development:

(1). Prove a local version of Theorem 2.1. Namely, let X_∞ be a Gromov–Hausdorff limit of a sequence of (incomplete) Kähler manifolds (X_i, ω_i) with diameter 1, uniformly bounded Ricci curvature, and satisfying a uniform volume non-collapsing condition, can we prove X_∞ is naturally a complex analytic space?

Notice in general one can not expect to fit X_i and X_∞ into a flat family in the absence of the line bundles, since one can imagine certain holomorphic cycles being contracted under the limit process. The answer to the above question will have applications in understanding convergence of Calabi–Yau metrics when Kähler class becomes degenerate, see Collins and Tosatti [2015]. In a related but different context, G. Liu [2016] studied the case when the Ricci curvature bound is replaced by a lower bound on the bisectional curvature, and used it to make substantial progress towards Yau's uniformization conjecture for complete

Kähler manifolds with non-negative bisectional curvature. Most generally, one would expect that in the above question to draw the complex-analytic consequence the most crucial assumption is a uniform lower bound on Ricci curvature, and the upper bound on Ricci curvature is more related to the regularity of the limit metrics.

(2). In general collapsing is un-avoidable. Can we describe the complex/ algebro-geometric meaning of the Gromov–Hausdorff limits?

Collapsing with uniformly bounded Riemannian sectional curvature has been studied extensively in the context of Riemannian geometry through the work of Cheeger–Fukaya–Gromov and others. In general one expects a structure of fibrations (in the generalized sense). Even in this case the above question is not well-understood. In general with only Ricci curvature bound there has been very few results on the regularity of the limit space itself (see Cheeger and Tian [2006] for results when $n = 2$).

Ultimately one would like to understand the case of constant scalar curvature or extremal Kähler metrics, where we are currently lacking the analogous foundations of the Cheeger–Colding theory which depends on comparison geometry of Ricci curvature, and so far we only have results in the non-collapsed case, see for example Tian and Viaclovsky [2008], Chen and Weber [2011].

3 Singularities

In this section we focus on finer structure of the Gromov–Hausdorff convergence studied in Theorem 2.1, and restrict to the case when (X_i, ω_i) is Kähler–Einstein. It is a folklore picture that when singularities occur certain non-compact Ricci-flat spaces must bubble off. To be more precise, suppose $p \in X_\infty$ is a singular point, and $p_i \in X_i$ is a sequence of points that converge to p. Take any sequence of integers $k_i \to \infty$ and consider the rescaled spaces $(X_i, L_i^{k_i}, k_i\omega_i, p_i)$, then by passing to subsequence, we always get a *pointed Gromov–Hausdorff limit* (Z, p_∞), which is a non-compact metric space.

Theorem 3.1 (Donaldson and Sun [2017])**.** *Any such limit Z is naturally a normal affine algebraic variety which admits a singular Ricci-flat Kähler metric.*

To explain the meaning of this, similar to Remark 2.2, we know the complex-analytic structure on Z is determined by the regular part of Z (in the sense of Cheeger, Colding, and Tian [2002]). To understand intrinsically the affine structure, we denote by $R(Z)$ the ring of holomorphic functions on Z that grow at most polynomially fast at infinity, then it is proved in Donaldson and Sun [2017] that $R(Z)$ is finitely generated and $\mathrm{Spec}(R(Z))$ is complex-analytically isomorphic to Z.

In dimension two, Z is an ALE Ricci-flat space possibly with orbifold singularities. In higher dimensions, by the volume non-collapsing condition we know Z is *asymptotically* *conical*. There has been extensive study on these spaces in the case when the tangent cone at infinity is smooth, see for example van Coevering [2011], Conlon and Hein [2015], C. Li [2015].

Let $\mathfrak{B}$ be the set of all *bubbles* at p, i.e. the set of pointed Gromov–Hausdorff limits of $(X_i, k_i\omega_i, p_i)$ with $p_i \to p$ and $k_i \to \infty$. It is an interesting question to find complex/algebro-geometric characterization of this set, which potentially forms a *bubble tree* structure at p. For each $Z \in \mathfrak{B}$, the Bishop–Gromov volume comparison defines an invariant $v(Z)$, namely, the asymptotic volume ratio of Z

$$v(Z) = \lim_{r \to \infty} Vol(B(p_\infty, r))r^{-2n}$$

A special element in $\mathfrak{B}$ is a metric tangent cone $C(Y)$ at p, which has the *smallest* asymptotic volume ratio among all the bubbles at p. The metric cone structure imposes an extra dilation symmetry on $C(Y)$, and this has the corresponding algebro-geometric meaning

Theorem 3.2 (Donaldson and Sun [2017]). *A tangent cone $C(Y)$ is naturally a normal affine algebraic cone.*

This requires some explanation. Let $R(C(Y))$ be the affine coordinate ring of $C(Y)$. On the regular part of $C(Y)$, we have a *Reeb* vector field $\xi = Jr\partial_r$ which is a holomorphic Killing vector field. It generates holomorphic isometric action of a compact torus $\mathbb{T}$ on $C(Y)$. This action induces a weight space decomposition of $R(C(Y))$, which can be written as

$$R(C(Y)) = \bigoplus_{\mu \in \mathbb{H}} R_\mu(C(Y)).$$

Here $R_\mu(C(Y))$ is the space of homogeneous holomorphic functions f on $C(Y)$ satisfying $\mathcal{L}_\xi f = i\mu f$ (i.e. homogeneous of degree μ), and the *holomorphic spectrum* $\mathbb{H}$ is the set of all $\mu \in \mathbb{R}_{\geq 0}$ such that $R_\mu(C(Y)) \neq 0$. In general we know $\mathbb{H}$ is contained in the set of algebraic numbers, but not necessarily a subset of $\mathbb{Q}$. This *positive* $\mathbb{R}$-grading on $R(C(Y))$ is the precise meaning for $C(Y)$ to be an affine algebraic *cone* in Theorem 3.2.

Theorem 3.3 (Donaldson and Sun [ibid.]). *Given any $p \in X_\infty$, there is a unique metric tangent cone at p, as an affine algebraic cone endowed with a singular Ricci-flat Kähler metric.*

One step in the proof is to show that the holomorphic spectrum $\mathbb{H}$ is a priori unique. The crucial observation is that the set of all possible tangent cones at p form a connected and compact set under the pointed Gromov–Hausdorff topology, and $\mathbb{H}$ consists of only algebraic numbers so must be rigid under continuous deformations. The latter uses the volume minimization principle of Martelli, Sparks, and Yau [2008] in Sasaki geometry. Recall that $C(Y)$ being Ricci-flat is equivalent to Y being *Sasaki–Einstein* possibly with singularities. Consider the open convex cone $\mathcal{C}$ in $Lie(\mathbb{T})$ consisting of elements η which also induce positive gradings on $R(C(Y))$. Then by Martelli, Sparks, and Yau [ibid.] we know ξ is the unique critical point of the (suitably normalized) *volume function* on $\mathcal{C}$, which is a convex rational function with rational coefficients (noticing there is a natural rational structure in $Lie(\mathbb{T})$). This fact leads to the algebraicity of $\mathbb{H}$.

To describe the relationship between the local algebraic singularity of X_∞ at p and the tangent cone $C(Y)$, we define a *degree* function on $\mathcal{O}_p$, the local ring of germs of holomorphic functions at p, by setting

$$d(f) = \lim_{r\to 0} \frac{\sup_{B(p,r)} \log|f|}{\log r}$$

By Donaldson and Sun [2014], for all nonzero f, $d(f)$ is always well-defined and it belongs to $\mathbb{H}$. Indeed d defines a *valuation* on $\mathcal{O}_p$. So we can define a graded ring associated to this

$$R_p = \bigoplus_{\mu\in\mathbb{H}} \{f \in \mathcal{O}_p | d(f) \geq \mu\}/\{f \in \mathcal{O}_p | d(f) > \mu\}.$$

Theorem 3.4 (Donaldson and Sun [2017]).

- *R_p is finitely generated and $Spec(R_p)$ defines a normal affine algebraic cone W, which can be realized as a weighted tangent cone of (X_∞, p) under a local complex analytic embedding into some affine space.*
- *There is an equivariant degeneration from W to $C(Y)$ as affine algebraic cones.*

Remark 3.5. The finite generation of R_p and the fact that W is normal put on very strong constraint on the valuation d. The proof depends on Theorem 3.2 and a three-circle type argument that relates elements in $\mathcal{O}_p$ and $R(C(Y))$. In the context of Theorem 3.1 there is a similar result relating Z and its tangent cone at *infinity*.

This situation is analogous to the Harder–Narasimhan–Seshadri filtration for unstable holomorphic vector bundles. It also suggests a *local* notion of stability for algebraic singularities, since using the extension of the Yau–Tian–Donaldson conjecture to affine algebraic cones by Collins and Székelyhidi [2012], one can view $C(Y)$ as a K-stable algebraic cone and W as a K-semistable algebraic cone.

One interesting point is that W is only an algebraic variety but does not support a natural metric structure. In Donaldson and Sun [2017] we conjectured that W and $C(Y)$ are both invariants of $\mathcal{O}_p$ and there should a purely algebro-geometric way of characterizing

W. C. Li [2015] made this conjecture more precise by giving an algebro-geometric interpretation of the volume of an affine cone, and formulating a corresponding conjecture that the valuation d should be the unique one that minimizes volume. This brings interesting connections with earlier work on asymptotic invariants and K-stability in algebraic geometry. It is an extension of the Martelli–Sparks–Yau volume minimization principle. There is much progress in this direction, see Blum [2016], C. Li and Y. Liu [2016], and C. Li and Xu [2017].

One of the motivation for studying metric tangent cones is related to precise understanding of the metric behavior of a singular Kähler–Einstein metric. The following result, which uses the result of Fujita [2015] and C. Li and Y. Liu [2016], gives the first examples of compact Ricci-flat spaces with isolated conical singularities.

Theorem 3.6 (Hein and Sun [2017])**.** *Let (X, L) be a $\mathbb{Q}$-Gorenstein smoothable projective Calabi–Yau variety with isolated canonical singularities, each locally complex-analytically isomorphic to a strongly regular affine algebraic cone which admits a Ricci-flat Kähler cone metric, then there is a unique singular Calabi–Yau metric $\omega \in 2\pi c_1(L)$ which is smooth away from the singular locus of X, and at each singularity is asymptotic to the Ricci-flat Kähler cone metric at a polynomial rate.*

Remark 3.7.

- The notion of *strong regularity* is a technical assumption which is equivalent to that the affine algebraic cone coincides with its Zariski tangent cone at the vertex.
- An important special case is when the singularities of X are ordinary double points, in which case the Ricci-flat Kähler cone metric can be explicitly written down, and Theorem 3.6 also implies the existence of *special lagrangian vanishing spheres* on a generic smoothing of X.

The above general strategy has other applications, one is to the study of the asymptotic behavior of geometric flows, as we shall describe in Section 5, and the other is to the study of singularities of Hermitian-Yang–Mills connections (c.f. Chen and Sun [2017]).

4 Moduli spaces

Theorem 2.1 gives a *Gromov–Hausdorff compactification* of the moduli space of Kähler–Einstein Fano manifolds in each fixed dimension, as a topological space. By Theorem 1.1 this is the same as a compactification of the moduli space of K-stable Fano manifolds, so it is natural to ask for algebro-geometric meaning of this moduli space itself; furthermore one would like to characterize them explicitly since there are many concrete examples of families of smooth Fano manifolds. Understanding this would also lead to new examples of K-stable Fano varieties, including singular ones.

In dimension two, there are only four families of Fano manifolds with non-trivial moduli. They are *del Pezzo surfaces* of anti-canonical degree $d \in \{1, 2, 3, 4\}$, i.e. the blown-ups of $\mathbb{CP}^2$ at $9 - d$ points in very general position. Let $\mathfrak{M}_d$ be the Gromov–Hausdorff compactification of moduli space of Kähler–Einstein metrics on del Pezzo surfaces of degree d.

Theorem 4.1 (Odaka, Spotti, and Sun [2016]). *Each $\mathfrak{M}_d$ is naturally homeomorphic to an explicitly constructed moduli space $\mathfrak{M}_d^{alg}$ of certain del Pezzo surfaces with orbifold singularities.*

The construction of $\mathfrak{M}_d^{alg}$ depends on the classical geometry of del Pezzo surfaces, whose moduli is closely related to geometric invariant theory.

- Objects in $\mathfrak{M}_3^{alg}$ are GIT stable[1] cubics in $\mathbb{P}^3$. These were classified by Hilbert.
- Objects in $\mathfrak{M}_4^{alg}$ are GIT stable complete intersections of two quadrics in $\mathbb{P}^4$. These were classified by Mabuchi and Mukai [1993], who also proved Theorem 4.1 in this case, with a more involved argument.
- Objects in $\mathfrak{M}_2^{alg}$ are either double covers of $\mathbb{P}^2$ branched along a GIT stable quartic curve, or double covers of the weighted projective plane $\mathbb{P}(1, 1, 4)$ branched along a curve of the form $z^2 = f_8(x, y)$ for a GIT stable octic in 2 variables. This moduli was constructed by Mukai [1995].
- Objects in $\mathfrak{M}_1^{alg}$ are more complicated to describe, but a generic element is a double cover of $\mathbb{P}(1, 1, 2)$ branched along a sextic curve that is GIT stable in a suitable sense (even though the automorphism group of $\mathbb{P}(1, 1, 2)$ is not reductive). $\mathfrak{M}_1^{alg}$ is a certain birational modification of this GIT moduli space.

We briefly describe the general strategy in the proof, which also applies in higher dimensions (see Theorem 4.2). For a more detailed survey see Spotti [n.d.].

- Show $\mathfrak{M}_d$ is non-empty. This can be achieved by studying a special element in each family, for example through computation of α-invariant (see Tian and Yau [1987]), or alternatively Arezzo, Ghigi, and Pirola [2006], or by a glueing construction.
- Rough classification of Gromov–Hasudorff limits. The Bishop–Gromov volume comparison yields that at any singularity of the form $\mathbb{C}^2/\Gamma$, we have $|\Gamma| < 12/d$. For larger d we get stronger control on Γ hence the corresponding $\mathfrak{M}_d$ is simpler. Using this one can estimate the *Gorenstein index* of the Gromov–Hausdorff limits,

[1] The stability in this article means *polystablity* in the usual literature.

and then understand their anti-canonical geometry. This is related to the explicit determination of the smallest number k_0 in Theorem 2.3.

By R. J. Berman [2016] all the objects X in $\mathfrak{M}_d$ are K-stable, and a crucial ingredient in Odaka, Spotti, and Sun [2016] is that one can often compare K-stability with GIT stability. This implies X is also GIT stable in appropriate sense, and suggests that $\mathfrak{M}_d$ is closely related to GIT moduli.

- Construction of $\mathfrak{M}_d^{alg}$ so that the natural map from $\mathfrak{M}_d$ to $\mathfrak{M}_d^{alg}$ is a homeomorphism. The key point is to make sure $\mathfrak{M}_d^{alg}$ is Hausdorff and the map is well-defined, i.e. any possible Gromov–Hausdorff limit in $\mathfrak{M}_d$ is included in $\mathfrak{M}_d^{alg}$. In general one can start with a natural GIT moduli space, and perform birational modifications that are suggested by the previous step. For example when $d = 2$, the natural GIT moduli of quartic curves contains a point that corresponds to a reducible surface, which we know can not be in $\mathfrak{M}_d$; this motivates one to blow-up the point and the exceptional divisor turns out to correspond to a different GIT as described above.

Theorem 4.2.

- *Spotti and Sun [2017]: For all n, the Gromov–Hausdorff compactification of the moduli space of Kähler–Einstein metrics on complete intersection of two quadrics in $\mathbb{P}^{n+2}$ is naturally homeomorphic to the GIT moduli space.*
- *Y. Liu and Xu [2017]: The Gromov–Hausdorff compactification of the moduli space of Kähler–Einstein metrics on cubics in $\mathbb{P}^4$ is naturally homeomorphic to the GIT moduli space.*

A major step is to prove the Gromov–Hausdorff limit has a well-defined canonical line bundle, i.e., is *Gorenstein*, and has large divisibility. This relies on the following deep theorem of K. Fujita proved via K-stability, and the later generalization by Y. Liu [2016] to give an improvement of the Bishop–Gromov volume comparison.

Theorem 4.3.

- *Fujita [2015]: Let X be a Kähler–Einstein Fano manifold in dimension n, then $(-K_X)^n \leq (n+1)^n$, and equality holds if and only if X is isomorphic to $\mathbb{P}^n$.*

It is very likely that similar results to Theorem 4.2 can be established for most families of Fano threefolds, and some classes of higher dimensional Fano manifolds with large anti-canonical volume. There is a related conjecture on a local analogue of Theorem 4.3. For more on this see Spotti and Sun [2017].

Now we move on to discuss general abstract results in higher dimension concerning moduli space of Kähler–Einstein/K-stable manifolds. As applications of Chen, Donaldson, and Sun [2015a,b,c] we have

- Odaka [2012a] and Donaldson [2015]: The moduli space of K-stable Fano manifolds with discrete automorphism group is Zariski open.
- Spotti, Sun, and Yao [2016]: A smoothable $\mathbb{Q}$-Fano variety admits a singular Kähler–Einstein metric if and only if it is K-stable.
- C. Li, X. Wang, and Xu [2014] and Odaka [2015]: The Gromov–Hausdorff compactification of moduli space of Kähler–Einstein Fano manifolds in a fixed dimension is naturally a proper separated algebraic space.

We remark that one important technical aspect is still open, namely, the *projectivity* of the moduli space. There is a well-defined CM line bundle on the moduli space. Over the locus parametrizing smooth Fano manifolds it admits a natural Wei–Peterson metric of positive curvature, and this locus has been shown to be quasi-projective C. Li, X. Wang, and Xu [2015].

There is also recent progress in the general type case. Here we already have a compactification using minimal model program, namely, the *KSBA moduli space*, where the boundary consists of varieties with semi-log-canonical singularities (in one dimension it is the same as being nodal). Odaka [2013, 2012b] proved that these are exactly the ones which are K-stable, and R. J. Berman and Guenancia [2014] established the existence of a unique singular Kähler–Einstein metric in a suitable weak sense. It is further shown by Song [2017] that under a KSBA degeneration, the Kähler–Einstein metric on smooth fibers converges in the pointed Gromov–Hausdorff sense to the metric completion of the log terminal locus on the central fiber. So far the proof uses deep results in algebraic geometry but one certainly hopes for a more differential-geometric theory in the future.

5 Optimal degenerations

Let (X, L, ω) be a polarized Kähler manifold with $[\omega] = 2\pi c_1(L)$. In this section we focus on two natural geometric flows emanating from ω. We first consider the *Ricci flow*

$$\frac{\partial}{\partial t}\omega(t) = \omega(t) - Ric(\omega(t)) \tag{5-1}$$

and restrict to the case when X is Fano and $L = K_X^{-1}$. This case is immediately related to the Yau–Tian–Donaldson conjecture; the general case is also interesting and is related to the analytic minimal model program, but is beyond the scope of this article.

Clearly a fixed point of (5-1) is exactly a Kähler–Einstein metric. There are also self-similar solutions to (5-1), i.e., solutions $\omega(t)$ that evolve by holomorphic transformations of X. These correspond to *Ricci solitons*, which are governed by the equation $Ric(\omega) = \omega + \mathfrak{L}_V\omega$, where V is a holomorphic vector field on X.

It is well-known that in our case a smooth solution $\omega(t)$ exists for all time $t > 0$ with $[\omega(t)] = 2\pi c_1(K_X^{-1})$. A folklore conjecture, usually referred to as the *Hamilton–Tian conjecture*, states that as $t \to \infty$ by passing to subsequence one should obtain Gromov–Hausdorff limits which are Ricci solitons off a singular set of small size. This is now confirmed by Chen and B. Wang [2014].

Theorem 5.1 (Chen and B. Wang [ibid.]). *As $t \to \infty$, by passing to a subsequence $(X, \omega(t))$ converges in the Gromov–Hausdorff sense to a $\mathbb{Q}$-Fano variety endowed with a singular Kähler–Ricci soliton metric $(X_\infty, V_\infty, \omega_\infty)$.*

This can be viewed as a generalization of the Cheeger–Colding theory and the results in Section 2 to the parabolic case. The proof makes use of the deep results of Perelman. In connecting with algebraic geometry we have

Theorem 5.2 (Chen, Sun, and B. Wang [2015]).

- *As $t \to \infty$, there is a unique Gromov–Hausdorff limit $(X_\infty, V_\infty, \omega_\infty)$.*
- *If X is K-stable, then X_∞ is isomorphic to X, $V_\infty = 0$, and ω_∞ is a smooth Kähler–Einstein metric on X_∞.*
- *If X is K-unstable, then the flow $\omega(t)$ defines a unique degeneration of X to a $\mathbb{Q}$-Fano variety $\bar{X}$ with a holomorphic vector field $\bar{V}$, and there is an equivariant degeneration from $(\bar{X}, \bar{V})$ to (X_∞, V_∞).*

The second item gives an alternative proof of the Yau–Tian–Donaldson conjecture for Fano manifolds. The third item requires slightly more explanation. The flow $\omega(t)$ induces a family of L^2 norms $\|\cdot\|_t$ on $H^0(X, K_X^{-k})$ for all k, and yields a notion of *degree* of a section $s \in H^0(X, L^k)$ by setting

$$d(s) = \lim_{t\to\infty} \frac{1}{t} \log \|s\|_t.$$

The main point in Chen, Sun, and B. Wang [ibid.] is that this is well-defined and gives a filtration of the homogeneous coordinate ring of (X, L); moreover, the associated graded ring defines a normal projective variety $\bar{X}$, and the grading determines a holomorphic vector field $\bar{V}$. So $(\bar{X}, \bar{V})$ is canonically determined by the flow $\omega(t)$, hence by the initial metric ω.

It is conjectured in Chen, Sun, and B. Wang [ibid.] that when X is K-unstable, both $(\bar{X}, \bar{V})$ and $(X_\infty, V_\infty, \omega_\infty)$ are invariants of X itself, i.e. are independent of the initial metric ω, and $(\bar{X}, \bar{V})$ defines a unique *optimal degeneration* of X. By W. He [2016], R. J. Berman and Nystrom [2014], and Dervan and Székelyhidi [2016] we know a partial answer to this, and it seems possible to eventually obtain a purely algebro-geometric characterization.

Now we turn to discuss the *Calabi flow*, starting from an initial metric ω with $[\omega] = 2\pi c_1(L)$. The equation takes the form

$$\frac{\partial}{\partial t}\omega(t) = -\Delta_{\bar{\partial}} Ric(\omega(t))(= -i\bar{\partial}\partial S(\omega(t))) \tag{5-2}$$

A fixed point is a Kähler metric with constant scalar curvature, and a self-similar solution is an extremal Kähler metric. From the viewpoint of the infinite dimensional moment map picture of Fujiki–Donaldson, the Calabi flow has an interesting geometric meaning, at least on a formal level. First it is the negative gradient flow of a geodesically convex functional (the *Mabuchi functional*) on the Kähler class $\mathcal{H}$, so it decreases a natural distance function on $\mathcal{H}$ (c.f. Calabi and Chen [2002]). If we transform it to a flow of integrable almost complex structures compatible with a fixed symplectic form then it is also the negative gradient flow of the *Calabi functional*.

A main difficulty in the study of Calabi flow (c.f. Chen and W. Y. He [2008]) arises from the fact it is a *fourth* order geometric evolution equation and the usual technique of maximum principle does not apply directly. There has been little progress on the problem of general long time existence. If we put aside all the analytic difficulties, then we do have a picture on the asymptotic behavior of the flow, analogous to Theorem 5.2.

Theorem 5.3 (Chen, Sun, and B. Wang [2015]). *Let $\omega(t)(t \in [0, \infty))$ be a smooth solution of the Calabi flow in the class $2\pi c_1(L)$, and assume the Riemannian curvature of $\omega(t)$ and the diameter are uniformly bounded for all t. Then*

- *There is a unique Gromov–Hausdorff limit $(X_\infty, L_\infty, V_\infty, \omega_\infty)$, where ω_∞ is a smooth extremal Kähler metric on a smooth projective variety X_∞ with $[\omega_\infty] = 2\pi c_1(L_\infty)$, and $V_\infty = \nabla S(\omega_\infty)$ is a holomorphic vector field.*
- *If (X, L) is K-stable, then (X_∞, L_∞) is isomorphic to (X, L), $V_\infty = 0$, and ω_∞ is a constant scalar curvature Kähler metric on X.*
- *If (X, L) is K-unstable, then it gives rise to an optimal degeneration of (X, L) to $(\bar{X}, \bar{L}, \bar{V})$, which minimizes the normalized Donaldson–Futaki invariant, and there is an equivariant degeneration from $(\bar{X}, \bar{L}, \bar{V})$ to $(X_\infty, L_\infty, V_\infty)$.*

There is also a generalized statement for extremal Kähler metrics Chen, Sun, and B. Wang [ibid.]. Notice in general we should not expect the Calabi flow to satisfy the strong geometric hypothesis in Theorem 5.3. First, the curvature may blow up and singularities can form, similar to the case of Ricci flow; second, the diameter can go to infinity (c.f. Székelyhidi [2009]) and collapsing may happen. The second issue is related to the folklore expectation that one may need to strengthen the notion of K-stability to certain *uniform*

K-stability in the statement of Yau–Tian–Donaldson conjecture. Nevertheless we expect Theorem 5.3 will lead to existence results of extremal Kähler metrics in concrete cases.

There are also recent progress on analytic study of the asymptotic behavior on the Calabi flow, related to the conjectural picture described by Donaldson [2004]. On one hand, in complex dimension two, H. Li, B. Wang, and Zheng [2015] proved that, assuming the existence of a constant scalar curvature Kähler metric ω_0 in the class $2\pi c_1(L)$, if a Calabi flow $\omega(t)$ in $2\pi c_1(L)$ exists for $t \in [0, \infty)$, then as $t \to \infty$ the flow must converge to ω_0, modulo holomorphic transformations of X. On the other hand, R. J. Berman, Darvas, and Lu [2017] proved a dichotomy for the behavior of *weak solution* to the Calabi flow in the sense of Streets [2014], to the effect that it either diverges to infinity with respect to a natural distance on $\mathcal{H}$, or it converges to a weak minimizer of the Mabuchi functional in a suitable sense. Finally, in Chen and Sun [2014] Calabi flow on a small complex structure deformation of a constant scalar curvature Kähler manifold is studied, which also leads to a generalized uniqueness result.

AN INVITATION TO HIGHER TEICHMÜLLER THEORY

Anna Wienhard

Abstract

Riemann surfaces are of fundamental importance in many areas of mathematics and theoretical physics. The study of the moduli space of Riemann surfaces of a fixed topological type is intimately related to the study of the Teichmüller space of that surface, together with the action of the mapping class group. Classical Teichmüller theory has many facets and involves the interplay of various methods from geometry, analysis, dynamics and algebraic geometry. In recent years, higher Teichmüller theory emerged as a new field in mathematics. It builds as well on a combination of methods from different areas of mathematics. The goal of my talk is to invite the reader to get to know and to get involved into higher Teichmüller theory by describing some of its many facets.

1 Introduction

Riemann surfaces are of fundamental importance in many areas of mathematics and theoretical physics. The study of the moduli space of Riemann surfaces of a fixed topological type is intimately related to the study of the Teichmüller space of that surface, together with the action of the mapping class group. Classical Teichmüller theory has many facets and involves the interplay of various methods from geometry, analysis, dynamics and algebraic geometry. In recent years, higher Teichmüller theory emerged as a new field in mathematics. It builds as well on a combination of methods from different areas of mathematics. The goal of this article is to invite the reader to get to know and to get involved into higher Teichmüller theory by describing some of its many facets. Along the way we point to open questions, and formulate some conjectures and task for the future. We will

Keywords: Higher Teichmüller theory, Total positivity, surface group representations, discrete subgroups of Lie groups, cluster algebras, geodesic flow, mapping class group.

not be able to discuss every aspect of higher Teichmüller theory, and will be very brief on most of them. In particular we will not touch upon universal or infinite higher Teichmüller spaces Labourie [2007a] and N. Hitchin [2016], or algebraic structures developed in Labourie [2017b] and Sun [2017a,b].

Higher Teichmüller theory is concerned with the study of representations of fundamental groups of oriented surface S of negative Euler characteristic into simple real Lie groups G of higher rank. The diversity of the methods involved is due partly to the one-to-one correspondence between representations, flat bundles, and Higgs bundles given by non-abelian Hodge theory Simpson [1991], which was established in work of Donaldson [1987, 1985], N. J. Hitchin [1987], Corlette [1988], and Simpson [1992].

We will introduce higher Teichmüller spaces below as special subsets of the representation variety $\mathrm{Hom}(\pi_1(S), G))/G$, namely as connected components consisting entirely of discrete and faithful representations. This is however a definition which only arose a posteriori. The first family of higher Teichmüller spaces, the Hitchin components, has been introduced by N. J. Hitchin [1992] using the theory of Higgs bundles. That they are higher Teichmüller spaces in the sense of our definition was in general only proven ten years later by Labourie [2006] and independently Fock and Goncharov [2006] through the study of the space of positive decorated local systems or positive representations. The second family of higher Teichmüller spaces, the spaces of maximal representations, was defined completely independently as the level set of a characteristic number on the representation variety, and its property of being a higher Teichmüller space in the sense of our definition was shown by Burger, Iozzi, and Wienhard [2003], motivated by previous work of W. M. Goldman [1988] in the context of classical Teichmüller space. The results of N. J. Hitchin [1992], Labourie [2006], Fock and Goncharov [2006] and Burger, Iozzi, and Wienhard [2003] arose completely independently, from different points of view and using very different methods. Only when comparing them it become apparent that the three spaces, Hitchin components, spaces of positive representations, and spaces of maximal representations, have many similarities and provide examples of a new phenomenon. Now we consider them as two families of what we call higher Teichmüller spaces. As the reader will see, we are still exploring the similarities and differences of these two families. It is interesting to note that the interplay between geometric and dynamical methods for representations of finitely generated groups and the more analytic and algebro-geometric methods from the theory of Higgs bundles are at the heart of several recent advances in our understanding of higher Teichmüller spaces.

Many questions in higher Teichmüller theory are motivated by the things we know about classical Teichmüller space, its properties and interesting geometric and dynamical structures it carries. However, there are also several new features that only arise for higher Teichmüller spaces and are not present in classical Teichmüller theory, see for example Section 4, Section 10 and Section 12. Higher Teichmüller theory is a very young and active field of mathematics. It is shaped by young mathematicians. There are still many open questions and unchartered territory to explore. We therefore hope that many young (and older) mathematicians will accept this invitation and contribute to the field in the future.

2 Classical Teichmüller space

Let S be a closed connected oriented topological surface of negative Euler characteristic $\chi(S) = 2 - 2g < 0$, where g is the genus of S. The Teichmüller space $\mathcal{T}(S)$ of S is the space of marked conformal classes of Riemannian metrics on S. It has been well studied using the theory of quasi-conformal maps as well as methods from hyperbolic geometry. By the uniformization theorem, there is a unique hyperbolic, i.e. constant curvature -1, metric in each conformal class. This identifies $\mathcal{T}(S)$ with the moduli space of marked hyperbolic structures. A marked hyperbolic structure is a pair (X, f_X), where X is a hyperbolic surface and $f_X : S \to X$ is an orientation preserving homeomorphism. Two marked hyperbolic structures (X, f_X) and (Y, f_Y) are equivalent if there exists an isometry $g : X \to Y$ such that $g \circ f_X$ is isotopic to f_Y. The mapping class group of S acts naturally on $T(S)$ by changing the marking. This action is properly discontinuous, and the quotient of $\mathcal{T}(S)$ by this action is the moduli space $\mathfrak{M}(S)$ of Riemann surfaces of topological type given by S. Teichmüller space is homeomorphic to $\mathbb{R}^{6g-6}$ and the universal cover of $\mathfrak{M}(S)$.

Higher Teichmüller theory builds on an algebraic realization of Teichmüller space. The universal cover $\tilde{X}$ of the hyperbolic surface X naturally identifies with the hyperbolic plane $\mathbb{H}^2$, and the fundamental group $\pi_1(X)$ acts as group of deck transformations by isometries on $\tilde{X} \cong \mathbb{H}^2$. Thus, upon fixing a base point, the marking induces a group homomorphism $(f_X)_* : \pi_1(S) \to \pi_1(X) < \mathrm{Isom}^+(\mathbb{H}^2) \cong \mathrm{PSL}(2, \mathbf{R})$, which is called the holonomy. Associating to a marked hyperbolic structure its holonomy gives a well defined injective map

$$\mathrm{hol} : \mathcal{T}(S) \to \mathrm{Hom}(\pi_1(S), \mathrm{PSL}(2, \mathbf{R}))/\mathrm{PSL}(2, \mathbf{R}).$$

The representation variety $\mathrm{Hom}(\pi_1(S), \mathrm{PSL}(2, \mathbf{R}))/\mathrm{PSL}(2, \mathbf{R})$ is the space of all group homomorphisms of $\pi_1(S)$ into $\mathrm{PSL}(2, \mathbf{R})$, up to conjugation by $\mathrm{PSL}(2, \mathbf{R})$. It carries a natural topology (induced from the topology of $\mathrm{PSL}(2, \mathbf{R})$). Teichmüller spce $\mathcal{T}(S)$ is a connected component of the representation variety $\mathrm{Hom}(\pi_1(S), \mathrm{PSL}(2, \mathbf{R}))/\mathrm{PSL}(2, \mathbf{R})$. It is one of the two connected components, which consist entirely of discrete and faithful representations of $\pi_1(S)$ into $\mathrm{PSL}(2, \mathbf{R})$. The other such component is $\mathcal{T}(\overline{S})$, where $\overline{S}$ is the surface with the opposite orientation.

Remark 1. From this point of, as set of discrete and faithful representation, $\mathcal{T}(S)$ was first studied by Fricke. Historically it would thus be more appropriate to call it Fricke space and the generalizations higher Fricke spaces, but it seems hard to change a name that is well established.

Classical Teichmüller space has many interesting properties and carries additional structure. It is a Kähler manifold which admits several Riemannian and non-Riemannian metrics, has nice explicit parametrizations, and carries interesting flows and dynamical systems. We will not be able to recall most of these interesting properties, but will come back to a few of them in the sequel.

3 What is higher Teichmüller theory?

We might interpret what higher Teichmüller theory is in a narrow or a broader sense. In a very broad sense it is the study of classes of representations of finitely generated groups into Lie groups of higher rank with particularly nice geometric and dynamical behaviour. In the narrow sense one could characterize it as the study of higher Teichmüller spaces as we define them below. In this article we restrict most of our discussion to this narrow interpretation. In the broad sense it is touched upon also in the contributions of Kassel [n.d.] and Potrie [n.d.].

Teichmüller space is a connected component of the representation variety $\mathrm{Hom}(\pi_1(S), \mathrm{PSL}(2,\mathbf{R}))/\mathrm{PSL}(2,\mathbf{R})$ - this is where higher Teichmüller theory takes it starting point. Instead of focussing on group homomorphisms of $\pi_1(S)$ into $\mathrm{PSL}(2,\mathbf{R})$, we replace $\mathrm{PSL}(2,\mathbf{R})$ by a simple Lie group G of higher rank (this is what the higher refers to), such as $\mathrm{PSL}(n,\mathbf{R})$, $n \geq 3$ or $\mathrm{Sp}(2n,\mathbf{R})$, $n \geq 2$, and consider the representation variety $\mathrm{Hom}(\pi_1(S), G)/G$. We make the following definition:

Definition 2. A higher Teichmüller space is a subset of $\mathrm{Hom}(\pi_1(S), G)/G$, which is a union of connected components that consist entirely of discrete and faithful representations.

Note that as soon as G is not locally isomorphic to $\mathrm{PSL}(2,\mathbf{R})$, the group $\pi_1(S)$ is not isomorphic to a lattice in G. Therefore the set of discrete and faithful representations is only a closed subset of $\mathrm{Hom}(\pi_1(S), G)/G$. It is thus not clear that higher Teichmüller spaces exist at all, and in fact they will only exist for special families of Lie groups G. In particular, when G is a simply connected complex Lie group, the representation variety $\mathrm{Hom}(\pi_1(S), G)/G$ is irreducible as an algebraic variety, and hence connected, and there cannot be any connected component consisting entirely of discrete and faithful representations. There are two known families of higher Teichmüller spaces, Hitchin components and spaces of maximal representations. They have been discovered from very different points of view and by very different methods. It then became clear that they share many properties, in particular the property requested in Definition 2. We describe a common underlying characterization, which also suggests the existence of two further families of higher Teichmüller spaces in Section 7.

Hitchin components $\mathcal{T}_H(S, G)$ are defined when G is a split real simple Lie group, the space of maximal representations $\mathcal{T}_{max}(S, G)$ is defined when G is a non-compact simple Lie group of Hermitian type. In the case when $G = \mathrm{PSL}(2, \mathbf{R})$, the Hitchin component and the space of maximal representations agree and coincide with Teichmüller space $\mathcal{T}(S)$. For other groups G not locally isomorphic to $\mathrm{PSL}(2, \mathbf{R})$, which are at the same time split and of Hermitian type, i.e. $\mathrm{Sp}(2n, \mathbf{R})$ or $\mathrm{SO}(2, 3)$, there is a proper inclusion $\mathcal{T}_H(S, G) \subset \mathcal{T}_{max}(S, G)$.

Remark 3. We assume that S is a closed surface.There is a related theory for surfaces with punctures or boundary components. However, in this case the corresponding subset of the representation variety is not a union of connected components. We comment on the situation for surfaces with punctures in Section 7.

We shortly review the definitions of Hitchin components and maximal representations. For more details and further properties we refer the reader to the survey Burger, Iozzi, and Wienhard [2014].

3.1 Hitchin components. Hitchin components are defined when G is a split real simple Lie group. Any split real simple Lie group G contains a three-dimensional principal subgroup, i.e. an embedding $\iota_p : \mathrm{SL}(2, \mathbf{R}) \to G$, which is unique up to conjugation. For the classical Lie groups $\mathrm{SL}(n, \mathbf{R})$, $\mathrm{Sp}(2n, \mathbf{R})$, and $\mathrm{SO}(n, n+1)$ this is just the irreducible representation of $\mathrm{SL}(2, \mathbf{R})$ in the appropriate dimension. Precomposing ι_p with a discrete embedding of $\pi_1(S)$ into $\mathrm{SL}(2, \mathbf{R})$ we obtain a representation $\rho_p : \pi_1(S) \to G$, which we call a principal Fuchsian representation.

Definition 4. The Hitchin component $\mathcal{T}_H(S, G)$ is the connected component of $\mathrm{Hom}(\pi_1(S), G)/G$ containing a principal Fuchsian representation $\rho_p : \pi_1(S) \to G$.

Remark 5. Note that we are a bit sloppy in our terminology, e.g. when $G = \mathrm{PSL}(3, \mathbf{R})$ there are 2 connected components in $\mathrm{Hom}(\pi_1(S), \mathrm{PSL}(3, \mathbf{R}))/\mathrm{PSL}(3, \mathbf{R})$ which consists of discrete and faithful representation which preserve the orientation. We refer to each of them as the Hitchin component.

Hitchin showed, using methods from the theory of Higgs bundle that the Hitchin component is homeomorphic to a vector space of dimension $\dim(G)(2g-2)$. He conjectured that these components are geometrically significant and parametrize geometric structures. This was supported by one example. W. M. Goldman [1990] had investigated the spaces of convex real projective structures on S and shown that it is isomorphic to $\mathbf{R}^{16g-16}$

and that the holonomy of a convex real projective structure is in the Hitchin component. Soon afterwards Choi and W. M. Goldman [1993] proved that in fact $\mathcal{T}_H(S, \mathrm{PSL}(3, \mathbf{R}))$ parametrizes the space of convex real projective structures on S. It took another ten years before further progress was made, when Labourie [2006] introduced methods from dynamical systems to the study of representations in the Hitchin component and showed that for $G = \mathrm{PSL}(n, \mathbf{R}), \mathrm{PSp}(2n, \mathbf{R})$, and $\mathrm{PO}(n, n+1)$ representations in the Hitchin component are discrete and faithful. That representations in any Hitchin component are discrete and faithful follows from work of Fock and Goncharov [2006]. They investigated the space of positive representations in $\mathrm{Hom}(\pi_1(S), G)/G$, when G is a split real simple Lie group, and showed that it coincides with the Hitchin component (see Section 7).

3.2 Maximal representations. Maximal representations are defined when the simple Lie group G is of Hermitian type. They are singled out by a characteristic number, the Toledo number, which for $G = PSL(2, \mathbf{R})$ is just the Euler number. W. M. Goldman [1988] showed that the Euler number distinguishes the connected components of $\mathrm{Hom}(\pi_1(S), \mathrm{PSL}(2, \mathbf{R}))/\mathrm{PSL}(2, \mathbf{R})$, and that Teichmüller space corresponds to the connected component formed by representation of Euler number $2g - 2$, which is the maximal value it can attain. In general, the Toledo number is bounded in terms of the Euler characteristic of S and the real rank of G, and constant on connected components of $\mathrm{Hom}(\pi_1(S), G)/G$. The space of maximal representations $\mathcal{T}_{max}(S, G)$ is the set of all representations for which the Toledo number assumes it maximal possible value. It is a union of connected components. Using methods from bounded cohomology, it was proven in Burger, Iozzi, and Wienhard [2003] that any maximal representation is faithful with discrete image.

Remark 6. There are two types of Hermitian Lie groups, those of tube type and those not of tube-type. Maximal representations into Lie groups that are not of tube type satisfy a rigidity theorem Toledo [1989], Hernàndez [1991], Burger, Iozzi, and Wienhard [2003], S. B. Bradlow, García-Prada, and Gothen [2003], and S. B. Bradlow, García-Prada, and Gothen [2006]: The image of a maximal representation is always contained in the stabilizer in G of a maximal subsymmetric space of tube type. This reduces the study of maximal representation essentially to the case when G is of tube type.

3.3 Anosov representations. Anosov representation are homomorphisms of finitely generated hyperbolic groups Γ into arbitrary reductive Lie groups G with special dynamical properties. They have been introduced by Labourie [2006] to investigate representations in the Hitchin component, and extended to hyperbolic groups in Guichard and Wienhard [2012]. The set of Anosov representations is an open subset of $\mathrm{Hom}(\Gamma, G)/G$, but in general not a union of connected components of $\mathrm{Hom}(\Gamma, G)/G$. Representations in the Hitchin component and maximal representations were the first examples of Anosov representations Labourie [2006], Burger, Iozzi, Labourie, and Wienhard [2005], Guichard and Wienhard [2012], and Burger, Iozzi, and Wienhard [n.d.]. We refer to Kassel's contribution Kassel [n.d.] for the definition, more details and more references on Anosov representations.

The following key properties of Hitchin representations and maximal representations follow from them being Anosov representations (with respect to certain parabolic subgroups).

1. Every representation in the Hitchin component and every maximal representation is discrete and faithful.

2. Let $\rho : \pi_1(S) \to G$ be a Hitchin representation, then there exists a ρ-equivariant continuous boundary map $\xi : S^1 \to G/B$ into the generalized flag variety G/B, where B is the Borel subgroup of G. The map sends distinct points in S^1 to transverse points in G/B.

3. Let $\rho : \pi_1(S) \to G$ be a maximal representation, then there exists a ρ-equivariant continuous boundary map $\xi : S^1 \to G/S$ into the generalized flag variety G/S, where S is a maximal parabolic subgroup of G which fixes a point in the Shilov boundary of the symmetric space $X = G/K$. The map sends distinct points in S^1 to transverse points in G/S.

4 Topology of the representation variety

For a connected Lie group G the obstruction to lifting a representation $\pi_1(S) \to G$ to the universal cover of G defines a characteristic invariant in $\mathrm{H}^2(S, \pi_1(G)) \cong \pi_1(G)$. For compact simple Lie groups Atiyah and Bott [1983] and complex simple Lie groups W. M. Goldman [1988] and J. Li [1993] the connected components of $\mathrm{Hom}(\pi_1(S), G)/G$ are in one to one correspondence with elements in $\pi_1(G)$. This does not hold anymore for real simple Lie groups in general. Of course, characteristic invariants in $\mathrm{H}^2(S, \pi_1(G))$ still distinguish some of the connected components, but they are not sufficient to distinguish all of them. N. J. Hitchin [1992] determined the number of connected components of $\mathrm{Hom}(\pi_1(S), \mathrm{PSL}(n, \mathbf{R}))/\mathrm{PSL}(n, \mathbf{R})$, and showed that Hitchin components have the same characteristic invariants as other components. The space of maximal representations, which is defined using characteristic invariants, in fact decomposes itself into several connected components, which hence cannot be distinguished by any characteristic invariant Gothen [2001] and S. B. Bradlow, García-Prada, and Gothen [2006].

A precise count of the number of connected components for several classical groups, and in particular for the connected components of the space of maximal representations has been given using the Morse theoretic methods on the moduli space of Higgs bundles Hitchin introduced A. G. Oliveira [2011], García-Prada and A. G. Oliveira [2014], S. B. Bradlow, García-Prada, and Gothen [2015], Gothen [2001], S. B. Bradlow, García-Prada, and Gothen [2006], García-Prada and Mundet i Riera [2004], and García-Prada, Gothen, and Mundet i Riera [2013]. The situation is particularly interesting for $G = \mathrm{Sp}(4, \mathbf{R})$ (and similarly for the locally isomorphic group $\mathrm{SO}^\circ(2,3)$) as there are $2g - 4$ connected components in which all representations are Zariski dense Guichard and Wienhard [2010] and S. B. Bradlow, García-Prada, and Gothen [2012]. Maximal representations in these components cannot be obtained by deforming an appropriate Fuchsian representation $\rho : \pi_1(S) \to \mathrm{SL}(2, \mathbf{R}) \to \mathrm{Sp}(4, \mathbf{R})$. An explicit construction of representations in these exceptional components is given in Guichard and Wienhard [2010]. Any maximal representations into $\mathrm{Sp}(2n, \mathbf{R})$ with $n \geq 3$ on the other hand can be deformed either to a principal Fuchsian representation (if it is in a Hitchin component) or to a (twisted) diagonal Fuchsian representation $\rho : \pi_1(S) \to \mathrm{SL}(2, \mathbf{R}) \times \mathrm{O}(n) < \mathrm{Sp}(2n, \mathbf{R})$. In order to distinguish the connected components in the space of maximal representations, additional invariants are necessary. Such additional invariants have been defined on the one hand using methods from the theory of Higgs bundles Gothen [2001], S. B. Bradlow, García-Prada, and Gothen [2006], Collier [2017], Baraglia and Schaposnik [2017], and Aparicio-Arroyo, S. Bradlow, Collier, García-Prada, Gothen, and A. Oliveira [2018] and on the other hand using the Anosov property of representations Guichard and Wienhard [2010].

We shortly describe the additional invariants arising from the Anosov property. If a representations is Anosov with respect to a parabolic subgroup $P < G$, then the pull-back of the associated flat G-bundle to $T^1 S$ admits a reduction of the structure group to L, where L is the Levi subgroup of P. The characteristic invariants of this L-bundle provide additional invariants of the representation. These additional invariants can be used in particular to further distinguish connected components consisting entirely of Anosov representation. Note that representations can be Anosov with respect to different parabolic subgroups - each such parabolic subgroup gives rise to additional invariants. For the case of maximal representations into $\mathrm{Sp}(2n, \mathbf{R})$ it is shown in Guichard and Wienhard [ibid.] that these additional invariants in fact distinguish all connected components.

Conjecture 7. *Let G be a simple Lie group of higher rank. The connected components of $\mathrm{Hom}(\pi_1(S), G)/G$ can be distinguished by characteristic invariants and by additional invariants associated to unions of connected components consisting entirely of Anosov representations.*

Note that, since Anosov representations are discrete and injective, any connected component consisting entirely of Anosov representations also provides an example of a higher Teichmüller space. Thus Conjecture 7 implies in particular the following

Conjecture 8. *There are connected components of* $\mathrm{Hom}(\pi_1(S), G)/G$ *which are not distinguished by characteristic invariants, if and only if there exist higher Teichmüller spaces in* $\mathrm{Hom}(\pi_1(S), G)/G$

Combining Conjecture 8 with Conjecture 19 gives a precise list of groups (see Theorem 17) for which we expect additional connected components to exist. A particularly interesting case is $\mathrm{SO}(p,q)$, $p \neq q$. Here additional components and additional invariants have recently been found via Higgs bundle methods Collier [2017], Baraglia and Schaposnik [2017], and Aparicio-Arroyo, S. Bradlow, Collier, García-Prada, Gothen, and A. Oliveira [2018].

5 Geometric Structures

Classical Teichmüller space $\mathcal{T}(S)$ is not just a space of representations, but in fact a space of geometric structures: every representation is the holonomy of a hyperbolic structure on S. For higher Teichmüller spaces, such a geometric interpretation is less obvious. The quotient of the symmetric space Y associated to G by $\rho(\pi_1(S))$ is of infinite volume. In order to find geometric structures on compact manifolds associated, other constructions are needed.

For any representation $\rho : \pi_1(S) \to G$ in the Hitchin component or in the space of maximal representation, there is t a domain of discontinuity in a generalized flag variety $X = G/Q$, on which ρ acts cocompactly. The quotient is a compact manifold M with a locally homogeneous (G, X)-structure. This relies on the the construction of domains of discontinuity for Anosov representations given by Guichard and Wienhard [2012] and generalized by Kapovich, Leeb, and Porti [2018]. We do not describe this construction here in detail, but refer the reader to Kassel [n.d.], where locally homogeneous (G, X)-structures, Anosov representations and the construction of domains of discontinuity are discussed in more detail.

The construction of the domains of discontinuity, together with some topological considerations, allows one to deduce the general statement

Theorem 9. *Guichard and Wienhard [2012] For every split real simple Lie group* G *there exists a generalized flag variety* X *and a compact manifold* M *such that* $\mathcal{T}_H(S, G)$ *parametrizes a connected component of the deformation space of* (G, X)*-structures on* M*. For every Lie group of Hermitian type* G *there exists a generalized flag variety* X *and a compact manifold* M *such that for every connected component* C *of* $\mathcal{T}_{max}(S, G)$ *the following holds: A Galois cover of* C *parametrizes a connected component of the deformation space of* (G, X)*-structures on* M*.*

In particular, any Hitchin representation or maximal representation is essentially the holonomy of a (G, X)-structures on a compact manifold. It is however quite hard to get an explicit description of the deformation space of (G, X)-structures they parametrize. First it is nontrivial to determine the topology of the quotient manifold, and second it is rather difficult to give a synthetic description of the geometric properties which ensure that the holonomy representation of a (G, X) structure lies in the Hitchin component or in the space of maximal representations. In three cases we such a synthetic description: the Hitchin component for $\mathcal{T}_H(S, \mathrm{PSL}(3, \mathbf{R}))$, the Hitchin component $\mathcal{T}_H(S, \mathrm{PSL}(4, \mathbf{R}))$ and $\mathcal{T}_H(S, \mathrm{PSp}(4, \mathbf{R}))$, the space of maximal representations $\mathcal{T}_{max}(S, \mathrm{SO}^\circ(2, n))$.

Theorem 10. Choi and W. M. Goldman [1993] *A representation $\rho : \pi_1(S) \to \mathrm{PSL}(3, \mathbf{R})$ is in Hitchin component $\mathcal{T}_H(S, \mathrm{PSL}(3, \mathbf{R}))$ if and only if it is the holonomy representation of a convex real projective structures on S*

A convex real projective structure on S is a realization of S as the quotient of a convex domain $\Omega \subset \mathbf{RP}^2$ by a group $\Gamma < \mathrm{PSL}(3, \mathbf{R})$ of projective linear transformation preserving Ω. One aspect which makes this case very special is that the group $\mathrm{PSL}(3, \mathbf{R})$ acts as transformation group on the two-dimensional homogeneous space $\mathbf{RP}^2$. The subgroup $\rho(\pi_1(S))$ preserves a convex domain Ω and acts cocompactly on it. The quotient is a surface homeomorphic to S. For more general simple Lie groups of higher rank, there is no two-dimensional generalized flag variety on which they act, and so the quotient manifold M is higher dimensional.

Theorem 11. Guichard and Wienhard [2008] *The Hitchin component $\mathcal{T}_H(S, \mathrm{PSL}(4, \mathbf{R}))$ parametrizes the space of properly convex foliated projective structures on the unit tangent bundle of S. The Hitchin component $\mathcal{T}_H(S, \mathrm{PSp}(4, \mathbf{R}))$ parametrizes the space of properly convex foliated projective contact structures on the unit tangent bundle of S.*

Theorem 12. Collier, Tholozan, and Toulisse [2017] *The space of maximal representations $\mathcal{T}_{max}(S, \mathrm{SO}^\circ(2, n))$ parametrizes the space of fibered photon structures on $\mathrm{O}(n)/\mathrm{O}(n-2)$ bundles over S.*

Conjecture 13 (Guichard-Wienhard)**.** *Let $\rho : \pi_1(S) \to G$ be a representation in a higher Teichmüller space, then there exists a generalized flag variety X and compact fiber bundle $M \to S$, such that $\overline{\rho} : \pi_1(M) \to \pi_1(S) \to G$, where $\pi_1(M) \to \pi_1(S)$ is induced by the bundle map and $\pi_1(S) \to G$ is given by ρ, is the holonomy of a locally homogeneous (G, X)-structure on M.*

In fact, we expect, that for any cocompact domain of discontintuity which is constructed through a balanced thickening in the sense of Kapovich, Leeb, and Porti [2018], the quotient manifold is homeomorphic to a compact fiber bundle M over S. A related conjecture has been made by Dumas and Sanders [2017b, Conjecture 1.1] for deformations of

Hitchin representations in the complexification of G. They proved the conjecture in the case of $\mathrm{PSL}(3,\mathbf{C})$. Guichard and Wienhard [2011a] determine the topology of the quotient manifold for maximal representations and Hitchin representations into the symplectic group, Alessandrini and Q. Li [2018] prove the conjecture for Hitchin representations into $\mathrm{PSL}(n,\mathbf{R})$, and their deformations into $\mathrm{PSL}(n,\mathbf{C})$, and Alessandrini, Maloni, and Wienhard [n.d.] analyze the topology of quotient manifold for complex deformations of symplectic Hitchin representations.

It is very interesting to note that the recent advantages Alessandrini and Q. Li [2018] and Collier, Tholozan, and Toulisse [2017] on understanding the topology of the quotient manifolds rely on a finer analysis and description of the Higgs bundle associated to special representations in the Hitchin component or in the space of maximal representations. That the explicit description of the Higgs bundles can be used to endow the domain of discontinuity naturally with the structure of a fiber bundle was first described by Baraglia [2010] for $\mathfrak{T}_H(S,\mathrm{PSL}(4,\mathbf{R}))$, where he recovered the projective structures on the unit tangent bundle from Theorem 11.

6 Relation to the moduli space of Riemann surfaces

The outer automorphism group fo $\pi_1(S)$ is isomorphic to the mapping class group of S. It acts naturally on $\mathrm{Hom}(\pi_1(S),G)/G$. This action is properly discontinuous on higher Teichmüller spaces - in fact more generally on the set of Anosov representations Labourie [2008], Wienhard [2006], and Guichard and Wienhard [2012]. It is natural to ask about the relation between the quotient of higher Teichmüller spaces by this action and the moduli space of Riemann surfaces $\mathfrak{M}(S)$. For Hitchin components Labourie made a very precise conjecture, based on Hitchin's parametrization of the Hitchin component. We state the parametrization and Labourie's conjecture for $G = \mathrm{PSL}(n,\mathbf{R})$ to simplify notation. Hitchin introduced the Hitchin component in N. J. Hitchin [1992] using methods from the theory of Higgs bundles. This requires the choice of a conformal structure on S. N. J. Hitchin [ibid.] showed, using methods from the theory of Higgs bundles, that the Hitchin component is homeomorphic to a vector space. Namely, it is homeomorphic to the space of holomorphic differentials on S with respect to a chosen conformal structure, i.e. $\mathfrak{T}_H(S,\mathrm{PSL}(n,\mathbf{R})) \cong \sum_{i=2}^n H^0(S,K^i)$ This parametrization depends on the choice of a conformal structure and is not invariant under the mapping class group.

Conjecture 14. *Labourie [2008] The quotient of $\mathfrak{T}_H(S,\mathrm{PSL}(n,\mathbf{R}))$ by the mapping class group is a holomorphic vector bundle over $\mathfrak{M}(S)$, with fiber equal to $\sum_{i=3}^n H^0(S,K^i)$.*

This conjecture has been proven by Labourie [2007b] and Loftin [2001] for $G = \mathrm{PSL}(3, \mathbf{R})$ and by Labourie [2017a], using Higgs bundle methods, for all split real Lie groups of rank 2. It is open in all other cases.

For maximal representations we expect similarly to get a mapping class group invariant projection from $\mathfrak{T}_{max}(S, G)$ to $\mathfrak{T}(S)$, see Alessandrini and Collier [2017, Conjecture 10]. For $G = \mathrm{SO}(2, n)$ such a projection is constructed in Collier, Tholozan, and Toulisse [2017]. For G of rank 2 Alessandrini and Collier [2017] construct a mapping class group invariant complex structure on $\mathfrak{T}_{max}(S, G)$. For $G = \mathrm{Sp}(4, \mathbf{R})$ they show that the quotient of $\mathfrak{T}_{max}(S, G)$ by the mapping class group is a holomorphic vector bundle over $\mathfrak{M}(S)$, and describe in detail the fiber over a point, which is rather complicated since the space of maximal representations has nontrivial topology and singular points.

7 Positivity

Hitchin components and maximal representation were introduced and studied by very different methods. It turns out that they do not only share many properties, but also admit a common characterization in terms of positive structures on flag varieties. Only the flag varieties and notions of positivity in question are different for Hitchin components and maximal representations.

For Hitchin components we consider full flag varieties and Lusztig's total positivity Lusztig [1994]. For maximal representations the flag variety in question is the Shilov boundary of the symmetric space of G and positivity is given by the Maslov cocycle. In order to keep the description simple, we illustrate both notions in examples. We consider $G = \mathrm{SL}(n, \mathbf{R})$ for Hitchin components, and $G = \mathrm{Sp}(2n, \mathbf{R})$ for maximal representations.

The relevant flag variety for $\mathfrak{T}_H(S, \mathrm{SL}(n, \mathbf{R}))$ is the full flag variety

$$\mathfrak{F}(\mathbf{R}^n) := \{F = (F_1, F_2, \cdots, F_{n-1}) \mid F_i \subset \mathbf{R}^n, \dim(F_i) = i, \; F_i \subset F_{i+1}\}.$$

Two flags F, F' are said to be transverse if $F_i \cap F'_{n-i} = \{0\}$. We fix the standard basis $(e_1, \cdots, e_n)$ of $\mathbf{R}^n$. Let $F \in \mathfrak{F}$ be the flag with $F_i = \mathrm{span}(e_1, \cdots, e_i)$, and $E \in \mathfrak{F}$ the flag with $E_i = \mathrm{span}(e_n, \cdots, e_{n-i+1})$.

Any flag T transverse to F, is the image of E under a unique unipotent matrix u_T. The triple of flags (E, T, F) is said to be *positive* if and only if u_T is a totally positive unipotent matrix. Note that a unipotent (here lower triangular) matrix is totally positive if and only of every minor is positive, except those that have to be zero by the condition that the matrix is unipotent. Any two transverse flags (F_1, F_2) can be mapped to (E, F) by an element of $\mathrm{SL}(n, \mathbf{R})$ and we can extend the notion of positivity to any triple of pairwise transverse flags.

Theorem 15. *Fock and Goncharov [2006], Labourie [2006], and Guichard [2008] Let $\rho : \pi_1(S) \to \mathrm{SL}(n, \mathbf{R})$ be a representation. Then $\rho \in \mathcal{T}_H(S, \mathrm{SL}(n, \mathbf{R}))$ if and only if there exists a continuous ρ-equivariant map $\xi : S^1 \to \mathcal{F}(\mathbf{R}^n)$ which sends positive triples in S^1 to positive triples in $\mathcal{F}(\mathbf{R}^n)$.*

To describe the analogous characterization of maximal representations into $\mathrm{Sp}(2n, \mathbf{R})$ we consider $\mathbf{R}^{2n}$ with the standard symplectic form ω and let $\{e_1, \cdots, e_n, f_1, \cdots f_n\}$ be a symplectic basis. Then

$$\mathcal{L}(\mathbf{R}^{2n}) := \{L \subset \mathbf{R}^{2n} \mid \dim L = n,\ \omega|_{L \times L} = 0\}$$

is the space of Lagrangian subspaces, and two Lagrangians L and L' are transverse if $L \cap L' = \{0\}$.

Fix $L_E = \mathrm{span}(e_1, \cdots, e_n)$ and $L_F = \mathrm{span}(f_1, \cdots, f_n)$. Any Lagrangian $L_T \in \mathcal{L}$ transverse to L_F is the image of L_E under an element $v_T = \begin{pmatrix} Id_n & 0 \\ M_T & Id_n \end{pmatrix} \in V$, where M_T is a symmetric matrix.

The triple of Lagrangians (L_E, L_T, L_F) is said to be *positive* if and only if $M_T \in \mathrm{Pos}(n, \mathbf{R}) \subset \mathrm{Sym}(n, \mathbf{R})$ is positive definite. This is equivalent to the Maslov cocycle of (L_E, L_T, L_F) being n, which is the maximal value it can attain. The symplectic group $\mathrm{Sp}(2n, \mathbf{R})$ acts transitively on the space of pairs of transverse Lagrangians and we can extend the notion of positivity to any triple of pairwise transverse Lagrangian.

Theorem 16. *Burger, Iozzi, and Wienhard [2003] Let $\rho : \pi_1(S) \to \mathrm{Sp}(2n, \mathbf{R}$ be a representation. Then $\rho \in \mathcal{T}_{max}(S, \mathrm{Sp}(2n, \mathbf{R}))$ if and only if there exists a continuous ρ-equivariant map $\xi : S^1 \to \mathcal{L}(\mathbf{R}^{2n})$ which sends positive triples in S^1 to positive triples in $\mathcal{L}(\mathbf{R}^{2n}$.*

In Guichard and Wienhard [2011c,b] we introduce the notion of Θ-positivity. It generalizes Lusztig's total positivity, which is only defined for split real Lie groups, to arbitrary simple Lie groups. There are four families of Lie groups admitting a Θ-positive structure:

Theorem 17. *Guichard and Wienhard [2011c, Theorem 4.3.] A simple Lie group G admits a Θ-positive structure if and only if:*

1. *G is a split real form.*
2. *G is of Hermitian type of tube type.*
3. *G is locally isomorphic to $\mathrm{SO}(p, q)$, $p \neq q$,.*
4. *G is a real form of F_4, E_6, E_7, E_8, whose restricted root system is of type F_4.*

Θ refers to a subset of the simple roots. If G admits a Θ-positive structure, then there is positive semigroup $U_\Theta^> \subset U_\Theta < P_\Theta$ with which we can define the notion of positivity for a triple of pairwise transverse points in the generalized flag variety G/P_Θ as above. Here P_Θ is the parabolic group associated to the subset of simple roots Θ, and U_Θ is its unipotent radical.

Definition 18. A representation $\rho : \pi_1(S) \to G$ is said to be Θ-positive if there exists a continuous ρ-equivariant map $\xi : S^1 \to G/P_\Theta$ which sends positive triples in S^1 to positive triples in G/P_Θ.

Conjecture 19 (Guichard-Labourie-Wienhard)**.** *The set of Θ-positive representations $\rho : \pi_1(\Sigma_g) \to G$ is open and closed in* $\mathrm{Hom}(\pi_1(S), G)/G$. *In particular, Θ-positive representations form higher Teichmüller spaces.*

For more details on Θ-positivity and Θ-positive representations we refer the reader to Guichard and Wienhard [2011c] and the upcoming papers Guichard and Wienhard [2011b] and Guichard, Labourie, and Wienhard [2011], in which Conjecture 13 will be partly addressed. In particular we prove that Θ-positive representations are P_Θ-Anosov and form an open subset of $\mathrm{Hom}(\pi_1(S), G)/G$, and a closed set, at least in the subset of irreducible representations.

The existence of a Θ-positive structure provides a satisfying answer on when and why higher Teichmüller spaces exist, and we expect that the families of Lie groups listed in Theorem 17 are the only simple Lie groups for which higher Teichmüller spaces in $\mathrm{Hom}(\pi_1(S), G)/G$ exist. A particular interesting case is the family of Θ-positive representations for $G = \mathrm{SO}(p, q)$. Here the connected components have recently been determined with Higgs bundle methods, and several of them contain Θ-positive representations Collier [2017] and Aparicio-Arroyo, S. Bradlow, Collier, García-Prada, Gothen, and A. Oliveira [2018].

8 Coordinates and Cluster structures

Teichmüller space carries several nice sets of coordinates. The best known are Fenchel-Nielsen coordinates, which encode a hyperbolic structure by the length of and the twist around a set of $3g-3$ disjoint simple closed non-homotopic curves which give a decomposition of S into a union of $2g-2$ pair of pants. W. M. Goldman [1990] introduced Fenchel-Nielsen type coordinates on the Hitchin component $\mathcal{T}_H(S, \mathrm{PSL}(3, \mathbf{R})$. Here, there are two length and two twist coordinates associated to the curves of a pants decomposition, and in addition two coordinates which associated to each of the pairs of pants. This a new feature arises because a convex real projective structure on a pair of pants is not uniquely determined by the holonomies around the boundary. For maximal representations, Fenchel-Nielsen type coordinates were constructed in Strubel [2015].

It is often easier to describe coordinates in the situation when the surface is not closed, but has at least one puncture. In this case one can consider decorated flat bundles (or decorated representations), which is a flat bundle or a representation together with additional information around the puncture. Fixing an ideal triangulation, i.e. a triangulation where all the vertices are punctures, this additional information can be used to define coordinates. Examples of this are Thurston shear coordinates or Penner coordinates for decorated Teichmüller space. In the context of higher Teichmüller spaces, for decorated representations into split real Lie groups Fock and Goncharov [2006] introduced two sets of coordinates, so called $\mathcal{X}$- coordinates, which generalize Thurston shear coordinates, and $\mathcal{A}$-coordinates, which generalize Penner coordinates. They show that when performing a flip of the triangulation (changing the diagonal in a quadrilateral formed by two adjacent triangles), the change of coordinates is given by a positive rational function. As a consequence, the set of decorated representations where all coordinates are positive, is independent of the triangulation. In fact, Fock and Goncharov prove that this set of positive representations is precisely the set of positive representations in the sense of Section 7, where the notion of positivity stems from Lusztig's positivity. In the case when $G = \mathrm{PSL}(n, \mathbf{R})$, the Fock-Goncharov coordinates admit a particularly nice geometric description based on triple ratios and cross ratios. In particular there is a close relation between the coordinates and cluster structures, which received a lot of attention. The change of coordinates associated to a flip of the triangulations is given by a sequence of cluster mutations. This has since been generalized to other classical groups in Le [n.d.(b)], see also Le [n.d.(a)] and Goncharov and Shen [2018] for general split real Lie groups. Related coordinates have been defined by Gaiotto, Moore and Neitzke, using the theory of spectral networks Gaiotto, Moore, and Neitzke [2013, 2014]. For an interpretation of the Weil-Petersson form in terms of cluster algebras see Gekhtman, Shapiro, and Vainshtein [2005].

Inspired by Fock-Goncharov coordinates for surfaces with punctures, Bonahon and Dreyer defined coordinates on the Hitchin component $\mathcal{T}_H(S, \mathrm{PSL}(n, \mathbf{R}))$ and showed that $\mathcal{T}_H(S, \mathrm{PSL}(n, \mathbf{R}))$ is real analytically homeomorphic to the interior of a convex polygon of dimension $(n^2-1)(2g-2)$ Bonahon and Dreyer [2014, 2017]. These coordinates are associated to a maximal lamination of the surface S and generalize Thurston's shear coordinates of closed surfaces. A special case for such a maximal lamination is an ideal triangulation of S which is subordinate to a pair of pants decomposition, i.e. the lamination consists of $3g-3$ disjoint simple closed non-homotopic curves which give a pair of pants decomposition, and three curves in each pair of pants, that cut the pair of pants into two ideal triangles. In this case, Zhang [2015a] provided a reparametrization of the Bonahon-Dreyer coordinates, which give a genuine generalization of Fenchel-Nielsen type coordinates for the Hitchin component $\mathcal{T}_H(S, \mathrm{PSL}(n, \mathbf{R}))$, see also Bonahon and Kim [2016] for a direct comparision with Goldman coordinates when $n = 3$.

In forthcoming work Alessandrini, Guichard, Rogozinnikov, and Wienhard [2017] we introduce $\mathcal{X}$-type and $\mathcal{A}$-type coordinates for decorated maximal representations of the fundamental group of a punctured surface into the symplectic group $\mathrm{Sp}(2n, \mathbf{R})$. These coordinates have the feature of behaving like the coordinates for $G = \mathrm{PSL}(2, \mathbf{R})$ but with values in the space of positive definite symmetric matrices $\mathrm{Pos}(n, \mathbf{R})$. In particular, even though they are noncommutative, they exhibit a cluster structure. This structure is similar to the noncommutative cluster structure considered by Berenstein and Retakh [2015], except for a difference in some signs.

It would be interesting to develop similar coordinates for Θ-positive representations, in particular for those into $\mathrm{SO}(p, q)$, and to investigate their properties. The properties of the Θ-positive structure suggests that in this case the cluster-like structure would combine noncommutative and commutative aspects.

Task 20. *Develop $\mathcal{X}$-type and $\mathcal{A}$-type coordinates for decorated Θ-positive representations into $\mathrm{SO}(p, q)$. Analyze their cluster-like structures.*

9 Symplectic geometry and dynamics

For any reductive Lie group, the representation variety of a closed surface $\mathrm{Hom}(\pi_1(S), G)/G$ is a symplectic manifold W. M. Goldman [1984]. On Teichmüller space this symplectic structure interacts nicely with Fenchel-Nielsen coordinates. The length and twist coordinates give global Darboux coordinates: the length coordinate associated to a simple closed curve in a pair of pants decomposition is symplectically dual to the twist coordinate associated to this curve, and the symplectic form can be expressed by Wolpert's formula as $\omega = \sum_{i=1}^{3g-3} dl_i \wedge d\tau_i$, where l_i is the length coordinate and τ_i is the twist coordinate Wolpert [1983]. The twist flows associated to a simple closed curve c on S is the flow given by cutting S along c and continuously twisting around this curve before gluing the surface back together. It is the Hamiltonian flow associated to the length coordinate defined by c. The twist flows associated to the $3g - 3$ simple closed curves in a pants decomposition on S commute. This gives Teichmüller space the structure of a complete integrable system. For more general reductive groups, the Hamiltonian flows associated to length functions on $\mathrm{Hom}(\pi_1(S), G)/G$ have been studied by W. M. Goldman [1986].

In Sun and Zhang [2017] provide a new approach to compute the Goldman symplectic form on $\mathcal{T}_H(S, \mathrm{PSL}(n, \mathbf{R}))$. This, in conjunction with a companion article by Sun, Wienhard, and Zhang [2017], gives rise to several nice statements. Given maximal lamination with finitely many leaves (and some additional topological data) we construct in Sun, Wienhard, and Zhang [ibid.] new families of flows on $\mathcal{T}_H(S, \mathrm{PSL}(n, \mathbf{R}))$. These flows give a trivialization of the Hitchin component, which is shown to be symplectic in Sun and Zhang [2017]. Consequently the flows are all Hamiltonian flows and provide $\mathcal{T}_H(S, \mathrm{PSL}(n, \mathbf{R})$ the structure of a completely integrable system.

Task 21. *The mapping class group* $\mathrm{Mod}(S)$ *acts naturally on the space of maximal laminations and the additional topological data, so that the symplectic trivializations of* $\mathcal{T}_H(S, \mathrm{PSL}(n, \mathbf{R}))$ *induce representations* $\pi_n : \mathrm{Mod}(S) \to \mathrm{Sp}(\mathbf{R}^{(n^2-1)(2g-2)})$. *Analyze these representations.*

A special situation arises when the maximal lamination is an ideal triangulation subordinate to a pants decomposition. In this situation we slightly modify the Bonahon-Dreyer coordinates, to get global Darboux coordinates on $\mathcal{T}_H(S, \mathrm{PSL}(n, \mathbf{R}))$ which consist of $(3g-3)(n-1)$ length coordinates, $(3g-3)(n-1)$ twist coordinates associated to the simple closed curves in the pants decomposition, and $2 \times \frac{(n-1)(n-2)}{2}$ coordinates for each pair of pants. The twist flows are the Hamiltonian flows associated to the length functions, and for each pair of pants we introduce $\frac{(n-1)(n-2)}{2}$ new flows, which we call eruption flows. Their Hamiltonian functions are rather complicated. Nevertheless, the twist flows and the eruption flows pairwise commute, providing a half dimensional subspace of commuting flows. In the case of $\mathrm{PSL}(3, \mathbf{R})$ the eruption flow has been defined in Wienhard and Zhang [2018], where it admits a very geometric description.

Classical Teichmüller space does not only admit twist flows, but carries several natural flows, for example earthquake flows, which extend twist flows, geodesic flows with respect to the Weil-Petersson metric or the Teichmüller metric or, and even an $\mathrm{SL}(2, \mathbf{R})$-action. None of this has yet been explored for higher Teichmüller spaces. A new approach for lifting Teichmüller dynamics to representation varieties for general Lie group G has recently been described by Forni and W. Goldman [2017].

10 Geodesic flows and entropy

Representations in higher Teichmüller space, and more generally Anosov representations, are strongly linked to dynamics on the surface S. Any such representation gives rise to a Hölder reparametrization of the geodesic flow on S and the representation can essentially be reconstructed from the periods of this reparametrized geodesic flow. This dynamical point of view has been first observed by Labourie [2006] and applied by Sambarino [2014a] and has been key in several interesting developments.

Using the thermodynamical formalism Bridgeman, Canary, Labourie, and Sambarino [2015] define the pressure metric on the Hitchin component $\mathcal{T}_H(S, \mathrm{PSL}(n, \mathbf{R}))$ and more generally spaces of Anosov representations. The pressure metric restricts to a multiple of the Weil-Petersson metric on the subset of principal Fuchsian representations. In the case of $\mathrm{PSL}(3, \mathbf{R})$ metrics on the space of convex real projective structures have also been constructed in Darvishzadeh and W. M. Goldman [1996] and Q. Li [2016].

Other important quantities that have been investigated using this dynamical viewpoint are the critical exponent and the topological entropy of Hitchin representations, which are related to counting orbit points on the symmetric space Sambarino [2015, 2014b] and Pollicott and Sharp [2014]. Here completely new features arise that are not present in classical Teichmüller space. On Teichmüller space both quantities are constant, but on Hitchin components these functions vary and provide information about the geometry of the representations. There are sequences of representations along which the entropy goes to zero Zhang [2015b,a]. The entropy is in fact bounded above. Tholozan for $n = 3$ Tholozan [2017], and Potrie and Sambarino in general, establish an entropy rigidity theorem: A representation saturates the upper bound for the entropy if and only if it is a principal Fuchsian representation Sambarino [2016] and Potrie and Sambarino [2017]. This has consequences for the volume of the minimal surface in the symmetric space associated to the representation. A key aspect in the work of Potrie and Sambarino has been the regularity of the map $\xi : S^1 \to G/B$ of a Hitchin representation.

For maximal representations which are not in the Hitchin component much less is known. One obstacle is the missing regularity of the boundary map $\xi : S^1 \to G/S$, which has rectifiable image, but is in general not smooth. Glorieux and Monclair [n.d.] study the entropy of Anti-de-Sitter Quasi-Fuchsian representations $\pi_1(S) \to \mathrm{SO}(2, n)$, some of their methods methods might also be useful to investigate maximal representation $\pi_1(S) \to \mathrm{SO}(2, n)$.

Task 22. *Investigate the topological entropy of maximal representations. Find and characterize sequences along which the entropy goes to zero. Find bounds for the topological entropy and geometrically characterize the representations that saturate these bounds.*

A lot of the geometry of Teichmüller space can be recovered from geodesic currents associated to the representations and from their intersection Bonahon [1988]. Recently Martone and Zhang [n.d.] have associated geodesic currents to positively ratioed representations, a class that includes Hitchin representations and maximal representations but should include also Θ-positive representations. Bridgeman, Canary, Labourie, and Sambarino [2018] define the Liouville current for a Hitchin representation which they use to construct the Liouville pressure metric. From the intersection of the geodesic currents one can recover the periods of the reparametrization of the geodesic flow and the periods of crossratios associated to the representation Labourie [2008] and Hartnick and Strubel [2012]. These geodesic currents and the corresponding crossratio functions also play an important role for the next topic we discuss.

11 Compactifications

Classical Teichmüller space admits various non-homeomorphic compactifications. One such compactification is the marked length spectrum compactification. The marked length spectrum of a representation $\rho : \pi_1(S) \to \mathrm{PSL}(2,\mathbf{R})$ associates to any conjugacy class in $[\gamma]$ in $\pi_1(S)$ the translation length of the element $\rho(\gamma)$ in $\mathbb{H}^2$. It is a basic result that for Teichmüller space the map $\Phi : \mathcal{T}(S) \to \mathbf{P}(\mathbf{R}^{\mathcal{C}})$ provides an embedding. The closure of $\Phi(\mathcal{T}(S))$ is the marked length spectrum compactification. It is homeomorphic to the Thurston compactification of $\mathcal{T}(S)$ by the space of projectivized measured laminations. This compactification has been reconstructed using geodesic currents by Bonahon [1988].

The marked length spectrum compactification has been generalized to compactifications of spaces of representations of finitely generated groups into reductive Lie groups by Parreau [2012], where the translation length in $\mathbb{H}^2$ is replaced by the vector valued translation length in the symmetric space associated to G. This can be applied to Hitchin components and spaces of maximal representations to provide marked length spectrum compactifications. The investigation of the fine structure of these compactifications has just begun. A key ingredient are generalizations of the Collar Lemma from hyperbolic geometry to Hitchin representations Lee and Zhang [2017] and to maximal representations Burger and M. B. Pozzetti [2017]. See also Labourie and McShane [2009], Vlamis and Yarmola [2017], and Fanoni and B. Pozzetti [n.d.] for generalizations of cross-ratio identities in the context of higher Teichmüller spaces. Burger, Iozzi, Parreau, and B. Pozzetti [2017] establish a new decomposition theorem for geodesic currents, which will play a crucial role in their program to understand the marked length spectrum compactification of maximal representations.

Compactifications of the space of positive representations (when S has punctures) have been constructed using explicit parametrizations and the theory of tropicalizations Fock and Goncharov [2006], Alessandrini [2008], and Le [2016].

In all these constructions it is a challenge to give a geometric interpretation of points in the boundary of the compactification. The most natural is in terms of actions on $\mathbf{R}$-buildings Parreau [2012], Le [2016], and Burger and M. B. Pozzetti [2017]. This naturally generalizes the description of boundary points of Teichmüller space by actions on $\mathbf{R}$-trees. However, Thurston's compactification gives an interpretation of boundary points by measured laminations on S. It would be interesting to get a description of boundary points of Hitchin components or spaces of maximal representations in terms of geometric objects on S that generalize measured laminations, and to relate the compactifications to degenerations of the geometric structures associated to Hitchin components and maximal representations in low dimensions (see Section 5). For convex real projective structures such an interpretation of boundary points in terms of a mixed structure consisting of a measured lamination and a HEX-metric has been announced by Cooper, Delp, D. Long, and Thistlethwaite [n.d.].

12 Arithmetics

Discrete Zariski dense subgroups of semisimple Lie groups have been studied for a long time. In recent years there has been a revived interest from number theory in discrete Zariski dense subgroups, which are contained in arithmetic lattices without being lattices themselves. Such groups have been coined thin groups Sarnak [2014]. Hitchin representations and maximal representations, and more generally Anosov representations, provide many examples of discrete Zariski dense subgroups of higher rank Lie groups which are not lattices. They are not necessarily contained in (arithmetic) lattices. However, there are many Hitchin representations and maximal representations that are even integral, i.e. up to conjugation contained in the integral points of the group G. This is a new feature that arises for higher Teichmüller spaces and is not present in classical Teichmüller space. The group $\mathrm{PSL}(2,\mathbf{Z})$ is a non-uniform lattice in $\mathrm{PSL}(2,\mathbf{R})$, consequently there is no discrete embedding of the fundamental group $\pi_1(S)$ of a closed oriented surface into $\mathrm{PSL}(2,\mathbf{R})$ which takes values in the integer points $\mathrm{PSL}(2,\mathbf{Z})$.

For $n = 3$ the first examples of integral Hitchin representations were given by Vinberg and Kac [1967], infinite families were constructed by Long, Reid, and Thistlethwaite with an explicit description using triangle groups.

Theorem 23. *D. D. Long, Reid, and Thistlethwaite [2011] Let $\Gamma = \langle a, b \mid a^3 = b^3 = (ab)^4 = 1\rangle$ be the (3,3,4) triangle group. There is an explicit polynomial map $\phi : \mathbf{R} \to$ $\mathrm{Hom}(\Gamma, \mathrm{PSL}(3,\mathbf{R}))$ whose image lies in the Hitchin component. For all $t \in \mathbf{Z}$, the image of $\phi(t)$ give a Zariski-dense subgroup of $\mathrm{PSL}(3,\mathbf{Z})$. The representations $\phi(t)$, $t \in Z$ are pairwise not conjugate in $\mathrm{PGL}(3,\mathbf{R})$.*

Since Γ contains subgroups of finite index which are isomorphic to the fundamental group $\pi_1(S)$ of a closed oriented surface S, Theorem 23 gives rise to infinitely many, non conjugate integral representations in $\mathcal{T}_H(\pi_1(S), \mathrm{PSL}(n,\mathbf{R}))$. The representations lie on different mapping class group orbits.

In unpublished work with Burger and Labourie we use bending to show the following

Theorem 24. *For $n \geq 5$ and odd there are infinitely many pairwise non conjugate integral representations in the Hitchin component $\mathcal{T}_H(\pi_1(S), \mathrm{PSL}(n,\mathbf{R}))$. These representations lie on different mapping class group orbits.*

Task 25. *Develop tools to count integral representations in $\mathcal{T}_H(\pi_1(S), \mathrm{PSL}(n,\mathbf{R}))$ modulo the action of the mapping class group. Investigate the counting functions and their asymptotics.*

A first step to start counting is to find appropriate height functions on $\mathfrak{T}_H(\pi_1(S), \mathrm{PSL}(n, \mathbf{R}))$ such that there are only finitely many integral representations of finite height. A height function, inspired by Thurston's asymmetric metric on Teichmüller space has been proposed by Burger and Labourie.

For more general constructions of surface subgroups in lattices of Lie groups, following the construction of Kahn and Markovic surface subgroups in three-manifold groups Kahn and Markovic [2012] we refer to work of Hamenstädt and Kahn [2017], and forthcoming work of Labourie, Kahn, and Mozes [2017]. Examples of integral maximal representations are constructed in Toledo [1987].

13 Complex Analytic Theory

In classical Teichmüller theory complex analytic methods and the theory of quasi-conformal mappings play a crucial role. These aspects are so far largely absent from higher Teichmüller theory. Dumas and Sanders started exploring the complex analytic aspects of discrete subgroups of complex Lie groups of higher rank in Dumas and Sanders [2017b]. They investigate in particular deformations of Hitchin representations and maximal representations in the complexifications of G, and establish important properties of the complex compact manifolds M that arise as quotients of domains of discontinuity of these representations (see Section 5). In a forthcoming paper Dumas and Sanders [2017a] the complex deformation theory of these representations will be investigated further.

14 Higher dimensional higher Teichmüller spaces

Fundamental groups of surfaces are not the only finitely generated groups for which there are special connected components in the representation variety $\mathrm{Hom}(\pi_1(S), G)/G$, which consist entirely of discrete and faithful representations. This phenomenon also arises for fundamental groups of higher dimensional manifolds, and even for more general finitely generated hyperbolic groups. The main examples are convex divisible representations, which have been introduced and studied by Benoist in a series of papers, starting with Benoist [2004]. They are generalizations of convex real projective structures on surfaces, and exist in any dimension.

Let N be a compact hyperbolic manifold of dimension n and $\pi_1(N)$ its fundamental group. A representation $\rho : \pi_1(N) \to \mathrm{PGL}(n+1, \mathbf{R})$ is convex divisible if there exists a strictly $\rho(\pi_1(N))$- invariant convex domain in $\mathbf{RP}^n$, on which $\rho(\pi_1(N))$ acts cocompactly.

Theorem 26. *Benoist [2005] The set of convex divisible representations is a union of connected components of* $\mathrm{Hom}(\pi_1(N), \mathrm{PGL}(n+1, \mathbf{R}))/\mathrm{PGL}(n+1, \mathbf{R})$ *consisting entirely of discrete and faithful representations.*

Barbot [2015] showed that a similar phenomenon arise for representations $\rho : \pi_1(N) \to \mathrm{SO}(2, n)$ that are Anti-de-Sitter Quasi-Fuchsian representation. In fact these are precisely Anosov representations of $\pi_1(N)$ into $\mathrm{SO}(2, n)$ with respect to the parabolic subgroup that stabilizes an isotropic line Barbot and Mérigot [2012].

Theorem 27 (Barbot [2015])**.** *The set of Quasi Fuchsian AdS representations in* $\mathrm{Hom}(\pi_1(N), \mathrm{SO}(2, n))/\mathrm{SO}(2, n)$ *is a connected component consisting entirely of discrete and faithful representations.*

In view of Definition 2 we might call these connected components of the representation variety $\mathrm{Hom}(\pi_1(N), G)/G$ containing only discrete and faithful representations higher dimensional higher Teichmüller spaces.

When N is of dimension two, the notion of Θ-positivity gives us a conjectural criterion why and when higher Teichmüller spaces exist. It would be interesting to find a unifying principle behind the existence of such special connected components in $\mathrm{Hom}(\pi_1(N), G)/G$.

Task 28. *Find the underlying principle for the existence of connected components of the representation variety* $\mathrm{Hom}(\pi_1(N), G)/G$ *which consist entirely of discrete and faithful representations.*

A first test case could be to analyze deformations of the representation $\rho_0 : \pi_1(N) \to \mathrm{SO}(1, n) \to \mathrm{SO}(k, n)$, or more generally deformations of representations $\rho_0 : \pi_1(N) \to \mathrm{SO}(1, n) \to G$, where the centralizer of $\mathrm{SO}(1, n)$ in G is compact and contained in the maximal compact subgroup of the Levi group of a parabolic subgroup containing the parabolic subgroup defined by $\mathrm{SO}(1, n)$. We expect all such deformations to be discrete and faithful.

K-THEORY AND ACTIONS ON EUCLIDEAN RETRACTS

Arthur Bartels

Abstract

This note surveys axiomatic results for the Farrell-Jones Conjecture in terms of actions on Euclidean retracts and applications of these to $\mathrm{GL}_n(\mathbb{Z})$, relative hyperbolic groups and mapping class groups.

Introduction

Motivated by surgery theory Hsiang [1984] made a number of influential conjectures about the K-theory of integral group rings $\mathbb{Z}[G]$ for torsion free groups G. These conjectures often have direct implications for the classification theory of manifolds of dimension ≥ 5. A good example is the following. An h-cobordism is a compact manifold W that has two boundary components M_0 and M_1 such that both inclusions $M_i \to W$ are homotopy equivalences. The Whitehead group $\mathrm{Wh}(G)$ is the quotient of $K_1(\mathbb{Z}[G])$ by the subgroup generated by the canonical units $\pm g$, $g \in G$. Associated to an h-cobordism is an invariant, the Whitehead torsion, in $\mathrm{Wh}(G)$, where G is the fundamental group of W. A consequence of the s-cobordism theorem is that for $\dim W \geq 6$, an h-cobordism W is trivial (i.e., isomorphic to a product $M_0 \times [0,1]$) iff its Whitehead torsion vanishes. Hsiang conjectured that for G torsion free $\mathrm{Wh}(G) = 0$, and thus that in many cases h-cobordisms are products.

The Borel conjecture asserts that closed aspherical manifolds are topologically rigid, i.e., that any homotopy equivalence to another closed manifold is homotopic to a homeomorphism. The last step in proofs of instances of this conjecture via surgery theory uses a vanishing result for $\mathrm{Wh}(G)$ to conclude that an h-cobordism is a product and that therefore the two boundary components are homeomorphic.

Farrell and Jones [1986] pioneered a method of using the geodesic flow on non-positively curved manifolds to study these conjectures. This created a beautiful connection between

The work has been supported by the SFB 878 in Münster.

Keywords: Farrell-Jones Conjecture, K- and L-theory of group rings.

K-theory and dynamics that led Farrell and Jones [1993b], among many other results, to a proof of the Borel Conjecture for closed Riemannian manifolds of non-positive curvature of dimension ≥ 5. Moreover, Farrell and Jones [1993a] formulated (and proved many instances of) a conjecture about the structure of the algebraic K-theory (and L-theory) of group rings, even in the presence of torsion in the group. Roughly, the Farrell-Jones Conjecture states that the main building blocks for the K-theory of $\mathbb{Z}[G]$ is the K-theory of $\mathbb{Z}[V]$ where V varies over the family of virtually cyclic subgroups of G. It implies a number of other conjectures, among them Hsiang's conjectures, the Borel Conjecture in dimension ≥ 5, the Novikov Conjecture on the homotopy invariant of higher signatures, Kaplansky's conjecture about idempotents in group rings, see Lück [2010] for a summary of these and other applications.

My goal in this note is twofold. The first goal is to explain a condition formulated in terms of existence of certain actions of G on Euclidean retracts that implies the Farrell-Jones Conjecture for G. This condition was developed in A. Bartels and Lück [2012c] and A. Bartels, Lück, and Reich [2008b] where the connection between K-theory and dynamics has been extended beyond the context of Riemannian manifolds to prove the Farrell-Jones Conjecture for hyperbolic and CAT(0)-groups. The second goal is to outline how this condition has been used in joint work with Lück, Reich and Rüping and with Bestvina to prove the Farrell-Jones Conjecture for $\mathrm{GL}_n(\mathbb{Z})$ and mapping class groups. A common difficulty for both families of groups is that their natural proper actions (on the associated symmetric space, respectively on Teichmüller space) is not cocompact. In both cases the solution depends on a good understanding of the action away from cocompact subsets and an induction on a complexity of the groups. As a preparation for mapping class groups we also discuss relatively hyperbolic groups.

The Farrell-Jones Conjecture has a prominent relative, the Baum-Connes Conjecture for topological K-theory of group C^*-algebras Baum and Connes [2000] and Baum, Connes, and Higson [1994]. The two conjectures are formally very similar, but methods of proofs are different. In particular, the conditions discussed in Section 2 are not known to imply the Baum-Conjecture. The classes of groups for which the two conjectures are known differ. For example, by work of Kammeyer, Lück, and Rüping [2016] all lattice in Lie groups satisfy the Farrell-Jones Conjecture; despite Lafforgue [2002] positive results for many property T groups, the Baum-Connes Conjecture is still a challenge for $\mathrm{SL}_3(\mathbb{Z})$. Wegner [2015] proved the Farrell-Jones Conjecture for all solvable groups, but the case of amenable (or just elementary amenable) groups is open; in contrast Higson and Kasparov [2001] proved the Baum-Connes Conjecture for all a-T-menable groups, a class of groups that contains all amenable groups. On the other hand, hyperbolic groups satisfy both conjectures. See Mineyev and Yu [2002] and Lafforgue [2012] for the Baum-Connes Conjecture and, as mentioned above, A. Bartels and Lück [2012c] and A. Bartels, Lück, and Reich [2008b] for the Farrell-Jones Conjecture. For a more comprehensive summary of the current status of the Farrell-Jones Conjecture the reader is directed to Lück [2017] and Reich and Varisco [2017].

Acknowledgments. It is a pleasure to thank my teachers, coauthors, and students for the many things they taught me.

1 The Formulation of the Farrell-Jones Conjecture

Classifying spaces for families. A family $\mathcal{F}$ of subgroups of a group G is a non-empty collection of subgroups that is closed under conjugation and subgroups. Examples are the family Fin of finite subgroups and the family VCyc of virtually cyclic subgroups (i.e., of subgroups containing a cyclic subgroup as a subgroup of finite index). For any family of subgroups of G there exists a G-CW-complex $E_{\mathcal{F}}G$ with the following property: if E is any other G-CW-complex such that all isotropy groups of E belong to $\mathcal{F}$, then there is a up to G-homotopy unique G-map $E \to E_{\mathcal{F}}G$. This space is not unique, but it is unique up to G-homotopy equivalence. Informally one may think about $E_{\mathcal{F}}G$ as a space that encodes the group G relative to all subgroups from $\mathcal{F}$. Often there are interesting geometric models for this space, in particular for $\mathcal{F} = \text{Fin}$. More information about this space can be found for example in Lück [2005]. An easy way to construct $E_{\mathcal{F}}G$ is as the infinite join $*_{i=0}^{\infty}(\coprod_{F\in\mathcal{F}} G/F)$. If $\mathcal{F}$ is closed under supergroups of finite index (i.e., if $F \in \mathcal{F}$ is a subgroup of finite index in F', then also $F' \in \mathcal{F}$), then the full simplicial complex on $\coprod_{F\in\mathcal{F}} G/F$ is also a model for $E_{\mathcal{F}}G$; we will denote this model later by $\Delta_{\mathcal{F}}(G)$.

The formulation of the conjecture. The original formulation of the Farrell and Jones [1993a] used homology with coefficients in stratified and twisted Ω-spectra. Here we use the equivalent Hambleton and Pedersen [2004] formulation developed by Davis and Lück [1998]. Given a ring R, Davis-Lück construct a homology theory $X \mapsto H_*^G(X;\mathbf{K}_R)$ for G-spaces with the property that $H_*^G(G/H;\mathbf{K}_R) \cong K_*(R[H])$.

Let $\mathcal{F}$ be a family of subgroups of the group G. Consider the projection map $E_{\mathcal{F}}G \to G/G$ to the one-point G-space G/G. It induces the $\mathcal{F}$-assembly map

$$\alpha_{\mathcal{F}}^G \colon H_*^G(E_{\mathcal{F}};\mathbf{K}_R) \to H_*^G(G/G;\mathbf{K}_R) \cong K_*(R[G]).$$

Conjecture 1.1 (Farrell-Jones Conjecture)**.** *For any group G and any ring R the assembly map* α_{VCyc}^G *is an isomorphism.*

This version of the conjecture has been stated in A. Bartels, Farrell, Jones, and Reich [2004]. The original formulation of Farrell and Jones [1993a] considered only the integral group ring $\mathbb{Z}[G]$. Moreover, Farrell and Jones wrote that they regard this and related conjectures *only as estimates which best fit the know data at this time*. However, the conjecture is still open and does still fit with all known data today.

Transitivity principle. Informally one can view the statement that the assembly map $\alpha^G_{\mathcal{F}}$ is an isomorphism for a group G and a ring R as the statement that $K_*(R[G])$ can be assembled from $K_*(R[F])$ for all $F \in \mathcal{F}$ (and group homology). If $\mathcal{V}$ is a family of subgroups of G that contains all subgroups from $\mathcal{F}$, then one can apply this slogan in two steps, for G relative to $\mathcal{V}$ and for each $V \in \mathcal{V}$ relative to the $F \in \mathcal{F}$ with $F \subseteq V$. The implementation of this is the following transitivity principle.

Theorem 1.2 (Farrell and Jones [1993a] and Lück and Reich [2005])**.** *For $V \in \mathcal{V}$ set $\mathcal{F}_V := \{F \mid F \in \mathcal{F}, F \subseteq V\}$. Assume that for all $V \in \mathcal{V}$ the assembly map $\alpha^V_{\mathcal{F}_V}$ is an isomorphism. Then $\alpha^G_{\mathcal{F}}$ is an isomorphism iff $\alpha^G_{\mathcal{V}}$ is an isomorphism.*

Twisted coefficients. Often it is beneficial to study more flexible generalizations of Conjecture 1.1. Such a generalization is the Fibred Isomorphism Conjecture of Farrell and Jones [1993a]. An alternative is the Farrell-Jones Conjecture with coefficients in additive categories A. Bartels and Reich [2007], here one allows additive categories with an action of a group G instead of just a ring as coefficients. This version of the conjecture applies in particular to twisted group rings. These generalizations of the Conjecture have better inheritance properties. Two of these inheritance property are stability under directed colimits of groups, and stability under taking subgroups. For a summary of the inheritance properties see Reich and Varisco [2017, Thm. 27(2)]. Often proofs of cases of the Farrell-Jones Conjecture use these inheritance properties in inductions or to reduce to special cases. We will mean by the statement that G satisfies the Farrell-Jones Conjecture relative to $\mathcal{F}$, that the assembly map $\alpha^G_{\mathcal{F}}$ is bijective for all additive categories $\mathcal{A}$ with G-action. However, this as a technical point that can be safely ignored for the purpose of this note.

Other theories. The Farrell-Jones Conjecture for K-theory discussed so far has an analog in L-theory, as it appears in surgery theory. For some of the applications mentioned before this is crucial. For example, the Borel Conjecture for a closed aspherical manifold M of dimensions ≥ 5 holds if the fundamental group of M satisfies both the K-and L-theoretic Farrell-Jones Conjecture. However, proofs of the Farrell-Jones Conjecture in K- and L-theory are by now very parallel. Recently, the techniques for the Farrell-Jones Conjecture in K- and L-theory have been extended to also cover Waldhausen's A-theory Enkelmann, Lück, Pieper, Ullmann, and Winges [2016], Kasprowski, Ullmann, Wegner, and Winges [2018], and Ullmann and Winges [2015]. In particular, the conditions we will discuss in Section 2 are now known to imply the Farrell-Jones Conjecture in all three theories.

2 Actions on compact spaces

Amenable actions and exact groups.

Definition 2.1 (Almost invariant maps)**.** Let X, E be G-spaces where E is equipped with a G-invariant metric d. We will say that a sequence of maps $f_n\colon X \to E$ is almost G-equivariant if for any $g \in G$

$$\sup_{x \in X} d(f_n(gx), gf_n(x)) \to 0 \quad \text{as} \quad n \to \infty.$$

For a discrete group G we equip the space $\operatorname{Prob}(G)$ of probability measures on G with the metric it inherits as subspace of $l^1(G)$. This metric generates the topology of pointwise convergence on $\operatorname{Prob}(G)$. We recall the following definition.

Definition 2.2. An action of a group G on a compact space X is said to be amenable if there exists a sequence of almost equivariant maps $X \to \operatorname{Prob}(G)$.

A group is amenable iff its action on the one point space is amenable. Groups that admit an amenable action on a compact Hausdorff space are said to be *exact* or *boundary amenable*. The class of exact groups contains all amenable groups, hyperbolic groups Adams [1994], and all linear groups Guentner, Higson, and Weinberger [2005]. Other prominent groups that are known to be exact are mapping class groups Hamenstädt [2009] and Kida [2008] and the group of outer automorphisms of free groups Bestvina, Guirardel, and Horbez [2017]. The Baum-Connes assembly map is split injective for all exact groups Higson [2000] and Yu [2000]. This implies the Novikov conjecture for exact groups. This is an analytic result for the Novikov conjecture, in the sense that it has no known proof that avoids the Baum-Connes Conjecture. There is no corresponding injectivity result for assembly maps in algebraic K-theory. For a survey about amenable actions and exact groups see Ozawa [2006].

Finite asymptotic dimension. Results for assembly maps in algebraic K-theory and L-theory often depend on a finite dimensional setting; the space of probability measures has to be replaced with a finite dimensional space. We write $\Delta(G)$ for the full simplicial complex with vertex set G and $\Delta^{(N)}(G)$ for its N-skeleton. The space $\Delta(G)$ can be viewed as the space of probability measures on G with finite support. We equip $\Delta(G)$ with the l^1-metric; this is the metric it inherits from $\operatorname{Prob}(G)$.

Definition 2.3 (N-amenable action)**.** We will say that an action of a group G on a compact space X is N-amenable if there exists a sequence of almost equivariant maps $X \to \Delta^{(N)}(G)$.

The natural action of a countable group G on its Stone-Čech compactification βG is N-amenable iff the asymptotic dimension of G is at most N Guentner, Willett, and Yu [2017, Thm. 6.5]. This condition (for any N) also implies exactness and therefore the Novikov conjecture Higson and Roe [2000]. For groups G of finite asymptotic dimension for which in addition the classifying space BG can be realized as a finite CW-complex, there is an alternative argument for the Novikov Conjecture Yu [1998] that has been translated to integral injectivity results for assembly maps in algebraic K-theory and L-theory A. C. Bartels [2003] and Carlsson and Goldfarb [2004]. These injectivity results have seen far reaching generalizations to groups of finite decomposition complexity Guentner, Tessera, and Yu [2012], Kasprowski [2015], and Ramras, Tessera, and Yu [2014].

***N*-$\mathfrak{F}$-amenable actions.** Constructions of transfer maps in algebraic K-theory and L-theory often depend on actions on spaces that are much nicer than βG. A good class of spaces to use for the Farrell-Jones Conjecture are Euclidean retracts, i.e., compact spaces that can be embedded as a retract in some $\mathbb{R}^n$. Brouwer's fixed point theorem implies that for an action of a group on an Euclidean retract any cyclic subgroup will have a fixed point. It is not difficult to check that this obstructs the existence of almost equivariant maps to $\Delta^{(N)}$ (assuming G contains an element of infinite order). Let $\mathfrak{F}$ be a family of subgroups of G that is closed under taking supergroups of finite index. Let $S := \coprod_{F \in \mathfrak{F}} G/F$ be the set of all left cosets to members of $\mathfrak{F}$. Let $\Delta_{\mathfrak{F}}(G)$ be the full simplicial complex on S and $\Delta_{\mathfrak{F}}^{(N)}(G)$ be its N-skeleton. We equip $\Delta_{\mathfrak{F}}(G)$ with the l^1-metric.

Definition 2.4 (N-$\mathfrak{F}$-amenable action)**.** We will say that an action of G on a compact space X is N-$\mathfrak{F}$-amenable if there exists a sequence of almost equivariant maps $X \to \Delta_{\mathfrak{F}}^{(N)}(G)$. If an action is N-$\mathfrak{F}$-amenable for some $N \in \mathbb{N}$, then we say that it is finitely $\mathfrak{F}$-amenable.

Remark 2.5. Let X be a G-CW-complex with isotropy groups in $\mathfrak{F}$ and of dimension $\leq N$. As $\Delta_{\mathfrak{F}}(G)$ is a model for $E_{\mathfrak{F}}G$ we obtain a cellular G-map $f : X \to \Delta_{\mathfrak{F}}^{(N)}(G)$; this map is also continuous for the l^1-metric. In particular, the constant sequence $f_n \equiv f$ is almost equivariant. Therefore one can view N-$\mathfrak{F}$-amenability for G-spaces as a relaxation of the property of being a G-CW-complex with isotropy in $\mathfrak{F}$ and of dimension $\leq N$.

This relaxation is necessary to obtain compact examples and reasonably small $\mathfrak{F}$: If a G-CW-complex is compact, then it has only finitely many cells. In particular, for each cell the isotropy group has finite index in G, so $\mathfrak{F}$ would have to contain subgroups of finite index in G.

Theorem 2.6 (A. Bartels and Lück [2012c] and A. Bartels, Lück, and Reich [2008b])**.** *Suppose that G admits a finitely $\mathfrak{F}$-amenable action on a Euclidean retract. Then G satisfies the Farrell-Jones Conjecture relative to $\mathfrak{F}$.*

Remark 2.7. The proof of Theorem 2.6 depends on methods from controlled topology/algebra that have a long history. An introduction to controlled algebra is given in Pedersen [2000]; an introduction to the proof of Theorem 2.6 can be found in A. Bartels [2016]. Here we only sketch a very special case, where these methods are not needed.

Assume that the Euclidean retract is a G-CW-complex X. As pointed out in Remark 2.5 this forces $\mathfrak{F}$ to contain subgroups of finite index in G. As X is contractible, the cellular chain complex of X provides a finite resolution C_* over $\mathbb{Z}[G]$ of the trivial G-module $\mathbb{Z}$. Note that in each degree $C_k = \bigoplus \mathbb{Z}[G/F_i]$ is a finite sum of permutation modules with $F_i \in \mathfrak{F}$ and F_i of finite index in G. For a finitely generated projective $R[G]$-module P we obtain a finite resolution $C_* \otimes_{\mathbb{Z}} P$ of P. Each module in the resolution is a finite sum of modules of the form $\mathbb{Z}[G/F] \otimes_{\mathbb{Z}} P$ with $F \in \mathfrak{F}$ and of finite index in G. Here $\mathbb{Z}[G/F] \otimes_{\mathbb{Z}} P$ is equipped with the diagonal G-action and can be identified with the $R[G]$-module obtained by first restricting P to an $R[F]$-module and then inducing back up from $R[F]$ to $R[G]$. In particular, $\big[\mathbb{Z}[G/F] \otimes_{\mathbb{Z}} P\big] \in K_0(R[G])$ is in the image of the assembly map relative to the family $\mathfrak{F}$. It follows that $[P] = \sum_k (-1)^k [C_k \otimes_{\mathbb{Z}} P]$ is also in the image. Therefore the assembly map $H_0(E_{\mathfrak{F}} G; \mathbf{K}_R) \to K_0(R[G])$ is surjective. (This argument did not use that $\mathfrak{F}$ is closed under supergroups of finite index.)

Example 2.8. Let G be a hyperbolic group. Its Rips complex can be compactified to a Euclidean retract Bestvina and Mess [1991]. The natural action of G on this compactification is finitely VCyc-amenable A. Bartels, Lück, and Reich [2008a].

To obtain further examples of finitely $\mathfrak{F}$-amenable actions on Euclidean retracts, it is helpful to replace VCyc with a larger family of subgroups $\mathfrak{F}$. Groups that act acylindrically hyperbolic on a tree admit finitely $\mathfrak{F}$-amenable actions on Euclidean retracts where $\mathfrak{F}$ is the family of subgroups that is generated by the virtually cyclic subgroups and the isotropy groups for the original action on the tree Knopf [2017]. Relative hyperbolic groups and mapping class groups are discussed in Section 4.

Remark 2.9. A natural question is which groups admit finitely VCyc-amenable actions on Euclidean retracts. A necessary condition for an action to be finitely VCyc-amenable is that all isotropy groups of the action are virtually cyclic. Therefore, a related question is which groups admit actions on Euclidean retracts such that all isotropy groups are virtually cyclic. The only groups admitting such actions that I am aware of are hyperbolic groups. In fact, I do not even know whether or not the group $\mathbb{Z}^2$ admits an action on a Euclidean retract (or on a disk) such that all isotropy groups are virtually cyclic. There are actions of $\mathbb{Z}^2$ on disks without a global fixed point. This is a consequence of Oliver's analysis of actions of finite groups on disks Oliver [1975]. On the other hand, there are finitely generated groups for which all actions on Euclidean retracts have a global fixed point Arzhantseva, Bridson, Januszkiewicz, Leary, Minasyan, and Świ tkowski [2009].

Homotopy actions. There is a generalization of Theorem 2.6 using homotopy actions. In order to be applicable to higher K-theory these actions need to be homotopy coherent. The passage from strict actions to homotopy actions is already visible in the work of Farrell-Jones where it corresponds to the passage from the asymptotic transfer used for negatively curved manifolds Farrell and Jones [1986] to the focal transfer used for non-positively curved manifolds Farrell and Jones [1993b].

Definition 2.10 (Vogt [1973] and Wegner [2012])**.** A *homotopy coherent action* of a group G on a space X is a continuous map

$$\Gamma\colon \coprod_{j=0}^{\infty}((G\times[0,1])^j\times G\times X) \to X$$

such that

$$\Gamma(g_k,t_k,\dots,t_1,g_0,x) = \begin{cases} \Gamma(g_k,\dots,g_j,\Gamma(g_{j-1},\dots,x)) & t_j=0 \\ \Gamma(g_k,\dots,g_jg_{j-1},\dots,x) & t_j=1 \\ \Gamma(g_k,\dots,t_2,g_1,x) & g_0=e, 0<k \\ \Gamma(g_k,\dots,t_{j+1}t_j,\dots,g_0,x) & g_j=e, 1\le j<k \\ \Gamma(g_{k-1},\dots,t_1,g_0,x) & g_k=e, 0<k \\ x & g_0=e, k=0 \end{cases}$$

Here $\Gamma(g,-)\colon X \to X$ should be thought of the action of g on X, the map $\Gamma(g,-,h,-)\colon [0,1]\times X \to X$ is a homotopy from $\Gamma(g,-)\circ\Gamma(h,-)$ to $\Gamma(gh,-)$ and the remaining data in Γ encodes higher coherences.

In order to obtain sequences of almost equivariant maps for homotopy actions it is useful to also allow the homotopy action to vary.

Definition 2.11 (N-$\mathfrak{F}$-amenability for homotopy coherent actions)**.** A sequence of homotopy coherent actions (Γ_n, X_n) of a group G is said to be N-$\mathfrak{F}$-amenable if there exists a sequence of continuous maps $f_n\colon X_n \to \Delta^{(N)}_{\mathfrak{F}}(G)$ such that for all k and all $g_k,\dots,g_0 \in G$

$$\sup_{x\in X, t_k,\dots,t_1\in[0,1]} d(f_n(\Gamma(g_k,t_k,\dots,t_1,g_0,x), g_k\cdots g_0 f_n(x)) \to 0 \quad \text{as} \quad n\to\infty.$$

Theorem 2.12 (A. Bartels and Lück [2012c] and Wegner [2012])**.** *Suppose that G admits a sequence of homotopy coherent actions on Euclidean retracts of uniformly bounded dimension that is finitely $\mathfrak{F}$-amenable. Then G satisfies the Farrell-Jones Conjecture relative to $\mathfrak{F}$.*

Remark 2.13. Groups satisfying the assumptions of Theorem 2.12 are said to be homotopy transfer reducible in Enkelmann, Lück, Pieper, Ullmann, and Winges [2016]. The original formulations of Theorems 2.6 and 2.12 were not in terms of almost equivariant maps, but in terms of certain open covers of $G \times X$.

We recall here the formulation used for actions. (The formulation for homotopy actions is more cumbersome.) A subset U of a G-space is said to be an $\mathfrak{F}$-subset if there is $F \in \mathfrak{F}$ such that $gU = U$ for all $g \in F$ and $U \cap gU = \varnothing$ for all $g \in G \setminus F$. A collection $\mathfrak{U}$ of subsets is said to be G-invariant if $gU \in \mathfrak{U}$ for all $g \in G$, $U \in \mathfrak{U}$. If no point is contained in more than $N+1$ members of $\mathfrak{U}$, then $\mathfrak{U}$ is said to be of order (or dimension) $\leq N$. A G-invariant cover by open $\mathfrak{F}$-subsets is said to be an $\mathfrak{F}$-cover.

For a compact G-space X we equip now $G \times X$ with the diagonal G-action. For $S \subseteq G$ finite an $\mathfrak{F}$-cover of $G \times X$ is said to be S-wide (in the G-direction) if

$$\forall\, (g, x) \in G \times X \;\; \exists\, U \in \mathfrak{U} \;\text{ such that }\; gS \times \{x\} \subseteq U.$$

Then the action of G on X is N-$\mathfrak{F}$-amenable iff for any $S \subset G$ finite there exists an S-wide $\mathfrak{F}$-cover $\mathfrak{U}$ for $G \times X$ of dimension at most N Guentner, Willett, and Yu [2017, Prop. 4.5]. A translation from covers to maps is also used in A. Bartels and Lück [2012c], A. Bartels, Lück, and Reich [2008b], and Wegner [2012]. From the point of view of covers (and because of the connection to the asymptotic dimension) it is natural to think of the N in N-$\mathfrak{F}$-amenable as a kind of dimension for the action of G on X, see Guentner, Willett, and Yu [2017] and Sawicki [2017].

A further difference between the formulations used above and in the references given is that the conditions on the topology of X are formulated differently, but certainly Euclidean retracts satisfy the condition from A. Bartels and Lück [2012c].

Example 2.14. Theorem 2.12 applies to CAT(0)-groups where $\mathfrak{F} = \mathrm{VCyc}$ is the family of virtually cyclic subgroups A. Bartels and Lück [2012b] and Wegner [2012]. An application of Theorem 2.12 to $\mathrm{GL}_n(\mathbb{Z})$ will be discussed in Section 4.

Remark 2.15 (The Farrell-Hsiang method). There are interesting groups for which one can deduce the Farrell-Jones Conjecture using Theorems 2.6 (or 2.12) and inheritance properties. However, it is not clear that these methods can account for all that is currently known. A third method, going back to work of Farrell and Hsiang [1978], combines induction results for finite groups Dress [1975] and Swan [1960] with controlled topology/algebra. An axiomatization of this method is given in A. Bartels and Lück [2012a]. In important part of the proof of the Farrell-Jones Conjecture for solvable groups Wegner [2015] is a combination of this method with Theorem 2.12.

Remark 2.16 (Trace methods). The K-theory Novikov Conjecture concerns injectivity of assembly maps in algebraic K-theory, i.e., lower bounds for the algebraic K-theory of group rings. For the integral group ring of groups, that are only required to satisfy a mild homological finiteness assumption, trace methods have been used by Bökstedt, Hsiang, and Madsen [1993] and Lück, Reich, Rognes, and Varisco [2017] to obtain rational injectivity results. The latter result in particular yields interesting lower bounds for Whitehead groups. For the group ring over the ring of Schatten class operators Yu [2017] proved rational injectivity of the Farrell-Jones assembly map for all groups. This is the only result I am aware of for the Farrell-Jones Conjecture that applies to all groups!

3 Flow spaces

The construction of almost equivariant maps often uses the dynamic of a flow associated to the situation.

Definition 3.1. A *flow space* for a group G is a metric space FS equipped with a flow Φ and an isometric G-action where the flow and the G-action commute. For $\alpha > 0$, $\delta > 0$, $c, c' \in FS$ we write

$$d_{fol}(c, c') < (\alpha, \delta)$$

to mean that there is $t \in [-\alpha, \alpha]$ such that $d(\Phi_t(c), c') < \delta$.

Example 3.2. Let G be the fundamental group of a Riemannian manifold M. Then the sphere bundle $S\tilde{M}$ equipped with the geodesic flow is a flow space for the fundamental group of M. For manifolds of negative or non-positive curvature this flow space is at the heart of the connection between K-theory and dynamics used to great effect by Farrell-Jones.

This example has generalizations to hyperbolic groups and CAT(0)-groups. For hyperbolic groups Mineyev's symmetric join is a flow space Mineyev [2005]. Alternatively, it is possible to use a coarse flow space for hyperbolic groups, see Remark 3.7 below. For groups acting on a CAT(0)-space a flow space has been constructed in A. Bartels and Lück [2012b]. It consists of all parametrized geodesics in the CAT(0)-space (technically all generalized geodesics) and the flow acts by shifting the parametrization.

Almost equivariant maps often arise as compositions

$$X \xrightarrow{\varphi} FS \xrightarrow{\psi} \Delta^{(N)}_{\mathfrak{F}}(G),$$

where the first map is almost equivariant in an (α, δ)-sense, and the second map is G-equivariant and contracts (α, δ)-distances to ε-distances. The following Lemma summarizes this strategy.

Lemma 3.3. *Let X be a G-space, where G is a countable group. Let $N \in \mathbb{N}$. Assume that there exists a flow space FS satisfying the following two conditions.*

(A) *For any finite subset S of G there is $\alpha > 0$ such that for any $\delta > 0$ there is a continuous map $\varphi\colon X \to FS$ such that for $x \in X$, $g \in S$ we have*

$$d_{fol}(\varphi(gx), g\varphi(x)) < (\alpha, \delta).$$

(B) *For any $\alpha > 0$, $\varepsilon > 0$ there are $\delta > 0$ and a continuous G-map $\psi : FS \to \Delta^{(N)}_{\mathfrak{F}}(G)$ such that*

$$d_{fol}(c, c') < (\alpha, \delta) \quad \Longrightarrow \quad d(\psi(c), \psi(c')) < \varepsilon$$

holds for all $c, c' \in FS$.

Then the action of G on X is N-$\mathfrak{F}$-amenable.

Proof. Let $S \subset G$ be finite and $\varepsilon > 0$. We need to construct a map $f : X \to \Delta^{(N)}_{\mathfrak{F}}(G)$ for which $d(f(gx), gf(x)) < \varepsilon$ for all $x \in X$, $g \in S$. Let α be as in (A) with respect to S. Choose now $\delta > 0$ and a G-map $\psi : FS \to \Delta^{(N)}_{\mathfrak{F}}(G)$ as in (B). Next choose $\varphi\colon X \to FS$ as in (A) with respect to this $\delta > 0$. Then $f := \psi \circ \varphi$ has the required property. □

Remark 3.4 (On the constructions of φ). Maps $\varphi\colon X \to FS$ as in condition (A) in Lemma 3.3 can in negatively or non-positively curved situations often be constructed using dynamic properties of the flow. We briefly illustrate this in a case already considered by Farrell and Jones.

Let G be the fundamental group of a closed Riemannian manifold of strict negative sectional curvature M. Let $\tilde{M}$ be its universal cover and S_∞ the sphere at infinity for $\tilde{M}$. The action of G on $\tilde{M}$ extends to S_∞. For each $x \in \tilde{M}$ there is a canonical identification between the unit tangent vectors at x and S_∞: every unit tangent vector v at x determines a geodesic ray c starting in x, the corresponding point $\xi \in S_\infty$ is $c(\infty)$. One say that v points to ξ. The geodesic flow Φ_t on $S\tilde{M}$ has the following property. Suppose that v and v' are unit tangent vectors at x and x' pointing to the same point in S_∞. Then $d_{fol}(\Phi_t(v), \Phi_t(v')) < (\alpha, \delta_t)$ where α depends only on $d(x, x_0)$ and $\delta_t \to 0$ uniformly in v, v' (still depending on $d(x, x_0)$). This statement uses strict negative curvature. (For closed manifolds of non-positive sectional curvature the vector v' has to be chosen more carefully depending on v and t; this necessitates the use of the focal transfer Farrell and Jones [1993b] respectively the use of homotopy coherent actions.)

This contracting property of the geodesic flow can be translated into the construction of maps as in (A). Fix a point $x_0 \in \tilde{M}$. Define $\varphi_0\colon S_\infty \to S\tilde{M}$ by sending ξ to the unit tangent vector at x_0 pointing to ξ. For $t \geq 0$ define $\varphi_t(\xi) := \Phi_t(\varphi_0(\xi))$. Using the contracting property of the geodesic flow is not difficult to check that for any $g \in G$ there is $\alpha > 0$ (roughly $\alpha = d(gx_0, x_0)$) such that for any $\delta > 0$ there is t_0 satisfying

$$\forall t \geq t_0,\ \forall \xi \in S_\infty \ \ d_{fol}(\varphi_t(g\xi), g\varphi_t(\xi)) < (\alpha, \delta).$$

Remark 3.5. Of course the space S_∞ used in Remark 3.4 is not contractible and therefore not a Euclidean retract. But the compactification $\tilde{M} \cup S_\infty$ of $\tilde{M}$ is a disk, in particular a Euclidean retract. As $\tilde{M}$ has the homotopy type of a free G-CW-complex, there is even a G-equivariant map $\tilde{M} \to \Delta^{(d)}(G)$ where d is the dimension of M. In particular, the action of G on $\tilde{M}$ is d-amenable. It is not difficult to combine the two statements to deduce that the action of G on $\tilde{M} \cup S_\infty$ is finitely $\mathfrak{F}$-amenable. This is best done via the translation to open covers of $G \times (\tilde{M} \cup S_\infty)$ discussed in Remark 2.13, see for example Sawicki [2017].

An important point in the formulation of condition (B) is the presence of $\delta > 0$ uniform over *FS*. If the action of G on *FS* is cocompact, then a version of the Lebesgue Lemma guarantees the existence of some uniform $\delta > 0$, i.e., it suffices to construct $\psi : FS \to \Delta_{\mathfrak{F}}^{(N)}(G)$ such that $d(\psi(c), \psi(\Phi_t(c)) < \varepsilon$ for all $t \in [-\alpha, \alpha]$, $c \in FS$.

Remark 3.6 (Long thin covers of *FS*). Maps φ as in condition (B) of Lemma 3.3 are best constructed as maps associated to long thin covers of the flow space. These long thin covers are an alternative to the long thin cell structures employed by Farrell and Jones [1986].

An open cover $\mathfrak{U}$ of *FS* is said to be an α-long cover for *FS* if for each $c \in FS$ there is $U \in \mathfrak{U}$ such that

$$\Phi_{[-\alpha,\alpha]}(c) \subseteq U.$$

It is said to be α-long and δ-thick if for each $c \in FS$ there is $U \in \mathfrak{U}$ containing the δ-neighborhood of $\Phi_{[-\alpha,\alpha]}(c)$. The construction of maps $FS \to \Delta_{\mathfrak{F}}^{(N)}(G)$ as in condition (B) of Lemma 3.3 amounts to finding for given α an $\mathfrak{F}$-cover $\mathfrak{U}$ of *FS* of dimension at most N that is α-long and δ-thick for some $\delta > 0$ (depending on α). For cocompact flow spaces such covers can be constructed in relatively great generality A. Bartels, Lück, and Reich [2008a] and Kasprowski and Rüping [2017]. Cocompactness is used to guarantee δ-thickness. For not cocompact flow spaces on can still find α-long covers, but without a uniform thickness, they do not provide the maps needed in (B).

Remark 3.7 (Coarse flow space). We outline the construction of the coarse flow space from A. Bartels [2017] for a hyperbolic group G. Let Γ be a Cayley graph for G. The vertex set of Γ is G. Adding the Gromov boundary to G we obtain the compact space $\overline{G} = G \cup \partial G$. Assume that Γ is δ-hyperbolic. The *coarse flow space CF* consists of all triples (ξ_-, v, ξ_+) with $\xi_\pm \in \overline{G}$ and $v \in G$ such that there is some geodesic from ξ_- to ξ_+ in Γ that passes v within distance $\leq \delta$. Informally, v coarsely belongs to a geodesic from ξ_- to ξ_+. The coarse flow space is the disjoint union of its coarse flow lines $CF_{\xi_-,\xi_+} := \{\xi_-\} \times \Gamma \times \{\xi_+\} \cap CF$. The coarse flow lines are are quasi-isometric to $\mathbb{R}$ (with uniform constants depending on δ).

There are versions of the long thin covers from Remark 3.6 for CF. For $\alpha > 0$ these are VCyc-covers $\mathcal{U}$ of bounded dimension that are α-long in the direction of the coarse flow lines: for $(\xi_-, v, \xi_+) \in CF$ there is $U \in \mathcal{U}$ such that $\{\xi_-\} \times B_\alpha(v) \times \{\xi_+\} \cap CF_{\xi_-,\xi_+} \subseteq U$.

There is also a coarse version of the map φ_t from Remark 3.4. To define it, fix a base point $v_0 \in G$. For $t \in \mathbb{N}$, φ_t sends $\xi \in \partial G$ to (v_0, v, ξ) where $d(v_0, v) = t$ and v belongs to a geodesic from v_0 to ξ. It is convenient to extend φ_t to a map $G \times \partial G \to CF$, with $\varphi_t(g, \xi) := (g v_0, v, \xi)$ where now $d(v_0, v) = t$ and v belongs to a geodesic from $g v_0$ to ξ. Of course v is only coarsely well defined. Nevertheless, φ_t can be used to pull long thin covers for CF back to $G \times \partial G$. For $S \subseteq G$ finite there are then $t > 0$ and $\alpha > 0$ such that this yields S-wide covers for $G \times \partial G$. The proof of this last statement uses a compactness argument and it is important at this point that Γ is locally finite and that G acts cocompactly on Γ.

4 Covers at infinity

The Farrell-Jones Conjecture for $\mathrm{GL}_n(\mathbb{Z})$. The group $\mathrm{GL}_n(\mathbb{Z})$ is not a CAT(0)-group, but it has a proper isometric action on a CAT(0)-space, the symmetric space $X := GL_n(\mathbb{R})/O(n)$. Fix a base point $x_0 \in X$. For $R \geq 0$ let B_R be the closed ball of radius R around x_0. This ball is a retract of X (via the radial projection along geodesics to x_0) and inherits a homotopy coherent action Γ_R from the action of $\mathrm{GL}_n(\mathbb{Z})$ on X. Let $\mathcal{F}$ be the family of subgroups generated by the virtually cyclic and the proper parabolic subgroups of $\mathrm{GL}_n(\mathbb{Z})$. The key step in the proof of the Farrell-Jones Conjecture for $\mathrm{GL}_n(\mathbb{Z})$ in A. Bartels, Lück, Reich, and Rüping [2014] is, in the language of Section 2, the following.

Theorem 4.1. *The sequence of homotopy coherent actions (B_R, Γ_R) is finitely $\mathcal{F}$-amenable.*

In particular $\mathrm{GL}_n(\mathbb{Z})$ satisfies the Farrell-Jones Conjecture relative to $\mathcal{F}$ by Theorem 2.12. Using the transitivity principle 1.2 the Farrell-Jones Conjecture for $\mathrm{GL}_n(\mathbb{Z})$ can then be proven by induction on n. The induction step uses inheritance properties of the Conjecture and that virtually poly-cyclic groups satisfy the Conjecture.

The verification of Theorem 4.1 follows the general strategy of Lemma 3.3 (in a variant for homotopy coherent actions). The additional difficulty in verifying assumption (B) is that, as the action of $\mathrm{GL}_n(\mathbb{Z})$ on the symmetric space is not cocompact, the action on the flow space is not cocompact either. The general results reviewed in Section 3 can still be used to construct for any $\alpha > 0$ an α-long cover $\mathcal{U}$ for the flow space. However it is not clear that the resulting cover is δ-thick, for a $\delta > 0$ uniformly over FS. The remedy for this short-coming is a second collection of open subsets of FS. Its construction starts with an $\mathcal{F}$-cover for X at ∞, meaning here, away from cocompact subsets. Points in the symmetric space can be viewed as inner products on $\mathbb{R}^n$ and moving towards ∞ corresponds to degeneration of inner products along direct summands $W \subset \mathbb{Z}^n \subset \mathbb{R}^n$. This in turn can be used to define horoballs in the symmetric space, one for each W, forming the desired cover Grayson [1984]. For each W the corresponding horoball is invariant for the parabolic subgroup $\{g \in GL_n(\mathbb{Z}) \mid gW = W\}$, more precisely, the horoballs are $\mathcal{F}$-subsets, but not VCyc-subsets. The precise properties of the cover at ∞ are as follows.

Lemma 4.2 (A. Bartels, Lück, Reich, and Rüping [2014] and Grayson [1984])**.** *For any $\alpha > 0$ there exists a collection $\mathcal{U}_\infty$ of open $\mathcal{F}$-subsets of X of order $\leq n$ that is of Lebesgue number $\geq \alpha$ at ∞, i.e., there is $K \subset X$ compact such that for any $x \in X \setminus \mathrm{GL}_n(\mathbb{Z}) \cdot K$ there is $U \in \mathcal{U}_\infty$ containing the α-ball $B_\alpha(x)$ in X around x.*

This cover can be pulled back to the flow space where it provides a cover at ∞ for the flow space that is both (roughly) α-long and α-thick at ∞. Then one is left with a cocompact subset of the flow space where the cover $\mathcal{U}$ constructed first is α-long and δ-thick.

This argument for $GL_n(\mathbb{Z})$ has been generalized to $GL_n(F(t))$ for finite fields F, and $GL_n(\mathbb{Z}[S^{-1}])$, for S a finite set of primes Rüping [2016] using suitable generalizations of the above covers at ∞. In this case the parabolic subgroups are slightly bigger, in particular the induction step (on n) here uses that the Farrell-Jones Conjecture holds for all solvable groups. Using inheritance properties and building on these results the Farrell-Jones Conjecture has been verified for all subgroups of $\mathrm{GL}_n(\mathbb{Q})$ Rüping [ibid.] and all lattices in virtually connected Lie groups Kammeyer, Lück, and Rüping [2016].

Relatively hyperbolic groups. We use Bowditch's characterization of relatively hyperbolic groups Bowditch [2012]. A graph is *fine* if there are only finitely many embedded loops of a given length containing a given edge. Let $\mathcal{P}$ be a collection of subgroups of the countable group G. Then G is hyperbolic relative to $\mathcal{P}$ if G admits a cocompact action on a fine hyperbolic graph Γ such that all edge stabilizers are finite and all vertex stabilizers belong to $\mathcal{P}$. The subgroups from $\mathcal{P}$ are said to be peripheral or parabolic. The requirement that Γ is fine encodes Farb's Bounded Coset Penetration property Farb [1998]. Bowditch assigned a compact boundary Δ to G as follows. As a set Δ is the union of the Gromov boundary $\partial\Gamma$ with the set of all vertices of infinite valency in Γ. The topology is the observer topology; a sequence x_n converges in this topology to x if given any finite set S of vertices (not including x), for almost all n there is a geodesic from x_n to x that misses S. (For general hyperbolic graphs this topology is not Hausdorff, but for fine hyperbolic graphs it is.)

The main result from A. Bartels [2017] is that if G is hyperbolic relative to $\mathcal{P}$, then G satisfies the Farrell-Jones Conjecture relative to the family of subgroups $\mathcal{F}$ generated by VCyc and $\mathcal{P}$ ($\mathcal{P}$ needs to be closed under index two supergroups here for this to include the L-theoretic version of the Farrell-Jones Conjecture). This result is obtained as an application of Theorem 2.6. The key step is the following.

Theorem 4.3 (A. Bartels [ibid.]). *The action of G on Δ is finitely $\mathfrak{F}$-amenable.*

This is a direct consequence of Propositions 4.4 and 4.5 below, using the characterization of N-$\mathfrak{F}$-amenability from Remark 2.13 by the existence of S-wide covers of $G \times \Delta$.

To outline the construction of these covers and to prepare for the mapping class group we introduce some notation. Pick a G-invariant proper metric on the set E of edges of Γ; this is possible as G and E are countable and the action of G on E has finite stabilizers. For each vertex v of Γ with infinite valency let E_v be the set of edges incident to v. Write d_v for the restriction of the metric to E_v. For $\xi \in \Delta$, $\xi \neq v$ we define its projection $\pi_v(\xi)$ to E_v as the set of all edges of Γ that are appear as initial edges of geodesics from v to ξ. This is a finite subset of E_v (this depends again of fineness of Γ). Fix a vertex v_0 of finite valence as a base point. For $g \in G$, $\xi \in \Delta$ define their *projection distance* at v by

$$d_v^{\pi}(g,\xi) := d_v(\pi_v(g v_0), \pi_v(\xi)).$$

For $\xi = v$, set $d_v^{\pi}(g, v) := \infty$. (For relative hyperbolic groups a related quantity is often called an *angle*; the terminology here is chosen to align better with the case of the mapping class group.) If we vary g (in a finite set) and ξ (in an open neighborhood) then for fixed v the projection distance $d_v^{\pi}(g,\xi)$ varies by a bounded amount. Useful is the following attraction property for projection distances: there is Θ_0 such that if $d_v^{\pi}(g,\xi) \geq \Theta_0$, then any geodesic from $g v_0$ to ξ in Γ passes through v. Conversely, if some geodesic from $g v_0$ to ξ misses v, then $d_v^{\pi}(g,\xi) < \Theta_0'$ for some uniform Θ_0'.

Projection distances are used to control the failure of Γ to be locally finite. In particular, provided all projection distances are bounded by a constant Θ, a variation of the argument for hyperbolic groups (using a coarse flow space), can be adapted to provide S-long covers for the Θ-small part of $G \times \Delta$. The following is a precise statement.

Proposition 4.4. *There is N (depending only on G and Δ) such that for any $\Theta > 0$ and any $S \subseteq G$ finite there exists a collection $\mathcal{U}$ of open* VCyc*-subsets of $G \times \Delta$ that is S-wide on the Θ-small part, i.e., if $(g,\xi) \in G \times \Delta$ satisfies $d_v^{\pi}(g,\xi) \leq \Theta$ for all vertices v, then there is $U \in \mathcal{U}$ with $gS \times \{\xi\} \subseteq U$.*

To deal with large projection distances an explicit construction can be used (similar to the case of $\mathrm{GL}_n(\mathbb{Z})$). For $(g,\xi) \in G \times \Delta$ let

$$V_{\Theta}(g,\xi) := \{v \mid d_v^{\pi}(g,\xi) \geq \Theta\}.$$

As a consequence of the attraction property, for sufficiently large Θ, the set $V_{\Theta}(g,\xi)$ consists of vertices that belong to any geodesic from $g v_0$ to ξ. In particular, it can be linearly ordered by distance from $g v_0$.

For a fixed vertex v and $\Theta > 0$ define $W(v,\Theta) \subset G \times \Delta$ as the (interior of the) set of all pairs (g,ξ) for which v is minimal in $V_{\Theta}(g,\xi)$, i.e., v is the vertex closest to $g v_0$

for which $d^\pi_v(g,\xi) \geq \Theta$. Then $\mathcal{W}(\Theta) := \{W(v,\Theta) \mid v \in V\}$ is a collection of pairwise disjoint open $\mathcal{P}$-subsets of $G\times\Delta$.

Proposition 4.5. *Let $S \subset G$ be finite. Then there are $\theta'' \gg \theta' \gg \theta \gg 0$ such that $\mathcal{W}(\theta) \cup \mathcal{W}(\theta')$ is a G-invariant collection of open $\mathcal{P}$-subsets of order ≤ 1 that is S-long on the θ''-large part of $G\times\Delta$: if $d^\pi_v(g,\xi) \geq \theta''$ for some vertex v, then there is $W \in \mathcal{W}(\theta) \cup \mathcal{W}(\theta')$ such that $gS\times\{\xi\} \subset W$.*

A difficulty in working with the $\mathcal{W}(v,\Theta)$ is that it is for fixed Θ not possible to control exactly how $V_\Theta(g,\xi)$ varies with g and ξ. In particular whether or not a vertex v is minimal in $V_\Theta(g,\xi)$ can change under small variation in g or ξ. A consequence of the attraction property that is useful for the proof of Proposition 4.5 is the following: suppose there are vertices v_0 and v_1 with $d^\pi_{v_i}(g,\xi) > \Theta' \gg \Theta$, then the segment between v_0 and v_1 in the linear order of $V_\Theta(g,\xi)$ is unchanged under suitable variations of (g,ξ) depending on Θ'.

Remark 4.6. A motivating example of relatively hyperbolic groups are fundamental groups G of complete Riemannian manifolds M of pinched negative sectional curvature and finite volume. These are hyperbolic relative to their virtually finitely generated nilpotent subgroups Bowditch [2012] and Farb [1998]. In this case we can work with the sphere at ∞ of the universal cover $\tilde{M}$ of M. The splitting of $G\times S_\infty$ into a Θ-small part and a Θ-large part can be thought of as follows. Fix a base point $x_0 \in \tilde{M}$. Instead of a number Θ we choose a cocompact subset $G \cdot K$ of $\tilde{M}$. The small part of $G\times\Delta$ consists then of all pairs (g,ξ) for which the geodesic ray from gx_0 to ξ is contained in X; the large part is the complement. Under this translation the cover from Proposition 4.5 can again be thought of as a cover at ∞ for $\tilde{M}$. Moreover, the vertices of infinite valency in Γ correspond to horoballs in $\tilde{M}$, and projection distances to time geodesic rays spend in horoballs.

Note that the action of G on the graph Γ in the definition of relative hyperbolicity we used is cocompact, but Γ is not a proper metric space. Conversely, in the above example the action of G on $\tilde{M}$ is no longer cocompact, but now $\tilde{M}$ is a proper metric space. A similar trade off (cocompact action on non proper space versus non-cocompact action on proper space) is possible for all relatively hyperbolic groups Groves and Manning [2008], assuming the parabolic subgroups are finitely generated.

The mapping class group. Let Σ be a closed orientable surface of genus g with a finite set P of p marked points. We will assume $6g + 2p - 6 > 0$. The mapping class group $\mathrm{Mod}(\Sigma)$ of Σ is the group of components of the group of orientation preserving homeomorphisms of Σ that leave P invariant. Teichmüller space $\mathcal{T}$ is the space of marked complete hyperbolic structures of finite area on $\Sigma \setminus P$. The mapping class group acts on Teichmüller space by changing the marking. Thurston defined an equivariant compactification of Teichmüller space $\overline{\mathcal{T}}$, see Fathi, Laudenbach, and Poénaru [2012]. As a space $\overline{\mathcal{T}}$

is a closed disk, in particular it is an Euclidean retract. The boundary of the compactification $\mathcal{PMF} := \overline{\mathcal{T}} \setminus \mathcal{T}$ is the space of projective measured foliations on Σ. The key step in the proof of the Farrell-Jones Conjecture for $\mathrm{Mod}(\Sigma)$ is the following.

Theorem 4.7 (A. Bartels and Bestvina [2016]). *Let $\mathcal{F}$ be the family of subgroups of* $\mathrm{Mod}(\Sigma)$ *that virtually fix a point in $\mathcal{PMF}$. The action of* $\mathrm{Mod}(\Sigma)$ *on $\mathcal{PMF}$ is finitely $\mathcal{F}$-amenable.*

From this it follows quickly that the action on $\overline{\mathcal{T}}$ is finitely $\mathcal{F}$-amenable as well, and applying Theorem 2.6 we obtain the Farrell-Jones Conjecture for $\mathrm{Mod}(\Sigma)$ relative to $\mathcal{F}$. Up to passing to finite index subgroups, the groups in $\mathcal{F}$ are central extensions of products of mapping class groups of smaller complexity. Using the transitivity principle and inheritance properties one then obtains the Farrell-Jones Conjecture for $\mathrm{Mod}(\Sigma)$ by induction on the complexity of Σ. The only additional input in this case is that the Farrell-Jones Conjecture holds for finitely generated free abelian groups.

The proof of Theorem 4.7 uses the characterization of N-$\mathcal{F}$-amenability from Remark 2.13 and provides suitable covers for $\mathrm{Mod}(\Sigma) \times \mathcal{PMF}$. Similar to the relative hyperbolic case the construction of these covers is done by splitting $\mathrm{Mod}(\Sigma) \times \mathcal{PMF}$ into two parts. Here it is natural to refer to these parts as the thick part and the thin part. (The thick part corresponds to the Θ-small part in the relative hyperbolic case.)

Teichmüller space has a natural filtration by cocompact subsets. For $\varepsilon > 0$ the ε-thick part $\mathcal{T}_{\geq\varepsilon} \subseteq \mathcal{T}$ consist of all marked hyperbolic structures such that all closed geodesics have length $\geq \varepsilon$. The action of $\mathrm{Mod}(\Sigma)$ on $\mathcal{T}_{\geq\varepsilon}$ is cocompact Mumford [1971]. Fix a base point $x_0 \in \mathcal{T}$. Given a pair $(g, \xi) \in \mathrm{Mod}(\Sigma) \times \mathcal{PMF}$ there is a unique Teichmüller ray c_g, that starts at $g(x_0)$ and is "pointing towards ξ" (technically, the vertical foliation of the quadratic differential is ξ). The ε-thick part of $\mathrm{Mod}(\Sigma) \times \mathcal{PMF}$ is defined as the set of all pairs (g, ξ) for which the Teichmüller ray $c_{g,\xi}$ stays in $\mathcal{T}_{\geq\varepsilon}$.

An important tool in covering both the thick and the thin part is the complex of curves $\mathcal{C}(\Sigma)$. A celebrated result of Mazur-Minsky is that $\mathcal{C}(\Sigma)$ is hyperbolic H. A. Masur and Minsky [1999]. Klarreich [1999] studied a coarse projection map $\pi \colon \mathcal{T} \to \mathcal{C}(\Sigma)$ and identified the Gromov boundary $\partial\mathcal{C}(\Sigma)$ of the curve complex. In particular, the projection map has an extension $\pi \colon \mathcal{PMF} \to \mathcal{C}(\Sigma) \cup \partial\mathcal{C}(\Sigma)$. (On the preimage of the Gromov boundary this extension is a continuous map; on the complement it is still only a coarse map.)

Teichmüller space is not hyperbolic, but its thick part $\mathcal{T}_{\geq\varepsilon}$ has a number of hyperbolic properties: The Masur criterion H. Masur [1992] implies that for (g, ξ) in the thick part, $c_{g,\xi}(t) \to \xi$ as $t \to \infty$. Moreover, the restriction of Klarreichs projection map $\pi \colon \mathcal{PMF} \to \mathcal{C}(\Sigma) \cup \partial\mathcal{C}(\Sigma)$ to the space of all such ξ is injective. A result of Minsky [1996] is that geodesics c that stay in $\mathcal{T}_{\geq\varepsilon}$ are contracting. This is a property they share with geodesics in hyperbolic spaces: the nearest point projection $\mathcal{T} \to c$ maps balls disjoint from c to uniformly bounded subsets. Teichmüller geodesics in the thick part $\mathcal{T}_{\geq\varepsilon}$ project to quasi-geodesics in the curve complex with constants depending only on ε. All these properties eventually allow for the construction of suitable covers of any thick part using a coarse flow space and methods from the hyperbolic case. A precise statement is the following.

Proposition 4.8. *There is d such that for any $\varepsilon > 0$ and any $S \subset \mathrm{Mod}(\Sigma)$ finite there exists a $\mathrm{Mod}(\Sigma)$-invariant collection $\mathcal{U}$ of $\mathcal{F}$-subsets of $\mathrm{Mod}(\Sigma)\times\mathcal{PMF}$ of order $\leq d$ such for any (g,ξ) for which $c_{g,\xi}$ stays in $\mathcal{T}_{\geq\varepsilon}$ there is $U \in \mathcal{U}$ with $gS\times\{\xi\} \subseteq U$.*

The action of the mapping class group on the curve complex $\mathcal{C}(\Sigma)$ does not exhibit the mapping class group as a relative hyperbolic group in the sense discussed before; the 1-skeleton of $\mathcal{C}(\Sigma)$ is not fine. Nevertheless, there is an important replacement for the projections to links used in the relatively hyperbolic case, the subsurface projections of H. A. Masur and Minsky [2000]. In this case the projections are not to links in the curve complex, but to curve complexes $\mathcal{C}(Y)$ of subsurfaces Y of Σ. (On the other hand, often links in the curve complex are exactly curve complexes of subsurfaces.) The theory is however much more sophisticated than in the relatively hyperbolic case. Projections are not always defined; sometimes the projection is to points in the boundary of $\mathcal{C}(Y)$ and the projection distance is ∞. Bestvina, Bromberg, and Fujiwara [2015] used subsurface projections to prove that the mapping class group has finite asymptotic dimension. In their work the subsurfaces of Σ are organized in a finite number N of families $\mathbf{Y}$ such that two subsurfaces in the same family will always intersect in an interesting way. This has the effect that the projections for subsurfaces in the same family interact in a controlled way with each other. Each family $\mathbf{Y}$ of subsurfaces is organized in Bestvina, Bromberg, and Fujiwara [ibid.] in an associated simplicial complex, called the projection complex. The vertices of the projection complex are the subsurfaces from $\mathbf{Y}$. A perturbation of the projection distances can thought of as being measured along geodesics in the projection complex and now behaves very similar as in the relative hyperbolic case, in particular the attraction property is satisfied in each projection complex. This allows the application of a variant of the construction from Proposition 4.5 for each projection complex that eventually yield the following.

Proposition 4.9. *Let $\mathbf{Y}$ be any of the finitely many families of subsurfaces. For any $S \subseteq G$ finite there exists $\Theta > 0$ and a $\mathrm{Mod}(\Sigma)$-invariant collection $\mathcal{U}$ of $\mathcal{F}$-subsets of $\mathrm{Mod}(\Sigma)\times\mathcal{PMF}$ of order ≤ 1 such for any (g,ξ) for which there is $Y \in \mathbf{Y}$ with $d^{\pi}_{Y}(g,\xi) \geq \Theta$ there is $U \in \mathcal{U}$ with $gS\times\{\xi\} \subseteq U$.*

The final piece, needed to combine Propositions 4.8 and 4.9 to a proof of Theorem 4.7, is a consequence of Rafi's analysis of short curves in Σ along Teichmüller rays Rafi [2005]:

for any $\varepsilon > 0$ there is Θ such that if some curve of Σ is ε-short on $c_{g,\xi}$ (i.e., if $c_{g,\xi}$ is not contained in $\mathfrak{T}_{\geq\varepsilon}$) then there is a subsurface Y such that $d^{\pi}_{Y}(g,\xi) \geq \Theta$.

Remark 4.10. Farrell and Jones [1998] proved topological rigidity results for fundamental groups of non-positively curved manifolds that are in addition A-regular. The latter condition bounds the curvature tensor and its covariant derivatives over the manifold. All torsion free discrete subgroups of $\mathrm{GL}_n(\mathbb{R})$ are fundamental groups of such manifolds. Similar to the examples discussed in this section a key difficulty in Farrell and Jones [ibid.] is that the action of the fundamental group G of the manifold on the universal cover is not cocompact. The general strategy employed by Farrell-Jones seems however different, in particular, it does not involve an induction over some kind of complexity of G. The only groups that are considered in an intermediate step are polycyclic groups, and the argument directly reduces from G to these and then uses computations of K-and L-theory for polycyclic groups.

This raises the following question: Can the family of subgroups in Theorem 4.1 be replaced with the family of virtually polycyclic subgroups? Recall that the cover constructed for the flow space at ∞ is both α-long and α-thick, while only δ-thickness is needed. So it is plausible that there exist thinner covers at ∞ that work for the family of virtually polycyclic subgroups.

For the mapping class group the family from Theorem 4.7 can not be chosen to be significantly smaller; all isotropy groups for the action have to appear in the family. But one might ask, whether there exist N-$\mathfrak{F}$-amenable actions (or N-$\mathfrak{F}$-amenable sequences of homotopy coherent actions) of mapping class groups on Euclidean retracts, where $\mathfrak{F}$ is smaller than the family used in Theorem 4.7.

KNOT CONTACT HOMOLOGY AND OPEN GROMOV–WITTEN THEORY

Tobias Ekholm

Abstract

Knot contact homology studies symplectic and contact geometric properties of conormals of knots in 3-manifolds using holomorphic curve techniques. It has connections to both mathematical and physical theories. On the mathematical side, we review the theory, show that it gives a complete knot invariant, and discuss its connections to Fukaya categories, string topology, and micro-local sheaves. On the physical side, we describe the connection between the augmentation variety of knot contact homology and Gromov–Witten disk potentials, and discuss the corresponding higher genus relation that quantizes the augmentation variety.

1 Introduction

If M is an oriented 3-manifold then its 6-dimensional cotangent bundle T^*M with the closed non-degenerate 2-form $\omega = -d\theta$, where $\theta = p\,dq$ is the Liouville or action 1-form, is a symplectic manifold. As a symplectic manifold, T^*M satisfies the Calabi–Yau condition, $c_1(T^*M) = 0$, and is thus a natural ambient space for the topological string theory of physics and its mathematical counterpart, Gromov–Witten theory.

If $K \subset M$ is a knot then its *Lagrangian conormal* $L_K \subset T^*M$ of covectors along K that annihilate the tangent vector of K is a Lagrangian submanifold (i.e., $\omega|_{L_K} = 0$) diffeomorphic to $S^1 \times \mathbb{R}^2$. Lagrangian submanifolds provide natural boundary conditions for open string theory or open Gromov–Witten theory, that counts holomorphic curves with boundary on the Lagrangian.

Here we will approach the Gromov–Witten theory of L_K from geometric data at infinity. At infinity, the pair (T^*M, L_K) has ideal contact boundary (ST^*M, Λ_K), the unit sphere cotangent bundle ST^*M with the contact form $\alpha = \theta|_{ST^*M}$ and Λ_K the *Legendrian conormal* ($\alpha|_{\Lambda_K} = 0$) $\Lambda_K = L_K \cap ST^*M$. In what follows we will restrict attention to the most basic cases of knots in 3-space or the 3-sphere, $M = \mathbb{R}^3$ or $M = S^3$.

1.1 Mathematical aspects of knot contact homology. There is a variety of holomorphic curve theories, all interconnected, that can be applied to distinguish objects up to deformation in contact and symplectic geometry. Knot contact homology belongs to a framework of such theories called Symplectic Field Theory (SFT) Eliashberg, Givental, and Hofer [2000]. More precisely, it is the most basic version of SFT, the Chekanov–Eliashberg dg-algebra $CE(\Lambda_K)$, of the Legendrian conormal torus $\Lambda_K \subset ST^*\mathbb{R}^3$ of a knot $K \subset \mathbb{R}^3$. The study of knot contact homology was initiated by Eliashberg, see Eliashberg [2007], around 2000 and developed from a combinatorial perspective by Ng [2008, 2011] and with holomorphic curve techniques in Ekholm, J. B. Etnyre, Ng, and M. G. Sullivan [2013] and Ekholm, J. Etnyre, Ng, and M. Sullivan [2013].

Our first result states that the contact deformation class of Λ_K encodes the isotopy class of K. Let $p \in \mathbb{R}^3$ be a point not on K and let $\Lambda_p \subset ST^*\mathbb{R}^3$ denote the Legendrian conormal sphere of p. We consider certain filtered quotients of $CE(\Lambda_K \cup \Lambda_p)$, called R_{Kp}, R_{pK}, and R_{KK}, together with a product operation $m\colon R_{Kp} \otimes R_{pK} \to R_{KK}$, borrowed from wrapped Floer cohomology.

Theorem 1.1. *Ekholm, Ng, and Shende [2017a, Theorem 1.1] Two knots $K, J \subset \mathbb{R}^3$ are isotopic if and only if the triples (R_{Kp}, R_{pK}, R_{KK}) and (R_{Jp}, R_{pJ}, R_{JJ}), with the product m, are quasi-isomorphic. It follows in particular that Λ_K and Λ_J are (parameterized) Legendrian isotopic if and only if K and J are isotopic.*

A version of this theorem was first proved by Shende [2016] using micro-local sheaves and was reproved using holomorphic disks in Ekholm, Ng, and Shende [2017a]. We point out that the Legendrian conormal tori of any two knots are smoothly isotopic when considered as ordinary submanifolds of $ST^*\mathbb{R}^3$. Theorem 1.1 and its relations to string topology, Floer cohomology, and micro-local sheaves are discussed in Section 3.

1.2 Physical aspects of knot contact homology. We start from Witten's relation between Chern–Simons gauge theory and open topological string Witten [1995] together with Ooguri–Vafa's study of large N duality for conormals of knots Ooguri and Vafa [2000, 2002]. Let M be a closed 3-manifold. Witten identified the partition function of $U(N)$ Chern–Simons gauge theory on M with the partition function of open topological string on T^*M with N branes on the Lagrangian zero-section M. In Chern–Simons theory, the n-colored HOMFLY-PT polynomial of a knot $K \subset M$ equals the expectation value of the holonomy around the knot of the $U(N)$-connection in the n^{th} symmetric representation. The generating function of n-colored HOMFLY-PT polynomials correspond on the string side to the partition function of open string theory in T^*M with N branes on M and one brane on the conormal L_K of the knot.

For $M = S^3$, large N duality says that the open string in T^*S^3 with N-branes on S^3 is equivalent to the closed string, or Gromov–Witten theory, in the non-compact Calabi–Yau manifold X which is the total space of the bundle $\mathcal{O}(-1)^{\oplus 2} \to \mathbb{C}P^1$ (the resolved conifold), provided area$(\mathbb{C}P^1) = Ng_s$, where g_s is the string coupling, or genus, parameter. As smooth manifolds, $X - \mathbb{C}P^1$ and $T^*S^3 - S^3$ are diffeomorphic. As symplectic manifolds they are closely related, in particular both are asymptotic to $[0,\infty) \times ST^*S^3$ at infinity.

If $K \subset S^3$ is a knot then after a non-exact shift, see Koshkin [2007], $L_K \subset T^*S^3 - S^3$, and we can view L_K as a Lagrangian submanifold in X. This leads to the following relation between the colored HOMFLY-PT polynomial and open topological string or open Gromov–Witten theory in X. Let $C_{\chi,r,n}$ be the count of (generalized) holomorphic curves in X with boundary on L_K, of Euler characteristic χ, in relative homology class $rt + nx$, where t is the class of $[\mathbb{C}P^1] \in H_2(X, L_K)$ and $x \in H_2(X, L_K)$ maps to the generator of $H_1(L_K)$ under the connecting homomorphism. If

$$F_K(e^x, g_s, Q) = \sum_{n,r,\chi} C_{n,r,\chi}\, g_s^{-\chi} Q^r e^{nx},$$

then

$$\Psi_K(x) := e^{F_K(x)} = \sum H_{K,n}(q,Q) e^{nx}, \quad q = e^{g_s},\ Q = q^N,$$

where $H_{K,n}$ denotes the n-colored HOMFLY-PT polynomial of K.

The colored HOMFLY-PT polynomial is q-holonomic Garoufalidis, Lauda, and Le [2016], which in our language can be expressed as follows. Let $e^{\hat{x}}$ denote the operator which is multiplication by e^x and $e^{\hat{p}} = e^{g_s \frac{\partial}{\partial x}}$. Then there is a polynomial $\hat{A}_K = \hat{A}_K(e^{\hat{x}}, e^{\hat{p}})$ such that $\hat{A}_K \Psi_K = 0$.

We view Q as a parameter and think of it as fixed. Then from the short-wave asymptotic expansion of the wave function Ψ_K,

$$\Psi_K(x) = e^{F_K} = \exp\left(g_s^{-1} W_K^0(x) + W_K^1(x) + g_s^{j-1} W_K^j(x) + \dots\right),$$

we find that $p = \frac{\partial W_K^0}{\partial x}$ parameterizes the algebraic curve $\{A_K(e^x, e^p) = 0\}$, where the polynomial A_K is the classical limit $g_s \to 0$ of the operator polynomial $\hat{A}_K$. In terms of Gromov–Witten theory, $W_K(x) = W_K^0(x)$ can be interpreted as the disk potential, the count of holomorhic disks ($\chi = 1$ curves) in X with boundary on L_K.

In Aganagic and Vafa [2012] it was observed (in computed examples) that the polynomial A_K agreed with the *augmentation polynomial* Aug_K of knot contact homology. To describe that polynomial, we consider a version $\mathcal{A}_K$ of $CE(\Lambda_K)$ with coefficients in the group algebra of the second relative homology $\mathbb{C}[H_2(ST^*S^3, \Lambda_K)] \approx \mathbb{C}[e^{\pm x}, e^{\pm p}, Q^{\pm 1}]$, where x and p map to the longitude and meridian generators of $H_1(\Lambda_K)$, and $Q = e^t$ for

$t = [ST_p^* S^3]$, the class of the fiber sphere. If $\mathbb{C}$ is considered as a dg-algebra in degree 0 then the *augmentation variety* V_K is the closure of the set in the space of coefficients where there is a chain map into $\mathbb{C}$:

$$V_K = \text{closure}\big(\{(e^x, e^p, Q) \colon \text{there exists a chain map } \epsilon \colon \mathcal{A}_K \to \mathbb{C}\}\big),$$

and the *augmentation polynomial* Aug_K is its defining polynomial. We have the following result that connects knot contact homology and Gromov–Witten theory at the level of the disk.

Theorem 1.2. *Aganagic, Ekholm, Ng, and Vafa [2014, Theorem 6.6 and Remark 6.7] If $W_K(x)$ is the Gromov–Witten disk potential of $L_K \subset X$ then $p = \frac{\partial W_K}{\partial x}$ parameterizes a branch of the augmentation variety V_K.*

The augmentation polynomial Aug_K of a knot K is obtained by elimination theory from explicit polynomial equations. Theorem 1.2 thus leads to a rather effective indirect calculation of the Gromov–Witten disk potential. It is explained in Section 4.

In Section 5 we discuss the higher genus counterpart of Theorem 1.2. We sketch the construction of a higher genus generalization of knot contact homology that we call *Legendrian SFT*. In this theory, the operators $e^{\hat{x}}$ and $e^{\hat{p}}$ have natural enumerative geometrical interpretations. Furthermore, in analogy with the calculation of the augmentation polynomial, elimination theory in the non-commutative setting should give the operator polynomial $\widehat{\text{Aug}}_K(e^{\hat{x}}, e^{\hat{p}})$ such that $\widehat{\text{Aug}}_K \Psi_K = 0$, and thus determine the recursion relation for the colored HOMFLY-PT.

Remark 1.3. Theorem 1.2 and other results about open Gromov–Witten theory presented here should be considered established from the physics point of view. From a more strict mathematical perspective, they are not rigorously proved and should be considered as conjectures.

Acknowledgments. I am much indebted to my coauthors, Aganagic, Cieliebak, Etnyre, Latchev, Lekili, Ng, Shende, Sullivan, and Vafa, of the papers on which this note is based.

2 Knot contact homology and Chekanov–Eliashberg dg-algebras

In this section we introduce Chekanov–Eliashberg dg-algebras in the cases we use them.

2.1 Background notions. Let M be an orientable 3-manifold and consider the unit cotangent bundle ST^*M with the contact 1-form α which is the restriction of the action form pdq. The hyperplane field $\xi = \ker(\alpha)$ is the contact structure determined by α and $d\alpha$ gives a symplectic form on ξ. The first Chern-class of ξ vanishes, $c_1(\xi) = 0$.

Let $\Lambda \subset ST^*M$ be a Legendrian submanifold, $\alpha|_\Lambda = 0$. Then the tangent spaces of Λ are Lagrangian subspaces of ξ. Since $c_1(\xi) = 0$ there is a Maslov class in $H^1(\Lambda; \mathbb{Z})$ that measures the total rotation of $T\Lambda$ in ξ. Here we will consider only Legendrian submanifolds with vanishing Maslov class.

The *Reeb vector field* R of α is characterized by $d\alpha(\cdot, R) = 0$ and $\alpha(R) = 1$. Flow segments of R that begin and end on Λ are called *Reeb chords*. The Reeb flow on ST^*M is the lift of the geodesic flow on M. Consequently, if $K \subset M$ is a knot (or any submanifold) then Reeb chords of Λ_K correspond to geodesics connecting K to itself and perpendicular to K at its endpoints.

2.2 Coefficients in chains on the based loop space. Let $M = \mathbb{R}^3$, $K \subset \mathbb{R}^3$ be a knot and $p \in \mathbb{R}^3 - K$ a point. Let $\Lambda_0 = \Lambda_p$, $\Lambda_1 = \Lambda_K$, and $\Lambda = \Lambda_0 \cup \Lambda_1$. The algebra $CE(\Lambda)$ is generated by the Reeb chords of Λ and homotopy classes of loops in Λ. We define the coefficient ring $\mathbf{k}_\Lambda$ as the algebra over $\mathbb{C}$ generated by idempotents e_j corresponding to Λ_j so that $e_i e_j = \delta_{ij} e_i$, $i, j \in \{0, 1\}$, where δ_{ij} is the Kronecker delta.

Note that Λ_0 is a sphere and Λ_1 is a torus. Fix generators λ and μ of $\pi_1(\Lambda_1)$ (corresponding to the longitude and the meridian of K) and think of them as generators of the group algebra $\mathbb{C}[\pi_1(\Lambda_1)] \approx \mathbb{C}[\lambda^{\pm 1}, \mu^{\pm 1}]$. We let $CE(\Lambda)$ be the algebra over $\mathbf{k}_\Lambda$ generated by Reeb chords c, and the homotopy classes λ and μ. The generators λ and μ satisfy the relations in the group algebra and the following additional relations hold:

$$ce_j = \begin{cases} c & \text{if } c \text{ starts on } \Lambda_j, \\ 0 & \text{otherwise,} \end{cases} \qquad e_k c = \begin{cases} c & \text{if } c \text{ ends on } \Lambda_k, \\ 0 & \text{otherwise,} \end{cases}$$
$$e_j \lambda_k = \lambda_k e_j = \delta_{jk} \lambda_k, \qquad e_j \mu_k = \mu_k e_j = \delta_{jk} \mu_k.$$

The grading of λ and μ is $|\lambda| = |\mu| = 0$ and Reeb chords are graded by the Conley–Zehnder index, which in the case of knot contact homology equals the Morse index of the underlying binormal geodesic, see Ekholm, J. B. Etnyre, Ng, and M. G. Sullivan [2013]. We can thus think of elements of $CE(\Lambda)$ as finite linear combinations of composable monomials $\mathbf{c}$ of the form

$$\mathbf{c} = \gamma_0 c_1 \gamma_1 c_2 \gamma_2 \dots \gamma_{m-1} c_m \gamma_m,$$

where γ_j is a homotopy class of loops in Λ and c_{j+1} is a Reeb chord, and composable means that c starts at the component of γ_j and ends at the component of γ_{j-1}. We then have the decomposition

$$CE(\Lambda) = \bigoplus_{i,j} CE(\Lambda)_{i,j},$$

where $CE(\Lambda)_{i,j}$ is generated by monomials which start on Λ_j and ends on Λ_i. The product of two monomials is given by concatenation if the result is composable and zero otherwise.

The differential is defined to be 0 on e_i and on elements of $\mathbb{Z}[\pi_1(\Lambda_1)]$ and is given by a holomorphic disk count on Reeb chord generators that we describe next. Fix a complex structure J on the symplectization $\mathbb{R} \times ST^*\mathbb{R}^3$, with symplectic form $d(e^t\alpha)$, $t \in \mathbb{R}$, that is invariant under the $\mathbb{R}$-translation and maps ξ to itself. If c is a Reeb chord then $\mathbb{R} \times c$ is a holomorphic strip with boundary on the Lagrangian submanifold $\mathbb{R} \times \Lambda$. Fix a base point in each component of Λ and fix for each Reeb chord endpoint a reference path connecting it to the base point. Consider a Reeb chord a and a composable word $\mathbf{b}$ of homotopy classes and Reeb chords of the form

$$\mathbf{b} = \gamma_0 b_1 \gamma_1 b_2 \gamma_2 \dots \gamma_{m-1} b_m \gamma_m,$$

where γ_0 lies in the component where a ends and γ_m in the component where a starts. We let $\mathfrak{M}(a;\mathbf{b})$ denote the moduli space of holomorphic disks

$$u\colon (D, \partial D) \to (\mathbb{R} \times ST^*\mathbb{R}^3, \mathbb{R} \times \Lambda), \quad du + J \circ du \circ i = 0,$$

with one positive and m negative boundary punctures, which are asymptotic to the Reeb chord strip $\mathbb{R} \times a$ at positive infinity at the positive puncture and to the Reeb chord strip $\mathbb{R} \times b_j$ at negative infinty at the j^{th} negative puncture and such that the closed off path between punctures j and $j+1$ lies in homotopy class γ_j, where puncture 0 and $m+1$ both refer to the positive puncture, see Figure 1. The dimension of the moduli space $\mathfrak{M}(a;\mathbf{b})$ equals $|a| - |\mathbf{b}|$.

We define

$$\partial a = \sum_{a - |\mathbf{b}| = 1} |\mathfrak{M}(a;\mathbf{b})| \mathbf{b}, \tag{1}$$

where $|\mathfrak{M}(a;\mathbf{b})|$ denotes the algebraic number of $\mathbb{R}$-families of disks in $\mathfrak{M}(a;\mathbf{b})$ and extend to monomials by Leibniz rule. For the count in (1) to make sense we need the solutions to be transversely cut out. Since disks with one positive puncture cannot be multiple covers, transversality is relatively straightforward. Furthermore, the sum is finite by the SFT version of Gromov compactness.

The basic result for Chekanov–Elisahberg algebras is then the following.

Lemma 2.1. *The map ∂ is a differential, $\partial \circ \partial = 0$ and the quasi-isomorphism class of $CE(\Lambda)$ is invariant under Legnedrian isotopies of Λ. Furthermore, the differential respects the decomposition $CE(\Lambda) = \bigoplus_{i,j} CE(\Lambda)_{i,j}$ which thus descends to homology.*

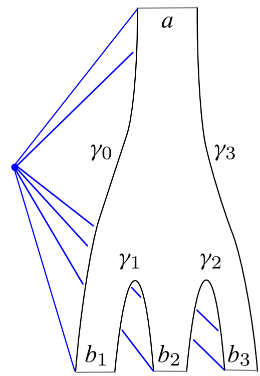

Figure 1: A disk contributing $\gamma_0 b_1 \gamma_1 b_2 \gamma_2 b_3 \gamma_3$ to ∂a.

Remark 2.2. For general contact manifolds, $CE(\Lambda)$ is an algebra over the so called orbit contact homology algebra. In the cases under study, $ST^*\mathbb{R}^3$ and ST^*S^3, the orbit contact homology algebra is trivial in degree 0 and can be neglected.

Remark 2.3. For general Legendrian submanifolds Λ, the version of $CE(\Lambda)$ considered here is more complicated. The group ring generators for torus components are replaced by chains on the based loop space of the corresponding components and moduli spaces of all dimensions contribute to the differential, see Ekholm and Lekili [2017].

Sketch of proof. If a is a Reeb chord then $\partial(\partial a)$ counts two level curves joined at Reeb chords. By gluing and SFT compactness such configurations constitute the boundary of an oriented 1-manifold and hence cancel algebraically. The invariance property can be proved in a similar way by looking at the boundary of the moduli space of holomorphic disks in Lagrangian cobordisms associated to Legendrian isotopies. See e.g. Ekholm, J. Etnyre, and M. Sullivan [2007] for details. □

2.3 Coefficients in relative homology. Our second version of the Chekanov–Eliashberg dg-algebra of the conormal $\Lambda_K \subset ST^*S^3$ of a knot $K \subset S^3$ is denoted $\mathfrak{A}_K$. The algebra $\mathfrak{A}_K$ is generated by Reeb chords graded as before. Its coefficient ring is the group algebra $\mathbb{C}[H_2(ST^*S^3, \Lambda_K)]$ and group algebra elements commute with Reeb chords. To define the differential we fix for each Reeb chord a disk filling the reference paths. Capping off punctured disks in the moduli space $\mathfrak{M}(a, \mathbf{b})$ with these disks we get a relative homology class and define the differential on Reeb chord generators of $\mathfrak{A}_K$ as

$$da = \sum_{|a|-|\mathbf{c}|=1} |\mathfrak{M}(a; \mathbf{c})|\mathbf{c}.$$

Here $\mathbf{c} = e^A c_1 \dots c_m$, where c_j are the Reeb chords at the negative punctures of the disks in the moduli space and $A \in H_2(ST^*S^3; \Lambda_K)$ is the relative homology class of the capped off disks. That d is a differential and the quasi-isomorphism invariance of $\mathcal{Q}_K$ under Legendrian isotopies follow as before.

2.4 Knot contact homology in basic examples. We calculate the knot contact homology dg-algebras (in the lowest degrees) for the unknot and the trefoil knot. For general formulas we refer to Ekholm, J. B. Etnyre, Ng, and M. G. Sullivan [2013] and Ekholm, J. Etnyre, Ng, and M. Sullivan [2013]. The expressions give the differential in $\mathcal{Q}_K$. for the differential in $CE(\Lambda_K)$, set $Q = 1$, $e^x = \lambda$, and $e^p = \mu$.

2.4.1 The unknot. Representing the unkot as a round circle in the plane we find that it has an S^1-Bott family of binormal geodesics and correspondingly an S^1-Bott family of Reeb chords. After small perturbation this gives two Reeb chords c and e of degrees $|c| = 1$ and $|e| = 2$. The differential can be computed using Morse flow trees, see Ekholm [2007] and Ekholm, J. B. Etnyre, Ng, and M. G. Sullivan [2013]. The result is

$$de = 0, \quad dc = 1 - e^x - e^p - Qe^x e^p. \tag{2}$$

2.4.2 The trefoil knot. Represent the trefoil knot as a 2-strand braid around the unkot. If the trefoil T lies sufficiently close to the unkot U, then its conormal torus Λ_T lies in a small neighborhood $N(\Lambda_U)$ of the unknot conormal, which can be identified with the neighborhood the zero section in its 1-jet space $J^1(\Lambda_U)$. The projection $\Lambda_T \to \Lambda_U$ is a 2-fold cover and holomorphic disks with boundary on $\mathbb{R} \times \Lambda_T$ correspond to holomorphic disks on Λ_U with flow trees attached, where the flow trees are determined by $\Lambda_T \subset J^1(\Lambda_U)$, see Ekholm, J. B. Etnyre, Ng, and M. G. Sullivan [2013]. This leads to the following description of $\mathcal{Q}_T$ in degrees ≤ 1. The Reeb chords are:

degree 1: $b_{12}, b_{21}, c_{11}, c_{12}, c_{21}, c_{22}$, degree 0: a_{12}, a_{21},

with differentials

$$\begin{aligned}
dc_{11} &= e^x e^p - e^x - (2Q - e^p)a_{12} - Qa_{12}^2 a_{21}, & dc_{12} &= Q - e^p + e^p a_{12} + Qa_{12}a_{21},\\
dc_{21} &= Q - e^p - e^x e^p a_{21} + Qa_{12}a_{21}, & dc_{22} &= e^p - 1 - Qa_{21} + e^p a_{12}a_{21},\\
db_{12} &= e^{-x} a_{12} - a_{21}, & db_{21} &= a_{21} - e^x a_{12}.
\end{aligned}$$

3 A complete knot invariant

In this section we discuss the completeness of knot contact homology as a knot invariant and describe its relations of to string topology, wrapped Floer cohomology, and microlocal sheaves.

3.1 Filtered quotients and a product. We use notation as in Section 2.2, $\Lambda = \Lambda_p \cup \Lambda_K = \Lambda_0 \cup \Lambda_1$, and consider $CE(\Lambda)$. The group ring $\mathbb{Z}[\pi_1(\Lambda_K)]$ is a subalgebra of $CE(\Lambda)$ generated by the longitude and meridian generators $\lambda^{\pm 1}$ and $\mu^{\pm 1}$. Other generators are Reeb chords that correspond to binormal geodesics. If γ is a geodesic we write c for the corresponding Reeb chord. The grading of Reeb chords with endpoints on the same connected component is well-defined, while the grading for *mixed chords* connecting distinct components are defined only up to an over all shift specified by a cetrain reference path connecting the two components. Let $\operatorname{ind}(\gamma)$ denote the Morse index of the geodesic γ.

Lemma 3.1. *Ekholm, Ng, and Shende [2017a, Proposition 2.3] There is a choice of reference path so that the grading in $CE(\Lambda)$ of a Reeb chord c corresponding to the geodesic γ is as follows: if c connects Λ_K to Λ_K or Λ_p to Λ_K then $|c| = \operatorname{ind}(\gamma)$, and if c connects Λ_K to Λ_p then $|c| = \operatorname{ind}(\gamma) + 1$.*

Consider the filtration on $CE(\Lambda)$ by the number of mixed Reeb chords, and the corresponding filtered quotients:

$$CE(\Lambda)_{1,1} = \mathfrak{F}^0_{11} \supset \mathfrak{F}^2_{11} \supset \mathfrak{F}^4_{11} \supset \dots, \quad CE^{(2k)}_{11} = \mathfrak{F}^{2k}_{11} / \mathfrak{F}^{2k+2}_{11},$$
$$CE(\Lambda)_{i,j} = \mathfrak{F}^1_{ij} \supset \mathfrak{F}^3_{ij} \supset \mathfrak{F}^5_{ij} \supset \dots, \quad CE^{(2k+1)}_{ij} = \mathfrak{F}^{2k+1}_{ij} / \mathfrak{F}^{2k+3}_{ij}, \text{ for } i \neq j,$$

where $\mathfrak{F}^r$ denotes the subalgebra generated by monomials with at least r mixed Reeb chords. The differential respects this filtration. Lemma 3.1 shows that $CE(\Lambda)$ is supported in non-negative degrees and that monomials of lowest degree $d(i,j) \in \{0,1\}$ in $CE(\Lambda)_{i,j}$ contain the minimal possible number $s(i,j) \in \{0,1\}$ of mixed Reeb chords. We then find that $H_{d(i,j)}(CE(\Lambda)_{i,j}) = H_{d(i,j)}(CE^{(s(i,j))}_{ij})$. We call

$$(R_{Kp}, R_{pK}, R_{KK}) := (H_0(CE(\Lambda)_{10}), H_1(CE(\Lambda)_{01}), H_0(CE(\Lambda)_{1,1}))$$

the *knot contact homology triple* of K. The concatenation product in $CE(\Lambda)$ turns R_{Kp} and R_{pK} into left and right modules, respectively, and R_{KK} into a left-right module over $\mathbb{Z}[\lambda^{\pm 1}, \mu^{\pm 1}]$.

We next consider a product for the knot contact homology triple that is closely related to the product in wrapped Floer cohomology. As the differential, it is defined in terms of moduli spaces of holomorphic disk but for the product there are two positive punctures rather than one.

Let a and b be Reeb chords connecting Λ_p to Λ_K and vice versa. Let $\mathbf{c}$ be a monomial in $CE(\Lambda_K)$. Define $\mathfrak{M}(a,b;\mathbf{c})$ as the moduli space of holomorphic disks $u\colon D \to \mathbb{R}\times T^*\mathbb{R}^3$ with two positive punctures asymptotic to a and b, such that the boundary arc between them maps to $\mathbb{R}\times\Lambda_p$, and such that the remaining punctured arc in the boundary maps to Λ_K with homotopy class and negative punctures according to $\mathbf{c}$. We then have

$$\dim(\mathfrak{M}(a,b;\mathbf{c})) = |a|+|b|-|\mathbf{c}|.$$

Define

$$m'(a,b) = \sum_{|\mathbf{c}|=|a|+|b|-1} |\mathfrak{M}(a,b;\mathbf{c})|\mathbf{c}$$

and use this to define the chain level product $m\colon CE(\Lambda)^{(1)}_{10}\otimes CE(\Lambda)^{(1)}_{01} \to CE(\Lambda)^{(0)}_{11}$ as $m(\mathbf{a}a, b\mathbf{b}) = \mathbf{a}m'(a,b)\mathbf{b}$.

Proposition 3.2. *Ekholm, Ng, and Shende [2017a, Proposition 2.13] The product m descends to homology and gives a product $m\colon R_{Kp}\otimes R_{pK} \to R_{KK}$. The knot contact homology triple as modules over $\mathbb{Z}[\pi_1(\Lambda_K)]$ and with the product m is invariant under Legendrian isotopy.*

3.2 String topology and the cord algebra. In this section we define a topological model for knot contact homology in low degrees that one can think of as the string topology of a certain singular space. Our treatment will be brief and we refer to Cieliebak, Ekholm, Latschev, and Ng [2017] and Ekholm, Ng, and Shende [2017a] for full details.

Let $K\subset\mathbb{R}^3$ be a knot and $p\in\mathbb{R}^3-K$ a point with Lagrangian conormals L_K and L_p. Let Σ be the union $\Sigma = \mathbb{R}^3\cup L_K\cup L_p \subset T^*\mathbb{R}^3$. Pick an almost complex structure J compatible with the metric along the zero section. Fix base points $x_K\in L_K-\mathbb{R}^3$ and $x_p\in L_p-\mathbb{R}^3$.

We consider broken strings which are paths $s\colon[a,b]\to\Sigma$ that connect base points, $c(a), c(b)\in\{x_p,x_K\}$ and that admit a subdivision $a<t_1<\dots<t_m<b$ such that $s|_{[t_i,t_{i+1}]}$ is a C^k-map into one of the irreducible components of Σ and such that the left and right derivatives at switches (i.e., points where c switches irreducible components) are related by $\dot c(t_j-) = J\dot c(t_j+)$.

For $\ell>0$, let Σ_ℓ denote the space of strings with ℓ switches at p and with the C^k-topology for some $k>0$. Write $\Sigma_\ell = \Sigma_\ell^{KK}\cup\Sigma_\ell^{Kp}\cup\Sigma_\ell^{pK}\cup\Sigma_\ell^{pp}$, where Σ_ℓ^{KK} denotes strings that start and end at x_K, etc. For $d>0$, let

$$C_d(\Sigma_\ell) = C_d(\Sigma_\ell^{KK})\oplus C_d(\Sigma_\ell^{Kp})\oplus C_d(\Sigma_\ell^{pK})\oplus C_d(\Sigma_\ell^{pp})$$

denote singular d-chains of Σ_ℓ in general position with respect to K. We introduce two string topology operations associated to K, $\delta_K^Q,\delta_K^N\colon C_k(\Sigma_\ell)\to C_{k-1}(\Sigma_{\ell+1})$. If σ is a generic d-simplex then $\delta_K^Q(\sigma)$ is the chain parameterized by the locus in σ of strings with components in S^3 that intersect K at interior points. The operation splits the curve at such intersection and inserts a spike in L_K, see Cieliebak, Ekholm, Latschev, and Ng [2017]. The operation δ_K^Q is defined similarly exchanging the role of $\mathbb{R}^3$ and L_K. There are also similar operations $\delta_p^Q, \delta_p^N : C_k(\Sigma_\ell) \to C_{k-2}(\Sigma_{\ell+1})$ at p that will play less of a role here.

Let ∂ denote the singular differential on $C_*(\Sigma_\ell)$ and let $C_m = \bigoplus_{k+\ell/2=m} C_k(\Sigma_\ell)$. We introduce a Pontryagin product which concatenates strings at p. We write R_{KK}^{st}, R_{Kp}^{st}, and R_{pK}^{st} for the degree 0 homology of the corresponding summands of C_*.

Proposition 3.3. *Cieliebak, Ekholm, Latschev, and Ng [2017] and Ekholm, Ng, and Shende [2017a] The map $d = \partial + \delta_K^Q + \delta_K^N + \delta_p^Q + \delta_p^N$ is a differential on C_*. The homology of d in degree 0 is the cokernel of $\partial + \delta_K^Q + \delta_K^N : C_1 \to C_0$ (where δ_p^Q and δ_p^N vanishes for degree reasons) and is as follows:*

$$R_{KK}^{\mathrm{st}} \approx \hat{R} + R(1-\mu), \quad R_{Kp}^{\mathrm{st}} \approx R, \quad R_{pK}^{\mathrm{st}} \approx R(1-\mu),$$

where $R = \mathbb{Z}[\pi_1(\mathbb{R}^3 - K)]$ and $\hat{R} = \mathbb{Z}[\pi_1(\Lambda_K)]$.

We next consider a geometric chain map of algebras $\Phi\colon CE(\Lambda) \to C_*$, where the multiplication on C_* is given by chain level concatenation of broken strings. The map is defined as follows on generators. If a is a Reeb chord let $\mathfrak{M}(a;\Sigma)$ denote the moduli space of holomorphic disks in T^*S^3 with boundary on Σ and Lagrangian intersection punctures at K. The evaluation map gives a chain of broken strings for each $u \in \mathfrak{M}(a;\Sigma)$. Let $[\mathfrak{M}(a;\Sigma)]$ denote the chain of broken strings carried by the moduli space and define $\Phi(a) = [\mathfrak{M}(a;\Sigma)]$.

Proposition 3.4. *Ekholm, Ng, and Shende [2017a] The map Φ is a chain map. It induces an isomorphism*

$$(R_{Kp}, R_{pK}, R_{KK}) \to \left(R_{Kp}^{\mathrm{st}}, R_{pK}^{\mathrm{st}}, R_{KK}^{\mathrm{st}}\right)$$

that intertwines the product m and the Pontryagin product at p.

Proof of Theorem 1.1. Propositions 3.3 and 3.4 imply that the knot contact homology triple knows the group ring of the knot group and the action of λ and μ. Properties of left-orderable groups together with Waldhausen's theorem then give the result, see Ekholm, Ng, and Shende [ibid.] for details. □

3.3 Partially wrapped Floer cohomology and Legendrian surgery. The knot contact homology of the previous section can also be interpreted, via Legendrian surgery, in terms of partially wrapped Floer cohomology that in turn is connected to the micro-local sheaves used by Shende [2016] to prove the completness result in Theorem 1.1. We give a very brief discussion and refer to Ekholm, Ng, and Shende [2017b, Section 6] for more details.

To a knot $K \subset \mathbb{R}^3$ we associate a Liouville sector W_K with Lagrangian skeleton $L = \mathbb{R}^3 \cup L_K$, this roughly means that L is a Lagrangian subvariety and that W_K is a regular neighborhood of L, see Sylvan [2016] and Ganatra, Pardon, and Shende [2017]. More precisely, W_K is obtained by attaching the cotangent bundle $T^*[0,\infty) \times \Lambda_K$ to $T^*\mathbb{R}^3$ along $\Lambda_K \subset ST^*\mathbb{R}^3$. We let C_K denote the cotangent fiber at $q \in [0,\infty) \times \Lambda_K$ and C_p the cotangent fiber at $p \in \mathbb{R}^3$. Such handle attachments were considered in Ekholm and Lekili [2017] where it was shown that there exists a natural surgery quasi-isomorphism $\Phi \colon CE(\Lambda_K) \to CW^*(C_K)$, where CW^* denotes wrapped Floer cohomology. There are directly analogous quasi-isomorphisms

$$CE_{01}^{(1)} \to CW^*(C_K, C_p), \quad CE_{10}^{(1)} \to CW^*(C_p, C_K), \quad CE_{11}^{(0)} \to CW^*(C_p, C_p),$$

under which the product m corresponds to the usual triangle product m_2 on CW^*.

In Shende [2016], the conormal torus Λ_K of a knot $K \subset \mathbb{R}^3$ was studied via the category of sheaves microsupported in L. This sheaf category can also be described as the category of modules over the wrapped Fukaya category of W_K which is generated by the two cotangent fibers C_K and C_p. The knot contact homology triple with m then have a natural interpretation as calculating morphisms in a category equivalent to that studied in Shende [ibid.].

4 Augmentations and the Gromov–Witten disk potential

Let $K \subset S^3$ be a knot and let L_K denote its conormal Lagrangian. Shifting L_K along the 1-form dual to its unit tangent vector we get a non-exact Lagrangian that is disjoint from the 0-section. We identify the complement of the 0-section in T^*S^3 with the complement of the 0-section in the resolved conifold X. Under this identification, L_K becomes a uniformly tame Lagrangian, see Koshkin [2007], which is asymptotic to $\mathbb{R} \times \Lambda_K \subset \mathbb{R} \times ST^*S^3$ at infinity. The first condition implies that L_K can be used as boundary condition for holomorphic curves and the second that at infinity, holomorphic curves on (X, L_K) can be identified with the $\mathbb{R}$-invariant holmorphic curves of $(\mathbb{R} \times ST^*S^3, \mathbb{R} \times \Lambda_K)$.

Since $c_1(X) = 0$ and the Maslov class of L_K vanishes, the formal dimension of any holomorphic curve in X with boundary on L_K equals 0. Fixing a perturbation scheme one then gets a 0-dimensional moduli space of curves. Naively, the open Gromov–Witten invariant of L_K would be the count of these rigid curves. Simple examples however show that such a count is not invariant under deformations, contradicting what topological string theory predicts.

To resolve this problem on the Gromov–Witten side, we count more involved configurations of curves that we call *generalized curves*. In this section we consider the simpler case of disks and then in Section 5 the case of general holomorphic curves. The problems of open Gromov–Witten theory in this setting was studied from the mathematical perspective also by Iacovino [2009a,b]. From the physical perspective, the appearance of more complicated configurations then bare holomorphic curves seems related to boundary terms in the path integral localized on the moduli space of holomorphic curves with boundary which, unlike in the case of closed curves, has essential codimension one boundary strata.

4.1 Augmentations of non-exact Lagrangians and disk potentials. We will construct augmentations induced by the non-exact Lagrangian filling $L_K \subset X$. In order to explain how this works we first consider the case of the exact filling $L_K \subset T^*S^3$. The exact case is a standard ingredient in the study of Chekanov–Eliashberg dg-algebras, see e.g. Ekholm, Honda, and Kálmán [2016]. Consider the algebra $\mathcal{A}_K$ with coefficients in $\mathbb{C}[e^{\pm x}, e^{\pm p}, Q^{\pm 1}]$. Here we set $e^p = 1$ since p bounds in L_K and $Q = 1$ since the cotangent fiber sphere bounds in ST^*S^3. If a is a Reeb chord of Λ_K, we let $\mathcal{M}_n(a)$ denote the moduli space of holomorphic disks with positive puncture at a and boundary on L_K that lies in the homology class nx. Then $\dim(\mathcal{M}_n(a)) = |a|$ and we define the map $\epsilon_0 \colon \mathcal{A}_K \to \mathbb{C}[e^{\pm x}]$ on degree 0 Reeb chords a as

$$\epsilon_0(a) = \sum_n |\mathcal{M}_n(a)| e^{nx}.$$

Lemma 4.1. *The map $\epsilon_0 \colon \mathcal{A}_K|_{Q=1, e^p=1} \to \mathbb{C}[e^{\pm x}]$ is a chain map, $\epsilon_0 \circ d = 0$.*

Proof. Configurations contributing to $\epsilon_0 \circ d$ are two level broken disks that are in one to one correspondence with the boundary of the oriented 1-manifolds $\mathcal{M}_n(c)$, $|c| = 1$. □

We next consider the case of the non-exact Lagrangian filling $L_K \subset X$. In this case, $Q = e^t$, where $t = [\mathbb{C}P^1] \in H_2(X)$ and we look for a chain map $\mathcal{A}_K \to \mathbb{C}[e^{\pm x}, Q^{\pm 1}]$. If a is a Reeb chord, then let $\mathcal{M}_{r,n}(a)$ denote the moduli space of holomorphic disks in X with boundary on L_K in relative homology class $rt + nx$.

Consider first the naive generalization of the exact case and define

$$\epsilon'(a) = \sum_{r,n} |\mathcal{M}_{r,n}(a)| Q^r e^{nx}.$$

We look at the boundary of 1-dimensional moduli spaces $\mathcal{M}_{r,n}(c)$, $|c| = 1$. Unlike in the exact case, two level broken curves do not account for the whole boundary of $\mathcal{M}_{r,n}(c)$ and consequently the chain map equation does not hold. The reason is that there are non-constant holomorphic disks without positive punctures on L_K and a 1-dimensional family of disks can split off non-trivial such disks under so called boundary bubbling. Together with two level disks, disks with boundary bubbles account for the whole boundary of the moduli spacce.

The problem of boundary bubbling is well-known in Floer cohomology and was dealt with there using the method of bounding cochains introduced by Fukaya, Oh, Ohta, Fukaya, Oh, Ohta, and Ono [2009]. We implement this method in the current set up by introducing non-compact bounding chains (with boundary at infinity) as follows. We use a perturbation scheme to make rigid disks transversely cut out energy level by energy level. For each transverse disk u we also fix a bounding chain σ_u, i.e., σ_u is a non-compact 2-chain in L_K that interpolates between the boundary ∂u and a multiple of a fixed curve ξ in Λ_K in the longitude homology class $x \in H_1(\Lambda_K)$ at infinity. This allows us to define the Gromov–Witten disk potential as a sum over finite trees Γ, where there is a rigid disk u_v at each vertex $v \in \Gamma$ and for every edge connecting vertices v and v' there is an intersection point between ∂u_v and $\sigma_{v'}$ weighted by $\pm\frac{1}{2}$, according to the intersection number. We call such a tree a *generalized disk* and define the Gromov–Witten disk potential $W_K(x, Q)$ as the generating function of generalized disks.

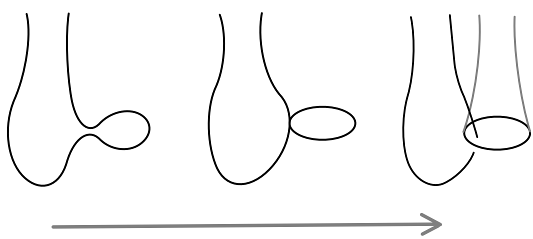

Figure 2: Bounding chains turn boundary breaking into interior points in moduli spaces: the disk family continues as a family of disks with the bounding chain inserted.

We then define $\mathfrak{M}'_{r,n}(a)$ as the moduli space of holomorphic disks with positive puncture at a and with insertion of bounding chains of generalized disks along its boundary such that the total homology class of the union of all disks in the configuration lies in the class $rt + nx$. Let $\epsilon\colon \mathfrak{A}_K \to \mathbb{C}[e^{\pm x}, Q^{\pm 1}]$ be the map

$$\epsilon(a) = \sum_{r,n} |\mathfrak{M}'_{r,n}(a)| Q^r e^{nx}.$$

Proposition 4.2. *If*

$$p = \frac{\partial W_K}{\partial x} \tag{3}$$

then ϵ is a chain map, $\epsilon \circ d = 0$. Consequently, (3) parameterizes a branch of the augmentation variety and Theorem 1.2 follows.

Proof. The bounding chains are used to remove boundary bubbling from the boundary of the moduli space, see Figure 2. As a consequence the boundary of the moduli space of disks with one positive puncture and with insertions of generalized disks correspond to two level disks with insertions. It remains to count the disks at infinity with insertions. At infinity all bounding chains are multiples of the longitude generator x. A bounding chain going n-times around x can be inserted nm times in a curve that goes m times around p. It follows that the substitution $e^p = e^{\frac{\partial W_K}{\partial x}}$ corresponds to counting disks with insertions. □

Corollary 4.3. *The Gromov–Witten disk potential W_K is an analytic function.*

Proof. The defining equation of the augmentation variety can be found from the knot contact homology differential by elimination theory. It is therefore an algebraic variety and the Gromov–Witten disk potential in (3) is an analytic function. □

4.2 Augmentation varieties in basic examples.

We calculate the augmentation variety from the formulas in Section 2.4.

4.2.1 The unknot.

The augmentation polynomial for the unknot U is determined directly by (2): the algebra admits an augmentation exactly when $dc = 0$ and

$$\mathrm{Aug}_U = 1 - e^x - e^p + Qe^xe^p.$$

4.2.2 The trefoil.

We need to find the locus where the right hand sides in Section 2.4.2 has common roots. The augmentation polynomial is found as:

$$\begin{aligned}
\mathrm{Aug}_T =&(e^xe^{2p} + Q^2)a_{12}(e^p(dc_{21}) - Q(dc_{22}))\\
&- (e^xe^{2p} + Q^2)(Q(dc_{21}) + e^xe^pd(c_{22}))\\
&+ e^x(e^{2p} - Q)(e^p(dc_{21}) - Q(dc_{22}))\\
&+ e^x(e^{2p} - Q)(e^xe^{2p} + Q^2)(db_{12})\\
&= e^{2x}(e^{4p} - e^{3p}) + e^x(e^{4p} - e^{3p}Q + 2e^{2p}(Q^2 - Q) - e^pQ^2 + Q^2)\\
&- (e^pQ^3 - Q^4).
\end{aligned}$$

5 Legendrian SFT and open Gromov–Witten theory

This section concerns the higher genus counterpart of the results in Section 4.

5.1 Additional geometric data for Legendrian SFT of knot conormals. We outline a definition of relevant parts of Legendrian SFT (including the open Gromov–Witten potential), for the Lagrangian conormal L_K of a knot $K \subset S^3$ in the resolved conifold, $L_K \subset X$. As in the case of holomorphic disks, see Section 4, the main point of the construction is to overcome boundary bubbling. In the disk case there is a 1-dimensional disk that interacts through boundary splitting/crossing with rigid disks. Since the moving disk is distinguished from the rigid disks, it is sufficient to use bounding chains for the rigid disks only.

In the case of higher genus curves there is no such separation. A 1-dimensional curve can boundary split on its own. To deal with this, we introduce additional geometric data that defines what might be thought of as dynamical bounding chains. We give a brief description here and refer to Ekholm and Ng [n.d.] for more details. The construction was inspired by self linking of real algebraic links (Viro's encomplexed writhe, Viro [2001]) as described in Ekholm [2002].

5.1.1 An auxiliary Morse function. Consider a Morse function $f : L_K \to \mathbb{R}$ without maximum and with the following properties. The critical points of f lie on K and are: a minimum κ_0 and an index 1 critical point κ_1. Flow lines of ∇f connecting κ_0 to κ_1 lie in K and outside a small neighborhood of K, ∇f is the radial vector field along the fiber disks in $L_K \approx K \times \mathbb{R}^2$. Note that the unstable manifold $W^{\mathrm{u}}(\kappa_1)$ of κ_1 is a disk that intersects Λ_K in the meridian cycle p.

5.1.2 A 4-chain with boundary twice L_K. Start with a 3-chain $\Gamma_K \subset ST^*S^3$ with the following properties: $\partial\Gamma_K = 2 \cdot \Lambda_K$, near the boundary Γ_K agrees with the union of small length $\epsilon > 0$ flow lines of $\pm R$ starting on Λ_K, and $\Gamma_K - \partial\Gamma_K$ is disjoint from Λ_K, see Ekholm and Ng [n.d.]. Identify $\big([0,\infty) \times ST^*S^3, [0,\infty) \times \Lambda_K\big)$ with $(X, L_K) - (\bar{X}, \bar{L}_K)$, where $(\bar{X}, \bar{L}_K)$ is compact, and let $C_K^{\infty} = [0,\infty) \times \Gamma_K$.

Consider the vector field $v(q) = \frac{\nabla f(q)}{|\nabla f(q)|}$, $q \in L_K - \{\kappa_0, \kappa_1\}$ and let G be the closure of the length $\epsilon > 0$ half rays of $\pm J v(q)$ starting at $q \in L_K$ in $\bar{L}_K$ and G' its boundary component that does not intersect L_K. A straightforward homology calculation shows that there exists a 4-chain C_K^0 in $X - L_K$ with boundary $\partial C_K^0 = G' \cup \partial C_K^{\infty}$. Define $C_K = C_K^{\infty} \times [0,\infty) \cup C_K^0 \cup G$. Then C_K is a 4-chain with regular boundary along $2 \cdot L_K$ and inward normal $\pm J\nabla f$. Furthermore, C_K intersects L_K only along its boundary and is otherwise disjoint from it. We remark that in order to achieve necessary transversality, we also need to perturb the Morse function and the chain slightly near the Reeb chord endpoints in order to avoid intersections with trivial strips, see Ekholm and Ng [ibid.].

5.2 Bounding chains for holomorphic curves. We next associate a bounding chain to each holomorphic curve $u\colon (\Sigma, \partial\Sigma) \to (X, L_K)$ in general position with respect to ∇f and C_K. Consider first the case without punctures. The boundary $u(\partial\Sigma)$ is a collection of closed curves contained in a compact subset of L_K. By general position, $u(\partial\Sigma)$ does not intersect the stable manifold of κ_1. Define σ_u' as the union of all flow lines of ∇f that starts on $u(\partial\Sigma)$. Since f has no index 2 critical points and since ∇f is vertical outside a compact, $\sigma_u' \cap (\{T\} \times \Lambda_K)$ is a closed curve, independent of T for all sufficiently large $T > 0$. Let $\partial_\infty \sigma_u' \subset \Lambda_K$ denote this curve and assume that its homology class is $nx + mp \in H_1(\Lambda_K)$. Define the bounding chain σ_u of u as

$$\sigma_u = \sigma_u' - m \cdot W^{\mathrm{u}}(\kappa_1). \tag{4}$$

Then σ_u has boundary $\partial\sigma_u = \partial u$ and boundary at infinity $\partial^\infty \sigma_u$ in the class $nx + 0p$.

Consider next the general case when $u\colon (\Sigma, \partial\Sigma) \to (X, L_K)$ has punctures at Reeb chords $c_1, \dots, c_m$. Let δ_j denote the capping disk of c_j and let $\bar{X}_T = \bar{X} \cup ([0, T] \times ST^*S^3)$. Fix a sufficiently large $T > 0$ and replace $u(\partial\Sigma)$ in the construction of σ_u' above by the boundary of the chain $(u(\Sigma) \cap \bar{X}_T) \cup \bigcup_{j=1}^m \delta_j$ and then proceed as there. This means that we cap off the holomorphic curve by adding capping disks and construct a bounding chains of this capped disk.

5.3 Generalized holomorphic curves and the SFT-potential. The SFT counterpart of the chain map equation for augmentations is derived from 1-dimensional moduli spaces of generalized holomorphic curves. The moduli spaces are stratified and the key point of our construction is to patch the 1-dimensional strata in such a way that all boundary phenomena in the compact part of (X, L_K) cancel out, leaving only splitting at Reeb chords and intersections with bounding chains at infinity. We start by describing the curves in the 1-dimensional strata.

As in the disk case we assume we have a perturbation scheme for transversality. Again the perturbation is inductively constructed, we first perturb near the simplest curves (lowest energy and highest Euler characteristic) and then continue inductively in the hierarchy of curves, making all holomorphic curves transversely cut out and transverse with respect to the Morse data fixed. We also need transversality with respect to C_K that we explain next. A holomorphic curve u in general position has tangent vector along the boundary everywhere linearly independent of ∇f. Let the *shifting vector field* ν along ∂u be a vector field that together with the tangent vector of ∂u and ∇f gives a positively oriented triple. Let ∂u_ν denote ∂u shifted slightly along ν. By construction ∂u_ν is disjoint from a neighborhood of the boundary of σ_u. Let $u_{J\nu}$ denote u shifted slightly along an extension of $J\nu$ supported near the boundary of u. We chose the perturbation so that $u_{J\nu}$ is transverse to C_K.

With such perturbation scheme constructed we define generalized holomorphic curves to consist of the following data.

- A finite oriented graph Γ with vertex set V_Γ and edge set E_Γ.
- To each $v \in V_\Gamma$ is associated a (generic) holomorphic curve u^v with boundary on L_K (and possibly with positive punctures).
- To each edge $e \in E_\Gamma$ that has its endpoints at distinct vertices, $\partial e = v_+ - v_-$, $v_+ \neq v_-$, is associated an intersection point of the boundary curve ∂u^{v_-} and the bounding chain $\sigma_{u^{v_+}}$.
- To each edge $e \in E_\Gamma$ which has its endpoints at the same vertex v_0, $\partial e = v_0 - v_0 = 0$, is associated either an intersection point in $\partial u_\nu^{v_0} \cap \sigma_{u^{v_0}}$ or an intersection point in $u_{J\nu}^{v_0} \cap C_K$.

We call such a configuration a *generalized holomorphic curve over* Γ and denote it $\Gamma_{\mathbf{u}}$, where $\mathbf{u} = \{u_v\}_{v \in V_\Gamma}$ lists the curves at the vertices.

Remark 5.1. Several edges of a generalized holomorphic curve may have the same intersection point associated to them.

We define the Euler characteristic of a generalized holomorphic curve $\Gamma_{\mathbf{u}}$ as

$$\chi(\Gamma_{\mathbf{u}}) = \sum_{v \in V_\Gamma} \chi(u_v) - \#E_\Gamma,$$

where $\#E_\Gamma$ denotes the number of edges of Γ, and the dimension of the moduli space containing $\Gamma_{\mathbf{u}}$ as

$$\dim(\Gamma_{\mathbf{u}}) = \sum_{v \in V_\Gamma} \dim(u_v),$$

where $\dim(u_v)$ is the formal dimension of u_v.

In particular, if $\dim(\Gamma_{\mathbf{u}}) = 0$ then u_v is rigid for all $v \in V_\Gamma$ and if $\dim(\Gamma_{\mathbf{u}}) = 1$ then $\dim(u_v) = 1$ for exactly one $v \in V_\Gamma$ and u_v is rigid for all other $v \in V_\Gamma$. The relative homology class represented by $\Gamma_{\mathbf{u}}$ is the sum of the homology classes of the curves u_v at its vertices, $v \in V_\Gamma$.

We define the SFT-potential to be the generating function of generalized rigid curves over graphs Γ as just described:

$$\mathbf{F}_K = \sum_{m,k,\mathbf{c}^+} F_{m,k,\chi,\mathbf{c}^+}\, g_s^{-\chi+\ell(\mathbf{c}^+)}\, e^{mx} Q^k\, \mathbf{c}^+,$$

where $F_{m,k,\chi,\mathbf{c}^+}$ counts the algebraic number of generalized curves $\Gamma_{\mathbf{u}}$ in homology class $mx + kt \in H_2(X, L_K)$ with $\chi(\Gamma_{\mathbf{u}}) = \chi$ and with positive punctures according to the Reeb chord word $\mathbf{c}^+$. A generalized curve $\Gamma_{\mathbf{u}}$ contributes to this sum by the product of the weights of the curves at its vertices (the count coming from the perturbation scheme) times $\pm\frac{1}{2}$ for each edge where the sign is determined by the intersection number.

Remark 5.2. For computational purposes we note that we can rewrite the sum for $\mathbf{F}_K$ in a simpler way. Instead of the complicated oriented graphs with many edges considered above, we look at unoriented graphs with at most one edge connecting every pair of distinct vertices and no edge connecting a vertex to itself. We call such graphs *simple graphs*. We map complicated graphs to simple graphs by collapsing edges to the basic edge and removing self-edges. Then the contribution from all graphs lying over a simple graph is given the product of weights at the vertices times the product of $e^{\mathrm{lk}_e\, g_s}$, where the linking coefficient of an edge e connecting vertices corresponding to the curves u and u' is the intersection number $\sigma_u \cdot \partial u' = \partial u \cdot \sigma_{u'}$, and $e^{\frac{1}{2}\,\mathrm{slk}_v\, g_s}$, where the linking coefficient slk_v of a vertex v is the sum of intersection numbers $\partial u_\nu \cdot \sigma_u + u_{J\nu} \cdot C_K$, where u is the curve at v.

5.4 Compactification of 1-dimensional moduli spaces. The generalized holomorphic curves that we defined in Section 5.3 constitute the open strata of the 1-dimensional moduli. More precisely, the generalized curve $\Gamma_{\mathbf{u}}$ has a *generic* curve of dimension one at exactly one vertex. Except for the usual holomorphic degenerations in 1-parameter families, there are new boundary phenomena arising from the 1-dimensional curve becoming non-generic relative ∇f and C_K. More precisely we have the following description of the boundary of 1-dimensional starta of generalized holomorphic curves (we write u_v for the curve at vertex $v \in \Gamma_{\mathbf{u}}$).

Lemma 5.3. *Ekholm and Ng [n.d.] Generic degenerations of the holomorphic curves u_v at the vertices $v \in V_\Gamma$ are as follows (see Figure 3):*

(1) *Splitting at Reeb chords.*

(2) *Hyperbolic boundary splitting.*

(3) *Elliptic boundary splitting.*

Generic degenerations with respect to ∇f, C_K, and capping paths are as follows:

(4) *Crossing the stable manifold of κ_1: the boundary of the curve intersects the stable manifold of κ_1.*

(5) *Boundary crossing: a point in the boundary mapping to a bounding chain moves out across the boundary of a bounding chain.*

(6) *Interior crossing: An interior marked point mapping to C_K moves across the boundary L_K of C_K.*

(7) *Boundary kink: The boundary of a curve becomes tangent to ∇f at one point.*

(8) *Interior kink: A marked point mapping to C_K moves to the boundary in the holomorphic curve.*

(9) *The leading Fourier coefficient at a positive puncture vanishes.*

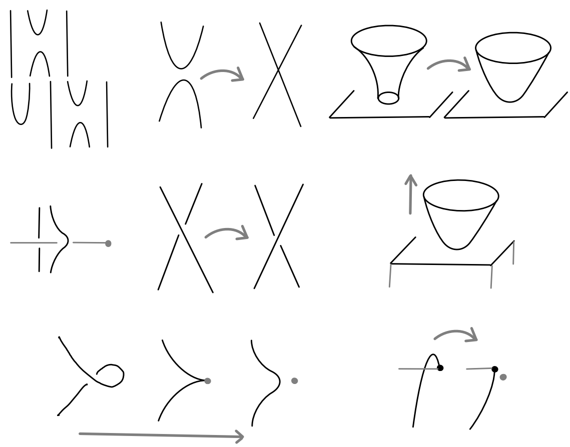

Figure 3: Degenerations in Lemma 5.3. Top row: (1), (2), (3), middle (4) (the dot is κ_1), (5), (6), bottom (7), (8) together, and (9) (gray dot represents $u_{J_\nu} \cap C_K$).

Proposition 5.4. *Boundaries of 1-dimensional strata of generalized holomorphic curves cancel out according to the following.*

(i) *The moduli space of generalized holomorphic curves does not change under degenerations* (4) *and* (9).

(ii) *Boundary splitting* (2) *cancel with boundary crossing* (5).

(iii) *Elliptic splitting* (3) *cancel with interior crossing* (6).

(iv) *Boundary kinks* (7) *cancel interior kinks* (8).

Proof. Consider (i). For (4), observe that as the boundary crosses the stable manifold of κ_1, the change in flow image is compensated by the change in the number of unstable manifold added. The invariance under (9) follows from a straightforward calculation using Fourier expansion near the Reeb chord: an intersection with the capping disk boundary turns into an intersection with C_K.

Consider (iv). A calculation in a local model for a generic tangency with ∇f shows that the self intersection of the boundary turns into an intersection with C_K. (This uses that the normal vector field of C_K is $\pm J\nabla f$.)

Consider (iii). Unlike (i) and (iv) this involves gluing holomorphic curves and therefore, as we will see, the details of the perturbation scheme (which also has further applications, see Ekholm and Shende [n.d.]).

At the hyperbolic boundary splitting we find a holomorphic curve with a double point that can be resolved in two ways, u_+ and u_-. Consider the two moduli spaces corresponding to m insertions at the corresponding intersection points between ∂u_+ and σ_{u_-} and ∂u_- and σ_{u_+}.

To obtain transversality at this singular curve for curves of any Euler characteristic we must separate the intersection points with the bounding chain. To this end, we use a perturbation scheme with multiple bounding chains that time-orders the boundary crossings. Each, now distinct, crossing can then be treated as a usual gluing. Consider gluing at m intersection points as ∂u_- crosses σ_{u_+}. This gives a curve of Euler characteristic decreased by m and orientation sign ϵ^m, $\epsilon = \pm 1$. Furthermore, at the gluing, the ordering permutation acts on the gluing strips and each intersection point is weighted by $\frac{1}{2}$. (The reason for the factor $\frac{1}{2}$ is that we count intersections between boundaries and bounding chains twice, for distinct curves both $\partial u \cap \sigma_v$ and $\partial v \cap \sigma_u$ contribute.) This gives a moduli space of additional weight

$$\epsilon^m \frac{1}{2^m m!} g_s^m.$$

The only difference between these configurations and those associated with the opposite crossing is the orientation sign. Hence the other gluing when ∂u_+ crosses σ_{u_-} gives the weight

$$(-1)^m \epsilon^m \frac{1}{2^m m!} g_s^m.$$

Noting that the original moduli space is oriented towards the crossing for one configuration and away from it for the other we find that the two gluings cancel if m is even and give a new curve of Euler characteristic decreased by m and of weight $\frac{2}{2^m m!}$ if m is odd. Counting ends of moduli spaces we find that the curves resulting from gluing at the crossing count with a factor

$$e^{\frac{1}{2}g_s} - e^{-\frac{1}{2}g_s}, \tag{5}$$

which cancels the change in linking number.

Cancellation (iii) follows from a gluing argument analogous to (ii): The curve with an interior point mapping to L_K can be resolved in two ways, one curve u^+ that intersects C_K at a point in the direction $+J\nabla f$ and one u^- that intersects C_K at a point in the direction $-J\nabla f$. A constant disk at the intersection point can be glued to the family of curves at the intersection with L_K. As in the hyperbolic case we separate the intersections and time order them to get transversality at any Euler characteristic. We then apply usual gluing and note that the intersection sign is part of the orientation data for the gluing problem, the calculation of weights is exactly as in the hyperbolic case above. (This time the $\frac{1}{2}$-factors comes from the boundary of C_K being twice L_K, $\partial C_K = 2[L_K]$.) We find again that glued configurations corresponds to multiplication by

$$e^{\frac{1}{2}g_s} - e^{-\frac{1}{2}g_s},$$

and cancels the difference in counts between $u^+_{J\nu} \cdot C_K$ and $u^-_{J\nu} \cdot C_K$. □

5.5 The SFT equation. We let $\mathbf{H}_K$ denote the count of generalized holomorphic curves $\Gamma_{\mathbf{u}}$, in $\mathbb{R} \times ST^*S^3$, rigid up to $\mathbb{R}$-translation. Such a generalized curve lies over a graph that has a main vertex corresponding to a curve of dimension 1, at all other vertices there are trivial Reeb chord strips. Consider such a generalized holomorphic curve $\Gamma_{\mathbf{u}}$. We write $\mathbf{c}^+(\mathbf{u})$ and $\mathbf{c}^-(\mathbf{u})$ for the monomials of positive and negative punctures of $\Gamma_{\mathbf{u}}$, write $w(\mathbf{u})$ for the weight of $\Gamma_{\mathbf{u}}$, $m(\mathbf{u})x + n(\mathbf{u})p + l(\mathbf{u})t$ for its homology class, and $\chi(\mathbf{u})$ for the Euler characteristic of the generalized curve of $\Gamma_{\mathbf{u}}$. Define the SFT-Hamiltonian

$$\mathbf{H}_K = \sum_{\dim(\Gamma_{\mathbf{u}})=1} w(\mathbf{u})\, g_s^{-\chi(\mathbf{u})+\ell(\mathbf{c}^+(\mathbf{u}))}\, e^{m(\mathbf{u})x+n(\mathbf{u})p+l(\mathbf{u})t}\, \mathbf{c}^+(\mathbf{u})\, \partial_{\mathbf{c}^-(\mathbf{u})},$$

where the sum ranges over all generalized holomorphic curves. As above this formula can be simplified to a sum over simpler graphs with more elaborate weights on edges.

Lemma 5.5. *Consider a curve u at infinity in class $mx + np + kt$. The count of the corresponding generalized curves with insertion along ∂u equals*

$$e^{-\mathbf{F}_K} e^{mx} Q^k e^{n g_s \frac{\partial}{\partial x}} e^{\mathbf{F}_K}.$$

Proof. Contributions from bounding chains of curves inserted r times along np corresponds to multiplication by

$$n^r \frac{1}{r!} g_s^{-r} \sum_{r_1+\cdots+r_j=r} \frac{\partial^{r_1}\mathbf{F}_K}{\partial x^{r_1}} \cdots \frac{\partial^{r_j}\mathbf{F}_K}{\partial x^{r_j}},$$

where a factor $\frac{\partial^s \mathbf{F}_K}{\partial x^s}$ corresponds to attaching the bounding chain of a curve s times. □

Theorem 5.6. *If K is a knot and $L_K \subset X$ its conormal Lagrangian then the SFT equation*

$$e^{-\mathbf{F}_K}\, \mathbf{H}_K|_{p=g_s \frac{\partial}{\partial x}}\, e^{\mathbf{F}_K} = 0 \tag{6}$$

holds.

Proof. Lemma 5.3, Proposition 5.4, and Lemma 5.5 show that the terms in left hand side of (6) counts the ends of a compact oriented 1-dimensional moduli space. □

Remark 5.7. We point out that Lemma 5.5 gives an enumerative geometrical meaning to the standard quantization scheme $p = g_s \frac{\partial}{\partial x}$ by counting insertions of bounding chains. See Ekholm [2014, Section 3.3] for a related path integral argument.

5.6 Framing and Gromov–Witten invariants.

Lemma 5.3 and Proposition 5.4 imply that the open Gromov–Witten potential of L_K is invariant under deformation. Recall from Section 1.2 that dualities between string and gauge theories imply that

$$\Psi_K(x,Q) = e^{F_K(x,Q)} = \sum_m H_m(e^{g_s},Q)e^{mx},$$

where H_m is the m-colored HOMFLY-PT polynomial. It is well-known that the colored HOMFLY-PT polynomial depends on framing. We derive this dependence here using our definition of generalized holomorphic curves. Assume that Ψ_K above is defined for a framing (x,p) of Λ_K. Then other framings are given by $(x',p') = (x+rp,p)$ where r is an integer. Let $\Psi^r_K(x',Q)$ denote the wave function defined using the framing (x',p').

Theorem 5.8. *If $\Psi_K(x,Q)$ is as above then*

$$\Psi^r_K(x',Q) = \sum_m H_m(e^{g_s},Q)\, e^{m^2 r g_s} e^{mx'}.$$

Proof. Note first that the actual holomorphic curves are independent of the framing. The change thus comes from the bounding chains: the boundaries at infinity $\partial_\infty \sigma_u$ must be corrected to lie in multiples of the new preferred class x'. Thus, for a curve that goes m times around the generator of $H_1(L_K)$, we must correct the bounding chain adapted to x by adding $mrW^{\mathrm{u}}(\kappa_1)$. Under such a change, the linking number in L_K in this class changes by $m^2 r$. □

5.7 Quantization of the augmentation variety in basic examples.

5.7.1 The unknot. Using Morse flow trees it is easy to see that there are no higher genus curves with boundary on Λ_U. As with the augmentation polynomial, there are no additional operators to eliminate for the unknot and $\mathbf{H}_U$ gives the operator equation directly:

$$\widehat{\mathrm{Aug}}_U = 1 - e^{\hat{x}} - e^{\hat{p}} - Qe^{\hat{x}}e^{\hat{p}},$$

which agrees with the the recursion relation for the colored HOMFLY-PT, see e.g. Aganagic and Vafa [2012].

5.7.2 The trefoil. It can be shown Ekholm and Ng [n.d.] that there are no higher genus curves with boundary on Λ_T. The SFT Hamiltonian can again be computed from disks with flow lines attached. If c is a chord with $|c| = 1$, we write $H(c)$ for the part of the Hamiltonian $\mathbf{H}_T$ with a positive puncture at c and leave out c from the notation. Then relevant parts of the Hamiltonian are:

$$\begin{aligned}
H(b_{12}) &= e^{-\hat{x}}\partial_{a_{12}} - \partial_{a_{21}} + \mathcal{O}(a)\\
H(c_{11}) &= e^{\hat{x}}e^{\hat{p}} - e^{-g_s}e^{\hat{x}} - ((1+e^{-g_s})Q - e^{\hat{p}})\partial_{a_{12}} - Q\partial^2_{a_{12}}\partial_{a_{21}} + \mathcal{O}(a)\\
H(c_{21}) &= Q - e^{\hat{p}} + e^{\hat{x}}e^{\hat{p}}\partial_{a_{21}} + Q\partial_{a_{12}}\partial_{a_{21}} + (e^{-g_s}-1)e^{\hat{x}}a_{12}\\
&\qquad + (e^{-g_s}-1)Qa_{12}\partial_{a_{12}} + \mathcal{O}(a^2)\\
H(c_{22}) &= e^{\hat{p}} - 1 - Q\partial_{a_{21}} + e^{\hat{p}}\partial_{a_{12}}\partial_{a_{21}} + (e^{g_s}-1)Qa_{12}\\
&\qquad + (e^{g_s}-1)e^{\hat{p}}a_{12}\partial_{a_{12}} + \mathcal{O}(a^2),
\end{aligned}$$

where $\mathcal{O}(a)$ represents order in the variables $a = (a_{12}, a_{21})$. The factors $(e^{g_s} - 1)$ in front of disks with additional positive punctures comes from the perturbation scheme and are related to the gluing analysis in the proof of Proposition 5.4, see Ekholm and Ng [ibid.]. In close analogy with the calculation at the classical level, the operators $\partial_{a_{12}}$ and $\partial_{a_{21}}$ can be eliminated and we get an operator equation which after change of framing to make x correspond to the longitude of T, i.e., 0-framing, becomes

$$\begin{aligned}
\widehat{\mathrm{Aug}}_T &= e^{g_s}Q^3e^{3\hat{p}}(Q - e^{-3g_s}e^{2\hat{p}})(Q - e^{-g_s}e^{\hat{p}})\cdot 1\\
&\quad + e^{-5g_s/2}(Q - e^{-2g_s}e^{2\hat{p}})\Big((e^{2g_s}e^{2\hat{p}} + e^{3g_s}e^{2\hat{p}} - e^{3g_s}e^{\hat{p}} + e^{4g_s})Q^2\\
&\qquad\qquad - (e^{g_s}e^{3\hat{p}} + e^{3g_s}e^{2\hat{p}} + e^{g_s}e^{2\hat{p}})Q + e^{4\hat{p}}\Big)\cdot e^{\hat{x}}\\
&\quad + (Q - e^{-g_s}e^{2\hat{p}})(e^{\hat{p}} - e^{g_s})\cdot e^{2\hat{x}},
\end{aligned}$$

in agreement with the recursion relation of the colored HOMFLY-PT in Garoufalidis, Lauda, and Le [2016].

CONSTRUCTING GROUP ACTIONS ON QUASI-TREES

Koji Fujiwara (藤原　耕二)

Abstract

A quasi-tree is a geodesic metric space quasi-isometric to a tree. We give a general construction of many actions of groups on quasi-trees. The groups we can handle include non-elementary hyperbolic groups, CAT(0) groups with rank 1 elements, mapping class groups and the outer automorphism groups of free groups. As an application, we show that mapping class groups act on finite products of Gromov-hyperbolic spaces so that orbit maps are quasi-isometric embeddings. It implies that mapping class groups have finite asymptotic dimension.

1 Introduction

1.1 Overview. Group actions are useful in the study of infinite (discrete) groups. One example is the theory of groups acting on simplicial trees by automorphisms, called *Bass-Serre theory*, Serre [1980]. Serre observed that $SL(2,\mathbb{Z})$ properly and co-compactly acts on an infinite simplicial tree, which is embedded in the upper half plane. On the other hand he proved that if $SL(3,\mathbb{Z})$ acts on any simplicial tree by automorphisms then there is a fixed point. Using the theory, he obtained a geometric proof of the theorem by Ihara saying that every torsion-free discrete subgroup of $SL(2,\mathbb{Q}_p)$ is free.

A central idea in Geometric group theory is to use *hyperbolicity* (in the sense of Gromov) of a space to prove algebraic properties of a group that acts on it. A tree is a most elementary example of a hyperbolic space. This method created the theory of *hyperbolic groups*, Gromov [1987]. Another example is an approach by Masur-Minsky to the mapping class group of a surface using the hyperbolicity of the curve complex of the surface. We will rely on their theory for our application.

This note is a survey of the work by Bestvina, Bromberg, and Fujiwara [2015], which uses *quasi-trees* to study groups. A quasi-tree is a geodesic metric space that is *quasi-isometric* to (ie, "looks like", see the precise definition later) a simplicial tree. A quasi-tree

I would like to thank my parents. This work is supported by KAKENHI (23244005, 15H05739).

Keywords: quasi-trees, projection complex, mapping class groups, hyperbolic groups, asymptotic dimension.

is always hyperbolic in the sense of Gromov. There are many advantages in this approach. One is that quasi-trees are more flexible than trees, so that there are in fact more groups that act on quasi-trees than on trees. Since quasi-trees are hyperbolic, many techniques and results that are obtained for groups acting on hyperbolic spaces apply, but moreover, we sometimes obtain stronger conclusions since quasi-trees are special and easier to handle.

Also, we introduce new methods to produce quasi-trees, called *projection complex*, equipped with an isometric group action by a given group. For that we only need to check a small set of axioms, which are satisfied by many examples (see Examples 4.3), including *hyperbolic groups*, mapping class groups and the outer automorphism group $Out(F_n)$ of a free group F_n of rank n, and are able to produce many actions that are sometimes hidden at a first glance. We also construct closely related space called *quasi-tree of metric spaces*. Using those constructions we prove new theorems and also recover some known ones.

1.2 Intuitive description of the main construction. To explain the idea by an example, consider a discrete group Γ of isometries of hyperbolic n-space $\mathbb{H}^n$ and let $\gamma \in \Gamma$ be an element with an axis (ie, a γ-invariant geodesic that γ acts on by a translation) $\ell \subset \mathbb{H}^n$. Denote by $\mathbf{Y}$ the set of all Γ-translates of ℓ, i.e. the set of axes of conjugates of γ. Now we will construct a quasi-tree Q with a G-action from the disjoint union of the translates of ℓ by joining pairs of translates by edges following a certain rule. We want: the resulting space Q is connected; Q looks like a tree, so Q should not contain larger and larger embedded circles (then Q is not a quasi-tree); so that we put edges as few as possible just enough to make Q to be connected; the connecting rule is G-equivariant to have a G action on Q. Intuitively, the rule we will use is simple. For elements (ie, lines) $A, B \in \mathbf{Y}$ we do not want to join them when there is another element C that is "between A and B" (then we would rather join A and C, and also C and B). So, we join A and B by an edge only when there is no element C between A and B.

But how do we define that "C is between A and B"? When $A, C \in \mathbf{Y}$, $A \neq C$, denote by $\pi_C(A) \subset C$ the image of A under the nearest point projection $\pi_C : \mathbb{H}^n \to C$. We call this set the *projection* of A to C and we observe:

(P0) The diameter $\operatorname{diam} \pi_C(A)$ is uniformly bounded by some constant $\theta \geq 0$, independently of $A, C \in \mathbf{Y}$.

This is a consequence of discreteness of G, because a line in $\mathbb{H}^n$ will have a big projection to another line only if the two lines have long segments with small Hausdorff distance between them, so that there is a uniform upper bound unless they coincide, since G is discrete. When $B \neq A \neq C$ we define a "distance" by

$$d_C^{\pi}(A, B) = \operatorname{diam}(\pi_C(A) \cup \pi_C(B)).$$

Now fix a constant $K >> \theta$. We say C is between A and B if $d^{\pi}_{C}(A, B) \geq K$. (In fact we slightly perturb the distance functions d^{π}_{C} at once in advance.) Now the rule is that if there is no such $C \in \mathbf{Y}$ then we join A and B by an edge connecting $\pi_A(B)$ and $\pi_B(A)$, which are small (imagine θ is small) sets by (P0). The resulting space, $\mathcal{C}(\mathbf{Y})$, turns out to be a quasi-tree.

One may think this example is special since each A is a line. Of course, $\mathcal{C}(\mathbf{Y})$ would not be a quasi-tree if $A \in \mathbf{Y}$ were not a quasi-tree since A is embedded in $\mathcal{C}(\mathbf{Y})$. By collapsing each A to a point in $\mathcal{C}(\mathbf{Y})$ we obtain a new space $\mathcal{P}(\mathbf{Y})$ (then the geometry of A becomes irrelevant), which is again a quasi-tree. Our discovery is that if we start with a given abstract data: a set $\mathbf{Y}$ and maps(projections) between any two elements in $\mathbf{Y}$ satisfying a small set of "Axioms", and construct a space $\mathcal{P}(\mathbf{Y})$ by the rule we explained, $\mathcal{P}(\mathbf{Y})$ is always a quasi-tree. It does not matter how we obtain the data as long as it satisfies the axioms.

The technical difficulty in the construction is to perturb the distance functions d^{π}_{A} by a bounded amount as we said (see Section 2.1 for details). Without this perturbation the resulting space may contain larger and larger loops and is not a quasi-tree even if the initial data satisfies the axioms (see Bestvina, Bromberg, and Fujiwara [2015] for a counter example).

1.3 Axioms for quasi-tree of metric spaces and projection complex. We continue with the example, and explain the Axioms behind the construction. First, the distance function d^{π}_{Y} is always symmetric and satisfies the triangle inequality (nothing to do with discreteness of G):

(P3) $d^{\pi}_{Y}(X, Z) = d^{\pi}_{Y}(Z, X)$;

(P4) $d^{\pi}_{Y}(X, Z) + d^{\pi}_{Y}(Z, W) \geq d^{\pi}_{Y}(X, W)$,

but in general we have $d^{\pi}_{A}(B, B) > 0$, so this is a pseudo-distance function (we frequently drop "pseudo") . We observe further, again since Γ is discrete, for a perhaps larger constant θ:

(P1) For any triple $A, B, C \in \mathbf{Y}$ of distinct elements, at most one of the following three numbers is greater than θ:

$$d^{\pi}_{A}(B, C), d^{\pi}_{B}(A, C), d^{\pi}_{C}(A, B).$$

(P2) For any $A, B \in \mathbf{Y}$ the following set is finite:

$$\{C \in \mathbf{Y} \mid d^{\pi}_{C}(A, B) > \theta\}.$$

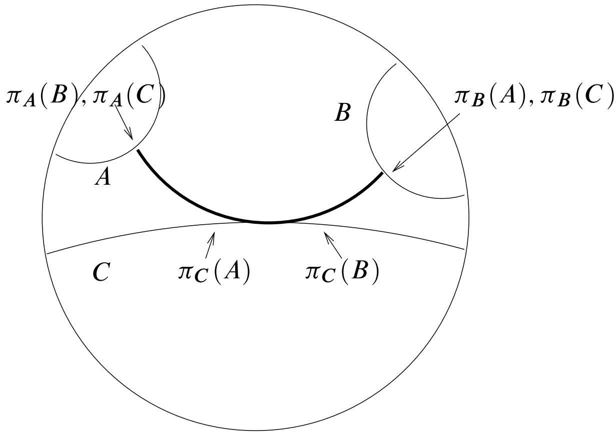

Figure 1: Axiom (P1). The bold line is the shortest segment between A and B in $\mathbb{H}^n$. Note that C and this segment stay close for a long time, therefore $d_C^\pi(A, B)$ is large, while $d_A^\pi(B, C)$ and $d_B^\pi(A, C)$ are small. (Figure from Bestvina, Bromberg, and Fujiwara [2015])

For an even more basic example where (P0)-(P2) hold with $\theta = 0$, consider the Cayley tree (Cayley graph) of the free group $F_2 = \langle a, b \rangle$ and for $\mathbf{Y}$ take the F_2-orbit of the axis of a.

We can show that (P0), (P1) and (P2) are sufficient *Axioms* for the space we construct to be a quasi-tree. We start with a collection of metric spaces $\mathbf{Y}$ and a collection of subsets $\pi_A(B) \subset A$ for $A \neq B$ with d_A^π satisfying (P0)-(P2). Note that (P3) and (P4) always hold for d_A^π. Then we construct a space by putting edges between (disjoint union of) the metric spaces in $\mathbf{Y}$ following our rule. Here is a summary theorem. (1) applies to the $\mathbb{H}^n$ example. In a way we "reconstruct" the ambient space with the group action from $\mathbf{Y}$. But the punch line is that we do not have to start with an ambient space and its subspaces in the theorem.

Theorem 1.1. *Bestvina, Bromberg, and Fujiwara [2015] Suppose $\mathbf{Y}$ is a collection of geodesic metric spaces and for every $A, B \in \mathbf{Y}$ with $A \neq B$ we are given a subset $\pi_A(B) \subset A$ such that (P0)-(P2) hold for the distance functions d_A^π for a constant θ.*

Then there is a geodesic metric space $\mathcal{C}(\mathbf{Y})$ that contains isometrically embedded, totally geodesic, pairwise disjoint copies of each $A \in \mathbf{Y}$ such that for all $A \neq B$ the nearest point projection of B to A in $\mathcal{C}(\mathbf{Y})$ is a uniformly bounded set uniformly close to $\pi_A(B)$ such that

(1) *The construction is equivariant, namely, if a group G acts isometrically on the disjoint union of the spaces in $\mathbf{Y}$ preserving projections, i.e., $g(\pi_A(B)) = \pi_{gA}(gB)$ for any $A, B \in \mathbf{Y}$ and $g \in G$, then the group action extends to $\mathcal{C}(\mathbf{Y})$.*

(2) *The quotient $\mathcal{C}(\mathbf{Y})/\mathbf{Y}$ obtained by collapsing the embedded copies of each $Y \in \mathbf{Y}$ to a point is a quasi-tree.*

Some explanations are in order. A subset $\mathcal{Y} \subset \mathcal{X}$ is *totally geodesic* if any geodesic in $\mathcal{X}$ joining two points in $\mathcal{Y}$ is contained in $\mathcal{Y}$. The space $\mathcal{C}(\mathbf{Y})$ is called a *quasi-tree of metric spaces*. Its construction will depend on the choice of a sufficiently large parameter $K >> \theta$, and it would be more precise to denote the space by $\mathcal{C}_K(\mathbf{Y})$. If $K < K'$ there is a natural Lipschitz map $\mathcal{C}_K(\mathbf{Y}) \to \mathcal{C}_{K'}(\mathbf{Y})$ which is in general not a quasi-isometry, and in fact unbounded sets may map to bounded sets.

The space $\mathcal{C}(\mathbf{Y})/\mathbf{Y}$ is called the *projection complex*, denoted by $\mathcal{P}(\mathbf{Y}) = \mathcal{P}_K(\mathbf{Y})$, which depends on K. We can think of the quasi-tree of metric spaces $\mathcal{C}(\mathbf{Y})$ as being obtained from $\mathcal{P}(\mathbf{Y})$, which is a quasi-tree by (2), by blowing up vertices to corresponding metric spaces. This explains the terminology.

Many properties that hold uniformly for the spaces in $\mathbf{Y}$ carry over to $\mathcal{C}(\mathbf{Y})$. For example (there will be the item (iii) later):

Theorem 1.2. *Bestvina, Bromberg, and Fujiwara [ibid.]. Let $\mathcal{C}(\mathbf{Y})$ be the quasi-tree of metric spaces $\mathbf{Y}$ constructed in Theorem 1.1.*

(i) *If each $X \in \mathbf{Y}$ is isometric to $\mathbb{R}$ then $\mathcal{C}(\mathbf{Y})$ is a quasi-tree; more generally, if all $X \in \mathbf{Y}$ are quasi-trees with a uniform bottleneck constant then $\mathcal{C}(\mathbf{Y})$ is a quasi-tree.*

(ii) *If each $X \in \mathbf{Y}$ is δ-hyperbolic with the same δ, then $\mathcal{C}(\mathbf{Y})$ is hyperbolic.*

Here, a geodesic metric space X satisfies the *bottleneck property* if there exists $\Delta \geq 0$ such that for any two points $x, y \in X$ the midpoint z of a geodesic between x and y satisfies the property such that any path from x to y intersects the Δ-ball centered at z. The constant Δ is called the *bottleneck constant*. Manning [2005] showed that X satisfying the bottleneck property is equivalent to X being a quasi-tree. Note that (i) in particular says that the space $\mathcal{C}(\mathbf{Y})$ obtained from an orbit of axes in $\mathbb{H}^n$ as in the example is a quasi-tree and not (quasi-isometric to) $\mathbb{H}^n$.

1.4 Asymptotic dimension.

We give another example of a property that descends from spaces in $\mathbf{Y}$ to $\mathcal{C}(\mathbf{Y})$. The notion of *asymptotic dimension* was introduced by Gromov Gromov [1993] as a large-scale analog of the covering dimension.

Definition 1.3 (Asymptotic dimension). A metric space X has *asymptotic dimension* $\operatorname{asdim}(X) \leq n$ if for every $R > 0$ there is a covering of X by uniformly bounded sets such that every metric R-ball intersects at most $n+1$ of the sets in the cover. More generally, a collection of metric spaces has asdim at most n *uniformly* if for every R there are covers of each space as above whose elements are uniformly bounded over the whole collection.

In **Theorem 1.2** we also have:

(iii) *If the collection* $\mathbf{Y}$ *has* asdim $\leq n$ *uniformly, then* $\text{asdim}(\mathcal{C}(\mathbf{Y})) \leq n+1$.

As an application we have:

Theorem 1.4. *Bestvina, Bromberg, and Fujiwara [2015]. Let Σ be a closed orientable surface, possibly with punctures, and $MCG(\Sigma)$ its mapping class group. Then* $\text{asdim}(MCG(\Sigma)) < \infty$.

The *Coarse Baum-Connes conjecture* (for torsion free subgroups of finite index) and therefore the *Novikov conjecture* for $MCG(\Sigma)$ follows from Theorem 1.4 by a work of Yu [1998], cf. Roe [2003]. Various other statements that imply the Novikov conjecture for $MCG(\Sigma)$ were known earlier (see Kida [2008], Hamenstädt [2009], and J. A. Behrstock and Minsky [2008]).

1.5 Some basic notions. We collect some standard definitions we use.

Let X, Y be two metric spaces. We often denote the distance between x, y by $|x-y|$. A map $f : X \to Y$ is a (K, L)-*quasi-isometric embedding* if for all points $x, y \in X$,

$$\frac{|x-y|}{K} - L \leq |f(x) - f(y)| \leq K|x-y| + L.$$

If it additionally satisfies that for all point $y \in Y$ there exists $x \in X$ such that $|y - f(x)| \leq L$, then we say f is a *quasi-isometry*, and X and Y are *quasi-isometric*. In those definitions, only the existence of constants K, L is important, and we sometimes omit them. Quasi-isometry is an equivalence relation among metric spaces.

Suppose a group G acts on a metric space X by isometries. We say the action is *co-compact/co-bounded* if the quotient is compact/bounded. We say the action is *proper* (or, *properly discontinuous*) if for any $R > 0$ and $x \in X$ the number of elements $g \in G$ with $|x - gx| \leq R$ is finitely many.

Let G be a finitely generated group and S a finite set of generators. We assume that if $s \in S$ then $s^{-1} \in S$. We form a graph as follows: there is a vertex for each element $g \in G$. We join two vertices $g, h \in G$ if there is $s \in S$ with $h = gs$. The graph is called a *Cayley graph* of G, denoted by $Cay(G, S)$. Since S generates G, the graph $Cay(G, S)$ is connected. G acts on the graph by automorphisms from the left: An element $g \in G$ sends a vertex $h \in G$ to a vertex $gh \in G$. By declaring each edge has length 1, $Cay(G, S)$ becomes a geodesic space. The action by G is proper and co-compact. The distance between the identity and $g \in G$ is denoted by $|g|$ and called the *word norm* of g.

Let $\Delta(a,b,c)$ be a geodesic triangle in the hyperbolic plane $\mathbb{H}^2$, where the three sides a,b,c are geodesics. Gauss-Bonnet theorem says that the area of Δ is at most π. It then follows that each side is contained in the 2-neighborhood of the union of the other two sides. Gromov turned this uniform thinness of geodesic triangles into a definition. A geodesic metric space X is *δ-hyperbolic* for a constant δ if all geodesic triangle in X is *δ-thin*, namely, each side is contained in the δ-neighborhood of the union of the other two. We often suppress δ and say X is *hyperbolic*. The hyperbolic spaces $\mathbb{H}^n$ are hyperbolic, trees are hyperbolic, but the Euclidean plane is not hyperbolic. A finitely generated group is a *(word) hyperbolic group* if it acts on a hyperbolic space properly and co-compactly by isometries, equivalently, if its Cayley graph is hyperbolic. If G contains $\mathbb{Z}^2$ then it is not hyperbolic. Another important class of spaces is of *CAT(0) spaces* (or *Hadamard spaces*), which are, roughly speaking, complete, simply connected, and "non-positively curved" geodesic spaces. See for example Ballmann [1995]. This class is a good source of examples.

The *translation length* $\tau(g)$ of an isometry $g : X \to X$ of a metric space X is

$$\tau(g) := \lim_{k\to\infty} \frac{d_X(x, g^k(x))}{k}.$$

The limit exists and is independent of $x \in X$. We say the isometry is *hyperbolic* if $\tau(g) > 0$.

We organize the rest of this note as follows: in Section 2 we define projection complex and quasi-tree of metric spaces from the beginning, which is independent from Section 1 (so that there is an overlap). In Section 3 we discuss application to mapping class groups. In Section 4 we give many examples that satisfy the axioms, and also discuss other applications.

Acknowledgments. I would like to thank Mladen Bestvina and Kenneth Bromberg. Most of the work presented here is from a long collaboration with them. I am grateful to Bestvina for reading a draft and giving useful suggestions.

2 Definition of projection complex and quasi-tree of metric spaces

We start over and will give a precise setting and conditions for our construction, Bestvina, Bromberg, and Fujiwara [2015]. To define the projection complex, we do not really need the projections $\pi_A(B)$ as in the example on $\mathbb{H}^n$; we only need the pseudo-distances $d_C^\pi(A,B)$.

2.1 Projection complex axioms. Let $\mathbf{Y}$ be a set, and assume that for each $Y \in \mathbf{Y}$ we have a function

$$d_Y^\pi : (\mathbf{Y} \setminus \{Y\}) \times (\mathbf{Y} \setminus \{Y\}) \longrightarrow [0, \infty).$$

Let $\theta \geq 0$ be a constant. Assume the following (PC1) - (PC4) are satisfied (they are same as (P1)-(P4) except for the order). We call them *projection complex axioms*.

(PC 1) $d_Y^\pi(X, Z) = d_Y^\pi(Z, X)$ for all distinct X, Y, Z;

(PC 2) $d_Y^\pi(X, Z) + d_Y^\pi(Z, W) \geq d_Y^\pi(X, W)$ for all distinct X, Y, Z, W (triangle inequality);

(PC 3) $\min\{d_Y^\pi(X, Z), d_Z^\pi(X, Y)\} \leq \theta$ for all distinct X, Y, Z;

(PC 4) for all $X, Z \in \mathbf{Y}$, $\#\{Y | d_Y^\pi(X, Z) > \theta\}$ is finite.

As an analog of (P0), uniform boundedness of the projections $\pi_Y(Z)$, we could require (PC0), but this will not be used to define a projection complex.

(PC 0) $d_Y^\pi(Z, Z) \leq \theta$ for all distinct Y, Z.

Before we define the projection complex, there is one technical difficulty we have to deal with. Given distance functions that satisfy (PC1) - (PC4), we modify them by a bounded amount for our purpose. This modification is a key to define an order on a set $\mathbf{Y}_K(X, Z)$ we define later.

For $X, Z \in \mathbf{Y}$ with $X \neq Z$ let $\mathcal{H}(X, Z)$ be the set of pairs $(X', Z') \in \mathbf{Y} \times \mathbf{Y}$ with $X' \neq Z'$ such that one of the following four holds:

- both $d_X^\pi(X', Z'), d_Z^\pi(X', Z') > 2\theta$;
- $X = X'$ and $d_Z^\pi(X, Z') > 2\theta$;
- $Z = Z'$ and $d_X^\pi(X', Z) > 2\theta$;
- $(X', Z') = (X, Z)$.

We then define the modified distance functions

$$d_Y : (\mathbf{Y} \setminus \{Y\}) \times (\mathbf{Y} \setminus \{Y\}) \to [0, \infty)$$

by $d_Y(X, Z) = 0$ if Y is contained in a pair in $\mathcal{H}(X, Z)$, and otherwise,

$$d_Y(X, Z) = \inf_{(X', Z') \in \mathcal{H}(X, Z)} d_Y^\pi(X', Z').$$

For example, if $d^\pi_Y(W,Z) > 2\theta$, then $(W,Z) \in \mathcal{H}(Y,Z)$ and $d_W(Y,Z) = 0$. Note that it is clear from the definition that $d_Y(X,Z) \le d^\pi_Y(X,Z)$ and therefore (PC3) and (PC4) still hold for d_Y with the same constant. (PC1) is trivial, but we have to modify (PC2), the triangle inequality.

One can prove that the modification is bounded, namely, for distinct X, Y, Z,

$$d^\pi_Y(X,Z) - 2\theta \le d_Y(X,Z) \le d^\pi_Y(X,Z).$$

It then follows from (PC2) that

(PC 2') $d_Y(X,Z) + d_Y(Z,W) + 4\theta \ge d_Y(X,W)$ (modified triangle inequality)

For a constant $K \ge \theta$ and distinct Y, Z we define a set, which is finite by (PC 4), as follows:

$$\mathbf{Y}_K(X,Z) = \{Y \in \mathbf{Y} | d_Y(X,Z) > K\}.$$

We say an element Y in $\mathbf{Y}_K(X,Z)$ is *between* X, Z. We are ready to define the projection complex.

Definition 2.1 (Projection complex). For a constant $K > 0$, the *projection complex* $\mathcal{P}_K(\mathbf{Y})$ is the following graph. The vertex set of $\mathcal{P}_K(\mathbf{Y})$ is $\mathbf{Y}$. Two distinct vertices X and Z are connected with an edge (of length 1) if $\mathbf{Y}_K(X,Z)$ is empty. Denote the distance function for this graph by $d(\ ,\ )$.

Note that for different values of K the spaces $\mathcal{P}_K(\mathbf{Y})$ are not necessarily quasi-isometric to each other (the vertex sets are the same, but for larger K there are more edges).

Here is the first main theorem.

Theorem 2.2. *Bestvina, Bromberg, and Fujiwara [2015, Theorem 3.16] Suppose functions $d^\pi_Y, Y \in \mathbf{Y}$ satisfy (PC1)- (PC4). Modify them to d_Y. If K is sufficiently large compared to θ, then the projection complex $\mathcal{P}_K(\mathbf{Y})$ is a quasi-tree.*

We make some comments on the proof. Suppose K is large. We first show that for X, Z, the subset $\mathbf{Y}_K(X,Z) \subset \mathbf{Y}$ gives a path between them in $\mathcal{P}_K(\mathbf{Y})$. In particular it implies

$$d(X,Z) \le |\mathbf{Y}_K(X,Z)| + 1.$$

In fact this path is a *quasi-geodesic* (ie, a quasi-isometric embedding of a segment) between the two points. This is the part where the modification to d_Y plays a role (without a modification the theorem is not true). Using the distances d_Y, we put a total order on $\mathbf{Y}_K(X,Z) \cup \{X,Z\}$ with X least and Z greatest: $Y < W$ if $d_W(X,Y) < \theta$. It takes some work to show this is well defined and gives a total order on the set $\mathbf{Y}_K(X,Z) \cup \{X,Z\}$. We then show this set form a path in $\mathcal{P}_K(\mathbf{Y})$ in this order. Recall the $\mathbb{H}^n$ example from the introduction. For axes X, Z, let σ be the shortest geodesic between them in $\mathbb{H}^n$. Then the set $\mathbf{Y}_K(X, Z)$ is roughly the collections of axes in $\mathbf{Y}$ that stay close to σ at least for distance K (cf. Figure 1). Because of (P 0), there is a bounded overlap between any two of them, so that there is an obvious order on $\mathbf{Y}_K(X, Z)$ in this picture.

There is also a lower bound of $d(X, Z)$. For a sufficiently large K' compared to K (roughly $5K$ is enough), if $Y \in \mathbf{Y}_{K'}(X, Z)$ then every geodesic from X to Z in $\mathcal{P}_K(\mathbf{Y})$ contains Y. This implies

$$d(X, Z) \geq |\mathbf{Y}_{K'}(X, Z)| + 1.$$

One can say that if X and Z has a "large projection" (ie, $\geq K'$) to Y, then every geodesic from X to Z has to pass Y.

2.2 Quasi-tree of metric spaces. To define a quasi-tree of metric spaces we need that each $Y \in \mathbf{Y}$ is a metric space. Here is the precise setup. Let $\mathbf{Y} = \{(Y, \rho_Y)\}$ be a collection of metric spaces and for each distinct $Y, Z \in \mathbf{Y}$ assume that we have sets $\pi_Y(Z) \subseteq Y$ and $\pi_Z(Y) \subseteq Z$. The π_Y are called *projection maps*. Fix a constant $\theta > 0$. Assume that for any $X \neq Y$,

(P 0) $\operatorname{diam}(\pi_X(Y)) \leq \theta$.

For any $X \neq Y \neq Z$, set

$$d_Y^\pi(X, Z) = \operatorname{diam}(\pi_Y(X) \cup \pi_Y(Z)),$$

where diam is ρ_Y-diameter. Then d_Y^π satisfy (PC1) and (PC2) trivially. Notice that (P0) implies (PC0). We assume that they also satisfy (PC3) and (PC4). Families of metric spaces with projection maps satisfying (PC0), (PC3) and (PC4) occur naturally in many contexts, see Examples 4.3.

Definition 2.3 (Quasi-tree of metric space). For $K > 0$, we build the *quasi-tree of metric spaces*, $\mathcal{C}_K(\mathbf{Y})$, by taking the union of the metric spaces in $\mathbf{Y}$ with an edge of length $L > 0$ (L depends on K) connecting every pair of points in $\pi_Y(X)$ and $\pi_X(Y)$ if $d_{\mathcal{P}_K(\mathbf{Y})}(X, Y) = 1$.

In other words, if $\mathbf{Y}_K(X, Y)$ is empty, we put edges between the sets $\pi_X(Y) \subset X$ and $\pi_Y(X) \subset Y$. $\mathcal{C}_K(\mathbf{Y})$ is a metric space. For example if each Y is a path metric space (which is the case in our applications), then $\mathcal{C}_K(\mathbf{Y})$ is path connected and there is an obvious metric on it. We denote the metric by $d_{\mathcal{C}_K(\mathbf{Y})}$.

To equip a group action on $\mathcal{C}_K(\mathbf{Y})$, consider a metric ρ (that is possibly infinite) on the disjoint union of elements of $\mathbf{Y}$ by setting $\rho(x_0, x_1) = \rho_X(x_0, x_1)$ if $x_0, x_1 \in X$, for some $X \in \mathbf{Y}$; and $\rho(x_0, x_1) = \infty$ if x_0 and x_1 are in different spaces in $\mathbf{Y}$. Assume that the group G acts isometrically on $\mathbf{Y}$ with this metric and that the projections π_X are G-invariant, i.e. $\pi_{gX}(gY) = g(\pi_X(Y))$. Then G naturally acts on $\mathcal{C}_K(\mathbf{Y})$ by isometries. This occurs in most examples.

2.3 Distance formula. In $\mathcal{P}_K(\mathbf{Y})$ we gave upper and lower bounds of $d(X, Z)$ using $\mathbf{Y}_K(X, Z)$ and $\mathbf{Y}_{K'}(X, Z)$. There are similar formula in $\mathcal{C}_K(\mathbf{Y})$ as follows. The projection $\pi_Y(X)$ is defined for $X \in \mathbf{Y}\backslash\{Y\}$, but since Y is a metric space in the current setting we extend the projection to each point $x \in X$ by $\pi_Y(x) = \pi_Y(X)$. Also, for a point $y \in Y$, we set $\pi_Y(y) = \{y\}$. The projection π_Y is now defined on $\mathcal{C}_K(\mathbf{Y})$, except for the edges.

Remark 2.4. Since $\mathcal{C}_K(\mathbf{Y})$ is a metric space we can also define $\pi_Y(x)$ using the nearest point projection. Then the Hausdorff distance between the sets we obtain in Y by the two different definitions is bounded. It is a part of Theorem 1.1.

As before, we then set $d_Y(x, z) = \operatorname{diam}(\pi_Y(x) \cup \pi_Y(z))$ for $x, z \in \mathcal{C}_K(\mathbf{Y})$. We also define

$$\mathbf{Y}_J(x, z) = \{Y \in \mathbf{Y} | d_Y(x, z) > J\}.$$

It is possible for X or Z, where $x \in X$ and $z \in Z$, to be in $\mathbf{Y}_J(x, z)$. Here is a *distance formula* in $\mathcal{C}_K(\mathbf{Y})$.

Theorem 2.5. *Bestvina, Bromberg, and Fujiwara [2015, Theorem 4.13] Let $K' > K$ be sufficiently large. Then for $x \in X, z \in Z$ we have*

$$\frac{1}{2} \sum_{W \in \mathbf{Y}_{K'}(x,z)} d_W(x, z) \le d_{\mathcal{C}_K(\mathbf{Y})}(x, z) \le 6K + 4 \sum_{W \in \mathbf{Y}_K(x,z)} d_W(x, z).$$

Some explanation is in order. In a way the lower bound is harder to get. Recall that if $W \in \mathbf{Y}_{K'}(X, Z)$ then every geodesic γ from X to Z in $\mathcal{P}_K(\mathbf{Y})$ has to visit the vertex W. In $\mathcal{C}_K(\mathbf{Y})$ the vertex W is replaced by the metric space W, so one changes γ to a path γ' in $\mathcal{C}_K(\mathbf{Y})$ by replacing the vertex W by a geodesic in W joining the subsets $\pi_W(x), \pi_W(z)$. Since the distance between those two sets is roughly $d_W(x, z)$, after those replacement the length of the path γ' is roughly bounded below by $\sum_{W \in \mathbf{Y}_{K'}(x,z)} d_W(x, z)$, which appears in the lower bound. The above formula is an analogy of the *Masur-Minsky distance formula* for a mapping class group (see Theorem 3.6).

3 Application to mapping class groups of surfaces

The family of mapping class groups of surfaces is an interesting object to study in Geometric group theory. We discuss applications of our construction to mapping class groups.

We recommend a book Farb and Margalit [2012] for a general reference of the theory of mapping class groups and a survey Minsky [2006] for the Masur-Minsky theory.

3.1 Definitions. Let $\Sigma = \Sigma_{g,b}$ be an orientable compact surface with genus g and b boundary components. The group of orientation preserving homeomorphisms of an oriented surface Σ to itself, taken modulo isotopy, is called the *mapping class group* of Σ, denoted by $MCG(\Sigma)$. $MCG(\Sigma)$ is a finitely presented group. An *essential* simple closed curve in Σ is an embedded circle in Σ that is homotopically non-trivial and not homotopic into the boundary (non-peripheral). We may just say simple closed curves. A mapping class, ie, an element in $MCG(\Sigma)$, that preserves a system of disjoint essential simple closed curves on Σ is called *reducible*. For example Dehn twists are reducible. Thurston classified the nontrivial conjugacy classes in $MCG(\Sigma)$ as reducible, finite-order, and *pseudo-Anosov*. A pseudo-Anosov mapping class does not preserve any finite set of closed curves, but instead preserves a pair of *measured geodesic laminations*.

For example, $MCG(\Sigma_{0,0})$ is trivial. For $\Sigma_{1,0}, \Sigma_{1,1}$, $MCG(\Sigma)$ is isomorphic to $SL(2,\mathbb{Z})$, and $MCG(\Sigma_{0,4})$ maps to $PSL(2,\mathbb{Z})$ with the kernel $(\mathbb{Z}/2\mathbb{Z})^2$. In particular they are hyperbolic groups. But $MCG(\Sigma)$ is not word-hyperbolic if $g \geq 2$ since it contains $\mathbb{Z}^2$ generated by commuting Dehn twists. One natural metric space $MCG(\Sigma)$ acts on by isometries is *the Teichmüller space*. The Teichmüller space for $\Sigma_{g,0}, g > 0$ is diffeomorphic to the Euclidean space of dimension $6g-6$, with the Teichmüller metric. The action by $MCG(\Sigma)$ is proper but not co-compact. There are a lot of negative curvature aspects on a Teichmuller space (cf. Minsky [1996]), but it is not δ-hyperbolic.

3.1.1 Curve graph. We recall another object which $MCG(\Sigma)$ acts on, and is useful for our approach. Let $\mathcal{C}_0(\Sigma)$ be the set of homotopy classes of essential simple closed curves and properly embedded simple arcs on Σ (when $\partial\Sigma$ is not empty) that are essential (not homotopic into $\partial\Sigma$). We then define the *curve graph*, $\mathcal{C}(\Sigma)$, to be the 1-complex obtained by attaching an edge to a pair of disjoint closed curves or arcs in $\mathcal{C}_0(\Sigma)$.

Remark 3.1. The graph we have constructed is often called the *curve and arc graph*, Masur and Minsky [2000]. The usual curve graph, whose vertices are only curves, is quasi-isometric to the curve and arc graph and so we will use the less cumbersome name of curve graph.

$\mathcal{C}(\Sigma)$ is connected, and $MCG(\Sigma)$ naturally acts on $\mathcal{C}(\Sigma)$ by automorphisms since homeomorphisms preserve disjointness, and the quotient is finite. The action is far from proper, but the homomorphism $MCG(\Sigma) \to Aut(\mathcal{C}(\Sigma))$ has at most finite kernel, and the index of the image is finite in $Aut(\mathcal{C}(\Sigma))$, (Ivanov, Luo, Korkmaz).

Masur and Minsky [1999], Masur and Minsky [2000] studies the geometry of a curve complex, and their work has a significant impact on the study of hyperbolic 3-manifolds and mapping class groups. The following result is the first important theorem (cf. Bestvina and Fujiwara [2007] for a non-orientable Σ). More recently, it is proved that δ is uniform for all Σ, Hensel, Przytycki, and Webb [2015].

Theorem 3.2. *$\mathcal{C}(\Sigma)$ is a δ-hyperbolic space, and $g \in MCG(\Sigma)$ is a hyperbolic isometry on $\mathcal{C}(\Sigma)$ if and only if g is a pseudo-Anosov element.*

Moreover, for a given surface Σ, there is a uniform positive lower bound on the translation length of a pseudo-Anosov element.

3.2 Applications. We explain a setting for us to apply projection complex to the study of $MCG(\Sigma)$. A set $\mathbf{Y}$ we take is very different from the $\mathbb{H}^n$ example in the introduction. $\mathbf{Y}$ is not a collection of subsets in some hyperbolic space, say, the curve graph of Σ, but it will be a certain collection of (isotopy classes of) *essential* subsurfaces $Y \subset \Sigma$. A subsurface is *essential* if it is π_1-injective and non-peripheral. To define a quasi-tree of metric spaces, we also need a metric space for each Y (here, we distinguish Y and the metric space associated to it). For that we take the curve complex $\mathcal{C}(Y)$ for each Y. We use *subsurface projection* to define projections between two subsurfaces in $\mathbf{Y}$, then apply our method after checking the axioms.

3.2.1 Subsurface projection. We say two essential subsurfaces *overlap* if $\partial Y \cap \partial Z \neq \emptyset$ (this means that the intersection is nonempty even after any isotopy). Following Masur and Minsky [2000], if Y and Z overlap, we define the *subsurface projection* $\pi_Y(Z) \subset \mathcal{C}(Y)$ by taking the intersection of ∂Z with Y and identifying homotopic curves and arcs. Also, when β is a simple closed curve that cannot be isotoped to be disjoint from Y, we similarly define a projection $\pi_Y(\beta) \subset \mathcal{C}(Y)$.

Also, we will need the curve graph for an essential simple closed curve γ. The definition has a somewhat different flavor and we do not recall a definition here. $\mathcal{C}(\gamma)$ is quasi-isometric to $\mathbb{Z}$, and the Dehn twist along γ, which leaves γ invariant, acts by a hyperbolic isometry. We will call γ a subsurface too. When a curve γ and the boundary of a subsurface Y intersect, we already defined $\pi_Y(\gamma)$ but we will also need $\pi_\gamma(Y) \subset \mathcal{C}(\gamma)$. More generally Y can be a curve. See for example Bestvina, Bromberg, and Fujiwara [2015, §5.1] for the precise definition of $\mathcal{C}(\gamma)$ and the projection.

Now we want to check that the projection complex axioms are satisfied.

Theorem 3.3. *Let $\mathbf{Y}$ be a collection of essential subsurfaces in Σ such that any two distinct subsurfaces intersect. For distinct $X, Y, Z \in \mathbf{Y}$ define $d^\pi_Y(X, Z) = \mathrm{diam}(\pi_Y(X) \cup \pi_Y(Z))$, where the diameter is measured in $\mathcal{C}(Y)$. Then $\{d^\pi_Y\}$ satisfy (P0)-(P2) for some constant $\theta(\Sigma)$, which depends only on Σ.*

Thus for every such family $\mathbf{Y}$ we obtain the projection complex $\mathcal{P}_K(\mathbf{Y})$ for a large K, and the quasi-tree of curve complexes $\mathcal{C}_K(\mathbf{Y})$ for $\{\mathcal{C}(Y), Y \in \mathbf{Y}\}$. We make comments on verifying the axioms (P0)-(P2) in this setting. Axiom (P0) follows easily from definitions. Axiom (P1) was established by J. A. Behrstock [2006]. We sometimes refer to Axiom (P1) in general as *Behrstock's inequality*. Axiom (P2) is by Masur-Minsky (a consequence of the Theorem 4.6 and Lemma 4.2 in Masur and Minsky [2000]). A central idea in Masur and Minsky [ibid.] is the notion of a *hierarchy* and this is used in the original verification of (P1) and (P2). This is a powerful tool but it is complicated to define and difficult to use. Leininger gave a very simple, hierarchy free proof of (P1) (see Mangahas [2010, 2013]) and also (P2) has a direct, hierarchy free proof (Bestvina, Bromberg, and Fujiwara [2015]).

3.2.2 Embedding MCG. Having Theorem 3.3, we now use Theorem 1.1 to embed the mapping class group in a *finite* product of *quasi-trees of curve complexes*. To use Theorem 3.3, we group the essential subsurfaces in Σ into finitely many subcollections $\mathbf{Y}^1, \mathbf{Y}^2, \cdots, \mathbf{Y}^k$, such that any X, Y in each family overlap, hence the projection $\pi_X(Y)$ is defined. The subcollections are the orbits of a certain subgroup $\mathcal{S}$ in $MCG(\Sigma)$, given in the following lemma.

Lemma 3.4 (Color preserving subgroup)**.** *Bestvina, Bromberg, and Fujiwara [ibid.]. There is a coloring $\phi : \mathcal{C}_0(\Sigma) \to F$ of the set of simple closed curves on Σ with a finite set F of colors so that if a, b span an edge then $\phi(a) \neq \phi(b)$. Moreover, there is a finite index subgroup $\mathcal{S}$ of the mapping class group $MCG(\Sigma)$ (where Σ is closed) such that every element of $\mathcal{S}$ preserves the colors.*

We call this subgroup *the color preserving subgroup*. Note that there are only finitely many $\mathcal{S}$-orbits of subsurfaces of Σ and any two subsurfaces in each $\mathcal{S}$-oribit overlap. Having Theorem 3.3, for each orbit $\mathbf{Y}^i$ we apply our construction to $\{\mathcal{C}(Y) | Y \in \mathbf{Y}^i\}$ and obtain $\mathcal{C}_K(\mathbf{Y}^i)$ for a large enough constant K. Everything (for example projection $\pi_X(Y)$) is done equivariantly in the construction, so that we have an equivariant orbit map

$$\Phi : MCG(\Sigma) \to \mathcal{C}_K(\mathbf{Y}^1) \times \mathcal{C}_K(\mathbf{Y}^2) \times \cdots \times \mathcal{C}_K(\mathbf{Y}^k),$$

sending $g \in MCG(\Sigma)$ to $g(o)$, where o is an arbitrary base point in the product. Note that an element in $\mathcal{S}$ preserves each factor, while other elements permute the factors. The choice of a base point will not be important for our purpose. We put the ℓ^1-metric on the product.

Since $MCG(\Sigma)$ is finitely generated, the map Φ is a Lipschitz map. Moreover, by some compactness argument regarding the set of curves on Σ, one can show Φ is a coarse embedding. A map between two metric spaces $f : X \to Y$ is a *coarse embedding* if there are constants A, B and a function $\Phi : [0, \infty) \to [0, \infty)$ with $\Phi(t) \to \infty$ as $t \to \infty$ such that

$$\Phi(|x - x'|) \leq |f(x) - f(x')| \leq A\,|x - x'| + B.$$

Moreover, it turns out that Φ is a quasi-isometric (QI) embedding. As each factor is hyperbolic by Theorem 1.2 (ii), we have the following theorem:

Theorem 3.5. *Bestvina, Bromberg, and Fujiwara [ibid.]. $MCG(\Sigma)$ equivariantly quasi-isometrically embeds in a finite product of hyperbolic spaces.*

The argument to show that Φ is a QI-embedding is by reinterpreting the remarkable Masur-Minsky distance formula (Theorem 6.12 in Masur and Minsky [2000]). To state it, let α be a finite *binding* collection of simple closed curves in Σ, ie, every essential curve in Σ intersects at least one curve in α. For x, M, the number $[x]_M$ is defined as x if $x > M$ and as 0 if $x \leq M$. Fix a finite generating set of $MCG(\Sigma)$, and let $|g|$ be the word norm.

Theorem 3.6 (Masur-Minsky distance formula)**.** *Suppose M is sufficiently large. Then there exist K, L such that for any $g \in MCG(\Sigma)$,*

$$\frac{1}{K}|g| - L \leq \sum_{Y} [d_{\mathcal{C}(Y)}(\pi_Y(\alpha), \pi_Y(g(\alpha)))]_M \leq K|g| + L,$$

where the sum is over all essential subsurfaces Y in Σ.

After arranging $K' = M$, notice that the sum in the middle of the above theorem appears in the left hand side (to be precise, we add them over all $\mathbf{Y}^i$'s) of the distance formula in a quasi-tree of metric spaces (Theorem 2.5) with $x = \pi_Y(\alpha), z = \pi_Y(g(\alpha))$. Combing those two estimates we obtain a desired estimate to show that Φ is a QI-embedding.

The following result follows easily from the definition of *asymptotic cones* (see J. Behrstock, Druţu, and Sapir [2011b,a]) and Theorem 3.5 since the asymptotic cone of a hyperbolic space is an $\mathbb{R}$-tree.

Theorem 3.7 (Behrstock-Druţu-Sapir)**.** *Every asymptotic cone of $MCG(\Sigma)$ embeds by a bi-Lipschitz map in a finite product of $\mathbb{R}$-trees.*

In fact they prove more including some information on the geometry of the image of the embedding, but their theorem does not imply Theorem 3.5. They use the notion of *tree-graded space* introduced in Druţu and Sapir [2005].

3.2.3 Asymptotic dimension. We discuss a further application to asymptotic dimension, which we stated as Theorem 1.4. We recall a few basic properties. Let $\mathcal{X}, \mathcal{Y}$ be metric spaces. If $\mathcal{X} \subset \mathcal{Y}$, with a metric on $\mathcal{Y}$ restricted to $\mathcal{X}$, then $\operatorname{asdim}(\mathcal{X}) \leq \operatorname{asdim}(\mathcal{Y})$.

We have Product Formula: $\operatorname{asdim}(\mathcal{X} \times \mathcal{Y}) \leq \operatorname{asdim}(\mathcal{X}) + \operatorname{asdim}(\mathcal{Y})$. It is straightforward from the definition that the asymptotic dimension is not only a quasi-isometric invariant but is also a *coarse invariant*. In particular $\operatorname{asdim}(\mathcal{X}) \leq \operatorname{asdim}(\mathcal{Y})$ if there exists a coarse embedding $f : \mathcal{X} \to \mathcal{Y}$ (Roe [2003]).

It is a theorem of Bell and Fujiwara [2008] that each curve complex has finite asymptotic dimension. Thus from Theorems 1.2 (iii) and 3.5 we obtain the following theorem, which motivated the work Bestvina, Bromberg, and Fujiwara [2015]:

Theorem 3.8. *(Theorem 1.4) Let Σ be a closed orientable surface, possibly with punctures. Then* $\operatorname{asdim}(MCG(\Sigma)) < \infty$.

The exact value of $\operatorname{asdim}(MCG(\Sigma))$ is unknown. Webb Webb [2015] found explicit bounds on the asymptotic dimension of curve complexes, which was improved to a linear bound by Bestvina and Bromberg [n.d.] by a different method. As a consequence, $\operatorname{asdim}(MCG(\Sigma))$ is bounded by an exponential function in the *complexity* of the surface, $\kappa(\Sigma_{g,b}) = 3g + b$.

We can also prove:

Theorem 3.9. *Bestvina, Bromberg, and Fujiwara [2015]. The Teichmüller space of Σ, with either the Teichmüller metric or the Weil-Petersson metric, has finite asymptotic dimension.*

3.2.4 Dehn twists as hyperbolic isometry. When X is a quasi-tree, an isometry with unbounded orbits is always hyperbolic, Manning [2006]. The following theorem uses the observation that the $MCG(\Sigma)$-orbit of a curve α in a surface Σ of even genus that separates Σ into subsurfaces of equal genus consists of pairwise intersecting curves. We then form a quasi-tree of metric spaces for the collection of those curves, viewed as subsurfaces as we explained (and their curve complexes), where the Dehn twist along α will be hyperbolic with an axis $\mathcal{C}(\alpha)$.

Theorem 3.10. *Bestvina, Bromberg, and Fujiwara [2015]. The mapping class groups in even genus can act on quasi-trees with at least one Dehn twist having unbounded orbits.*

In the case of odd genus one has to pass to the color preserving subgroup $\mathcal{S}$. In any case, it follows that for each Dehn twist g, the word norm $|g^n|$ has linear growth on n in $MCG(\Sigma)$ (not only in $\mathcal{S}$). Thus we recover the theorem by Farb, Lubotzky, and Minsky [2001] (the other types of elements are easy):

Theorem 3.11. *For each element g of infinite order in $MCG(\Sigma)$, the word norm $|g^n|$ has linear growth.*

3.2.5 Promoting actions to CAT(0) spaces or trees. Theorem 3.10 provides a sharp contrast to a result of Bridson [2010], who showed that in semi-simple actions of mapping class groups (of genus >2) on complete CAT(0) spaces Dehn twists are always elliptic. A group action is *semi-simple* if each element has either a bounded orbit or positive translation length.

By a *thickening* of a metric space X we mean a quasi-isometric embedding $X \to Y$. When X is a graph with edges of length 1 and $d \geq 1$, there is a particular thickening $X \to P_d(X)$ called the *Rips complex* of X. The space $P_d(X)$ is a simplicial complex with the same vertex set as X and with simplices consisting of finite collections of vertices with pairwise distance at most d. The Dehn twists that are hyperbolic in Theorem 3.10 stay hyperbolic in any thickning of the quasi-tree. Now by the theorem of Bridson, a thickning is never CAT(0). This give the following theorem:

Theorem 3.12. *Bestvina, Bromberg, and Fujiwara [2015]. There is an isometric action of a group on a graph X which is a quasi-tree such that no equivariant thickening admits an equivariant $CAT(0)$ metric. In particular, for no $d \geq 1$, the Rips complex $P_d(X)$ admits an equivariant $CAT(0)$ metric.*

We make some comments on the background. It is a long-standing open question whether every hyperbolic group acts co-compactly and properly by isometries on a CAT(0) space. One approach is to consider the Rips complex $P_d(X)$ for the Cayley graph X of the group and large d. Theorem 3.12 is not a counterexample to this approach since our X is not locally finite, but it does point out difficulties. Note that in light of Mosher, Sageev, and Whyte [2003] the quasi-trees that arise in our construction are necessarily locally infinite, since otherwise we would be able to promote our group actions on quasi-trees to group actions on simplicial trees without fixed points, which is not possible for certain groups, for example, non-elementary hyperbolic groups that have property (T), eg, uniform lattices in $\mathrm{Sp}(n,1)$.

3.2.6 Uniform uniform exponential growth of $MCG(\Sigma)$. We discuss applications to the exponential growth of groups. Let Γ be a group and S a finite set in Γ. Assume that $1 \in S$ and $S = S^{-1}$. Set

$$h(S) := \lim_{n\to\infty} \frac{1}{n} \log |S^n|.$$

Let Γ be a finitely generated group. Set $h(\Gamma) = \inf_S \{h(S) | \langle S\rangle = \Gamma\}$, where S runs over all finite generating subsets. If $h(\Gamma) > 0$ we say Γ has *uniform exponential growth*, of *growth rate* $h(\Gamma)$.

Using quasi-trees of metric spaces, Breuillard and Fujiwara [n.d.] recovers the following theorem by Mangahas, Mangahas [2010]:

Theorem 3.13 (UUEG of MCG). *Let Σ be a compact oriented surface possibly with punctures. Then there exists a constant $N(\Sigma)$ such that for any finite set $S \subset MCG(\Sigma)$ with $S = S^{-1}$, either $\langle S \rangle$ is virtually abelian or S^N contains g, h that produces a free semi-group. In particular: $h(S) \geq \frac{1}{N} \log 2$.*

It follows that for each surface Σ there is a constant $c(\Sigma) > 0$ such that for any finite set S in $MCG(\Sigma)$, $h(S) \geq c(\Sigma)$ unless $\langle S \rangle$ is virtually abelian. We say $MCG(\Sigma)$ has "uniform uniform exponential growth" (UUEG). The proof of Theorem 3.13 in Breuillard and Fujiwara [n.d.] applies a standard "Ping-Pong" argument to the actions of the color preserving subgroup $\mathcal{S}$ on the $\mathcal{C}_K(\mathbf{Y}^i)$'s. A key property of those actions is that any non-trivial element of infinite order in $\mathcal{S}$ is hyperbolic for at least one of the actions. Mangahas' proof is different and does not use our complexes. Also she proves more, that g, h produces a free group of rank-two, maybe for a larger constant $N(\Sigma)$.

3.2.7 Stable commutator length. Let G be a group, and $[G, G]$ its commutator subgroup. For an element $g \in [G, G]$, let $cl(g) = cl_G(g)$ denote the *commutator length* of g, the least number of commutators whose product is equal to g. We define $cl(g) = \infty$ for an element g not in $[G, G]$. For $g \in G$, the *stable commutator length*, $\mathrm{scl}(g) = \mathrm{scl}_G(g)$, is defined by

$$\mathrm{scl}(g) = \liminf_{n \to \infty} \frac{cl(g^n)}{n} \leq \infty.$$

It is clear that $\mathrm{scl}(g^n) = n\,\mathrm{scl}(g)$ and $\mathrm{scl}(hgh^{-1}) = \mathrm{scl}(g)$. We recommend a monograph Calegari [2009] as a reference on scl.

One theme in the subject is to classify elements g in a given group for which $scl(g) > 0$. To verify $scl(g) > 0$ for an element g, the notion of quasi-morphisms is useful. A function $H : G \to \mathbb{R}$ is a *quasi-morphism* if

$$\Delta(H) := \sup_{x,y \in G} |H(xy) - H(x) - H(y)| < \infty.$$

$\Delta(H)$ is called the *defect* of H. It is a simple exercise to show that if there exists a quasi-morphism $f : G \to \mathbb{R}$ which is unbounded on the powers of g, then $scl(g) > 0$. Also, the converse holds by so called *Bavard duality*. For example, Brooks [1981] showed that in free groups G, $scl(g) > 0$ for every nontrivial element g by constructing a quasi-morphism $f : G \to \mathbb{R}$ which is unbounded on the powers of g.

On the other hand, it is straightforward from the definition that in the following situations $cl(g^n)$ is bounded and therefore $scl(g) = 0$:

(a) g has finite order,

(b) more generally, g is *achiral*, i.e. g^k is conjugate to g^{-k} for some $k \neq 0$.

For example, Epstein and Fujiwara [1997], generalizing the Brooks construction of quasi-morphisms, proved that in hyperbolic groups G the above obstruction (b) is the only one, namely, if g is *chiral* (i.e. not achiral) then $scl(g) > 0$. They use the hyperbolicity of the Cayley graph of G to construct a suitable quasi-morphism for g.

There are three more conditions one can directly check from the definition for $cl(g^n)$ being bounded and therefore $scl(g) = 0$, cf. Bestvina, Bromberg, and Fujiwara [2016b]:

(c) $g = g_1 g_2^{-1}$ such that $g_1 g_2 = g_2 g_1$, and g_1 is conjugate to g_2,

(d) more generally, g is expressed as a commuting product $g = g_1 \cdots g_p$ such that $g_i^{n_i}$ are all conjugate for some $n_i \neq 0$ and that $\sum_i \frac{1}{n_i} = 0$,

(e) $g = g_1 \cdots g_p$ is a commuting product and $cl(g_i^n)$ are bounded for all i.

Now, we are interested in the question to decide when $scl(g) = 0$ for $g \in MCG(\Sigma)$. Some partial answers were known. Using 4-manifold invariants, Endo and Kotschick [2001] and Korkmaz [2004] prove that $scl(g) > 0$ if g is a Dehn twist. Endo and Kotschick [2007] also note the obstruction (c): in $MCG(\Sigma)$ for example this occurs if g_1, g_2 are Dehn twists in disjoint curves in the same $MCG(\Sigma)$-orbit. By contrast, Calegari and Fujiwara [2010] prove that if g is pseudo-Anosov and chiral then $scl(g) > 0$, ie, (b) is the only obstruction among pseudo-Anosov elements. They use Theorem 3.2 to construct a suitable quasi-morphism for g.

We state our result in the following vague form. See the precise statement in Bestvina, Bromberg, and Fujiwara [2016b]. It covers all cases in a unified way and in particular we recover the result on Dehn-twists.

Theorem 3.14. *Let $G < MCG(\Sigma)$ be a subgroup of finite index and $g \in G$. Then there is a characterization of elements g with $scl_G(g) > 0$ in terms of the "Nielsen-Thurston form" of g.*

The new and more complicated case is on a reducible element g. By Nielsen-Thurston form, a power of such g is written as a commuting product of powers of Dehn twists and pseudo-Anosov maps on disjoint subsurfaces on Σ, after removing a system of g-invariant curves. We argue that either $cl(g^n)$ is bounded applying (a)-(e) to the Nielsen-Thurston form of g, or else we can construct a suitable quasi-morphism on $\mathcal{S} \cap G$ to show $scl(g) > 0$. A key point is g is hyperbolic on one of the $\mathcal{C}_K(\mathbf{Y}^i)$'s. Also we prove the following theorem. The *Torelli subgroup* is the kernel of the action of $MCG(\Sigma)$ on $H_1(\Sigma, \mathbb{Z})$. It has infinite index as a subgroup.

Theorem 3.15. *If $G = \mathcal{T}$ is the Torelli subgroup in $MCG(\Sigma)$ and $1 \neq g \in G$ then $scl_G(g) > 0$.*

4 Other applications

4.1 Contracting geodesics and WPD. In the introduction we explained how we build a quasi-tree from a discrete group G of isometries of $\mathbb{H}^n$, and extracted the axioms we need. The axioms are satisfied since $\mathbb{H}^n$ is hyperbolic and G is discrete. We can relax the assumptions keeping the axioms satisfied.

Let X be a geodesic space, and $Y \subset X$ a subset. For a constant $B > 0$ we say that Y is *B-contracting* if the nearest point projection (this is a *coarse map*, ie, the image of a point may contain more than one point) to Y of any metric ball disjoint from Y has diameter bounded by B. See Bestvina and Fujiwara [2009]. For example if X is δ-hyperbolic and Y is a geodesic, then Y is 10δ-contracting. Let γ be a hyperbolic isometry of X, and let O be the γ-orbit of a point x in X. We say γ is *rank 1* if O is B-contracting for some B. This notion does not depend on the choice of x, and also, one can take an axis of γ, if it exists, instead of an orbit O for an equivalent definition, Bestvina, Bromberg, and Fujiwara [n.d.]. Any hyperbolic isometry on a hyperbolic space is rank 1.

Assume that a group Γ acts by isometries on a geodesic metric space X, and $\gamma \in \Gamma$ acts hyperbolically. We say γ is a *WPD element* if for all $D > 0$ and $x \in X$ there exists $M > 0$ such that the set

$$\{g \in \Gamma \mid d(x, g(x)) \le D, d(f^M(x), gf^M(x)) \le D\}$$

is finite. Bestvina and the author Bestvina and Fujiwara [2002] introduced this notion and proved that every pseudo-Anosov element in $MCG(\Sigma)$ is WPD on $\mathcal{C}(\Sigma)$, in view of an application to computing the *second bounded cohomology* of a subgroup A, $H_b^2(A, \mathbb{R})$, in $MCG(\Sigma)$. Note that if the action of G on X is proper, then any hyperbolic isometry is WPD. WPD stands for *weak proper discontinuous*. There is even a weaker notion, called *WWPD*, introduced in Bestvina, Bromberg, and Fujiwara [2015]. This notion is needed to prove Theorem 3.14. Delzant [2016] found an application of WWPD and the projection complex to Kähler groups. Handel and Mosher [n.d.] found an application of WWPD to computing the second bounded cohomology of subgroups in $Out(F_n)$.

The $\mathbb{H}^n$ example in the introduction is a special case of the following theorem.

Theorem 4.1. *Bestvina, Bromberg, and Fujiwara [2015], Bestvina, Bromberg, and Fujiwara [n.d.]. Let Γ act on a geodesic metric space X such that some $\gamma \in \Gamma$ is a hyperbolic WPD element. Assume the γ-orbit of some point, O, is B-contracting for some B (ie, γ is rank 1). Then the collection of parallel classes of Γ-translates of the orbit O with nearest point projections satisfies (P0)-(P2) and thus Γ acts on a quasi-tree, Q. In addition, in this action γ is a hyperbolic WPD element.*

Some explanation is in order. We say that two orbits are *parallel* if their Hausdorff distance is finite. The quasi-tree Q in the theorem is a quasi-tree of metric spaces for the

Γ-translates of O, each of which is quasi-isometric to a line. We do not assume that X is hyperbolic nor CAT(0). The main part of the proof consists of verifying (P0)-(P2) and applying Theorem 1.1 in this situation.

Remark 4.2. If an infinite geodesic γ bounds a Euclidean half plane, then clearly γ is not B-contracting for any B. This condition, *the flat half plane condition*, was important in the study of $CAT(0)$-space X, see Ballmann [1995]. If X is a locally compact $CAT(0)$-space and γ is an axis of a hyperbolic isometry g then γ being B-contracting for some B is equivalent to that γ does not bound a flat half plane, Bestvina and Fujiwara [2009]. See also Charney and Sultan [2015] for a recent development. The flat half plane conditions and the notion of rank 1 are first defined in the study of Riemannian manifolds of nonpositive sectional curvature.

Examples 4.3. The following examples all satisfy Theorem 4.1. One considers the translates of an axis, or more generally the orbit of a point, of a hyperbolic WPD element, γ.

(1) As a generalization of discrete subgroups in $\mathbb{H}^n$, Γ is a group of isometries of a δ-hyperbolic space X that contains a hyperbolic, WPD element, γ. For example, in the action of a hyperbolic group on its Cayley graph, any element of infinite order is hyperbolic and WPD. The class of hyperbolic groups contains many groups with Kazhdan's property (T) and therefore every isometric action on a simplicial tree has a fixed point (cf. de la Harpe and Valette [1989]). For the action of $MCG(\Sigma)$ on the curve complex, every pseudo-Anosov element is hyperbolic and WPD Bestvina and Fujiwara [2002].

(2) Let G be the fundamental group of a *rank-1 manifold* M, ie, M is a complete Riemannian manifold of non-positive curvature of finite volume such that the universal cover X of M is not a Riemannian product nor a symmetric space of non-compact type of rank at least two. Then G properly acts on X and by the *Rank rigidity theorem* Ballmann [1985], G contains a hyperbolic isometry γ which is rank-1.

(3) Γ is a discrete group of isometries (i.e. the group action is proper) of a $CAT(0)$-space that contains a hyperbolic rank-1 element γ. Also, pseudo-Anosov mapping classes are rank 1 elements in the action of $MCG(\Sigma)$ on the Weil-Petersson completion of Teichmüller space, which is CAT(0). Those elements are WPD although the action of $MCG(\Sigma)$ is not properly discontinuous. See Bestvina and Fujiwara [2009]. There are classifications of rank 1 elements in Coxeter groups Caprace and Fujiwara [2010], right angled Artin groups J. Behrstock and Charney [2012] and cube complexes Caprace and Sageev [2011].

(4) Γ is $MCG(\Sigma)$ acting on Teichmüller space with Teichmüller metric, and γ is a pseudo-Anosov mapping class. By Minsky [1996] the axis of γ is B-contracting. It is WPD since the action is properly discontinuous.

(5) $\Gamma = Out(F_n)$ acting on Culler-Vogtmann's Outer space CV_n Culler and Vogtmann [1986], equipped with the Lipschitz metric (not symmetric, see Algom-Kfir and Bestvina [2012]). The action is properly discontinuous. CV_n is not δ-hyperbolic. See for example Vogtmann [2006] for more information on $Out(F_n)$ and Outer space. As an analogue of a pseudo-Anosov element in a mapping class group, an element f of $Out(F_n)$ is *fully irreducible* if there are no conjugacy classes of proper free factors of F_n which are f-periodic. Such elements are hyperbolic with axes in CV_n, see Bestvina [2011], which are B-contracting (Algom-Kfir [2011]) .

(6) *The Cremona group*, G, of all birational transformations of the projective plane $\mathbb{P}^2_k$, where k is an algebraically closed field. G acts on a hyperbolic space, and it contains a hyperbolic WPD element, which was shown by Cantat and Lamy [2013]. It then follows that Cremona groups are not simple. We explain this implication in the next section.

4.2 Acylindrically hyperbolic groups and hyperbolically embedded subgroups. Dahmani, Guirardel, and Osin [2017] introduced the notion of *hyperbolically embedded subgroups*, a generalization of the concept of a *relatively hyperbolic group* (see their paper for the precise definition). They proved

Theorem 4.4. *If G is not virtually cyclic and acts on a hyperbolic space X such that G contains γ that is hyperbolic and WPD, then G contains a proper infinite hyperbolically embedded subgroup H.*

Here, we can take H to be virtually cyclic containing $\langle\gamma\rangle$. They use projection complex as a key tool in the argument. They further proved that for a sufficiently large N, γ^N normally generates a free subgroup (of maybe infinite rank) whose non-trivial elements are all hyperbolic on X. In particular G is not simple. This is the implication we mentioned in Examples 4.3 (6), and it applies to groups G in Examples 4.3 by Theorem 4.1. Also, by this method, they produce a free normal subgroup in $MCG(\Sigma)$, unless it is virtually cyclic, whose non-trivial elements are all pseudo-Anosov.

An isometric group action is *acylindrical* if for every $D > 0$ there exist $R, N > 0$ such that $d(x, y) \geq R$ implies that the set

$$\{g \in G \mid d(x, g(x)) \leq D, d(y, g(y)) \leq D\}$$

has cardinality at most N. Notice that this property implies WPD for any hyperbolic element. If a group action is proper and co-compact then it is acylindrical. Sela [1997] introduced the acylindricity of a group action on simplicial trees, then Bowditch [2008] formulated this definition for hyperbolic spaces and proved that the action of $MCG(\Sigma)$ on $\mathcal{C}(\Sigma)$ is acylindrical. Based on this definition, Osin [2016] develops a theory of *acylindrically hyperbolic groups*: these are groups that admit a non-elementary acylindrical isometric action on a hyperbolic space. Here, an action of G on a hyperbolic spce X is *non-elementary* if the limit set of the G-orbit of a point in X contains at least three points. He proved the following theorem.

Theorem 4.5. *Osin [ibid.] Let a group Γ, which is not virtually cyclic, act on a δ-hyperbolic metric space X such that $\gamma \in \Gamma$ is a hyperbolic WPD element. Then Γ is an acylindrically hyperbolic group. Thus all groups in Examples 4.3 are acylindrically hyperbolic.*

We make comments on his argument. By Theorem 4.4, G contains a hyperbolically embedded subgroup H. To construct a hyperbolic space for G to act on acylindrically, he uses an idea similar to projection complex with $\mathbf{Y}$ to be translates of an orbit of H. It has been improved in Balasubramanya [n.d.] so that the hyperbolic space in Theorem 4.5 can be taken to be a quasi-tree. In Bestvina, Bromberg, Fujiwara, and Sisto [n.d.] we recover this improvement by a different axiomatic construction: we start with $\mathbf{Y}$, the translates of an orbit of γ in X, which satisfies (PC0) -(PC4), then slightly change the definition of the projection $\pi_X(Y)$. For this new projection, the resulting projection complex by the usual definition is a quasi-tree, acted by G acylindrically.

4.3 Actions on CAT(0) square complex. Recall that Burger and Mozes [2000] constructed an example of a simple group, which acts freely and co-compactly on the product of two trees. Thus the quotient is a finite non-positively curved square complex with finitely-presented, infinite simple fundamental group. A square complex Z, built from unit Euclidean squares, is *non-positively curved* if the universal cover is CAT(0). Caprace and Delzant pointed out the following curious corollary of Theorem 4.1, which can be thought of a converse of the Burger-Mozes theorem.

Corollary 4.6 (see Bestvina, Bromberg, and Fujiwara [2015]). *Suppose Z is a finite non-positively curved square complex with no free edges whose fundamental group is simple. Then the universal cover $\tilde{Z}$ is isometric to the product of two trees.*

They argue that by the Ballmann-Brin Rank Rigidity Theorem Ballmann and Brin [1995, Th C] (see also Caprace and Sageev [2011]) the universal cover $\tilde{Z}$ is either the product of two trees or the deck group contains a rank 1 element. But in the latter case, by Theorem 4.1, $\pi_1(Z)$ acts on a quasi-tree and contains a hyperbolic WPD element γ. Also, $\pi_1(Z)$ is non virtually cyclic since it is simple and torsion-free. Now as we explained $\pi_1(Z)$ is not simple, impossible.

4.4 Bounded cohomology and QFA. Manning [2005] gave a construction of an action of a group G on a quasi-tree starting with a quasi-morphism $G \to \mathbb{R}$ but it is not clear when such actions are *non-elementary* (i.e. have unbounded orbits and do not fix an end nor a pair of ends). Groups G in Examples 4.3 have isometric actions on quasi-trees, and if G is non-elementary (ie, not virtually cyclic), then the action is non elementary. Conversely, if one has actions of a group G on a quasi-tree (with a hyperbolic WPD element), one can use such actions to give unified constructions of quasi-morphisms on G (cf. Epstein and Fujiwara [1997], Fujiwara [2000], Fujiwara [1998], Bestvina and Fujiwara [2002]), and even *quasi-cocycles* with coefficients in unitary representations in "uniformly convex" Banach spaces, for example, the regular representation on $\ell^2(G)$, which is of particular importance (see Monod [2006]). As a consequence, we prove

Theorem 4.7. *Bestvina, Bromberg, and Fujiwara [2016a] Let G be an acylindrically hyperbolic group with no non-trivial finite normal subgroup, and ρ a unitary representation of G in a uniformly convex Banach space, then the second bounded cohomology $H^2_b(G;\rho)$ is infinite dimensional.*

By contrast, there are many groups that do not admit nontrivial (namely, orbits are unbounded) actions on a quasi-tree. A group G satisfies *QFA* if every action on a quasi-tree has bounded orbits. For example, $SL_n(\mathbb{Z})$, $n \geq 3$ satisfies QFA, Manning [2006]. More recently, Haettel [n.d.] proves that if G is a lattice in (a product of) a higher rank semi-simple Lie group with finite center, then G satisfies QFA. He even proved that an action on any hyperbolic space X by such G has either a bounded orbit in X or has a fixed point in the ideal boundary of X.

4.5 $Out(F_n)$. A version of Theorem 3.5 for $Out(F_n)$ is known. There are several analogs of the curve graph $\mathcal{C}(\Sigma)$, for example the complex of free factors and the complex of free splittings. Both have been shown to be hyperbolic, the former in Bestvina and Feighn [2014a] and the latter in Handel and Mosher [2013]. The analog of subsurface projections was defined by Bestvina-Feighn in Bestvina and Feighn [2014b] and they show using the projection complex technique:

Theorem 4.8. *Bestvina and Feighn [ibid.] $Out(F_n)$ acts isometrically on a finite product of hyperbolic spaces so that every element of "exponential growth" acts with positive translation length.*

It is unknown if $Out(F_n)$ acts on a finite product of hyperbolic spaces that gives a QI-embedding. While a finite product of hyperbolic spaces satisfies a quadratic *isoperimetric inequality*, it is known that the isoperimetric inequality of $Out(F_n)$ is exponential (cf. Bridson and Vogtmann [1995]), but that is not an obstruction for QI-embeddings because we do not require that an embedding is (quasi-)convex. Theorem 1.4 (finiteness of asymptotic dimension) is unknown for $Out(F_n)$, but recently Bestvina-Guirardel-Horbez proved that $Out(F_n)$ is *boundary amenable*, therefore satisfies the Novikov conjecture on higher signatures Bestvina, Guirardel, and Horbez [n.d.].

4.6 Farrell-Jones conjecture for MCG. Bartels and Bestvina [n.d.] prove the *Farrell-Jones Conjecture* for mapping class groups:

Theorem 4.9 (Bestvina-Bartels)**.** *The mapping class group $Mod(\Sigma)$ of any oriented surface Σ of finite type satisfies the Farrell-Jones Conjecture.*

The main step of the proof is the verification of a regularity condition, called *finite $\mathfrak{F}$-amenability* (see Bartels and Bestvina [ibid.] for a precise definition). Using subsurface projections by Masur-Minsky, combined with the projection complex technique, they prove the action of $MCG(\Sigma)$ on the space $\mathfrak{PMF}$ of projective measured foliations on Σ is finitely $\mathfrak{F}$-amenable, for a certain family $\mathfrak{F}$ of subgroups in $MCG(\Sigma)$. Theorem 4.9 is then a consequence of the axiomatic results of Lück, Reich and Bartels for the Farrell-Jones Conjecture (cf. Bartels and Lück [2012]) and an induction on the complexity of the surface.

$MCG(\Sigma)$ has finite asymptotic dimension (Theorem 1.4). As we said this implies the integral Novikov conjecture, i.e., the integral injectivity of the assembly maps in algebraic K-theory and L-theory relative to the family of finite subgroups. This is related to the Farrell-Jones conjecture (see Bartels and Bestvina [n.d.]).

GEOMETRIC STRUCTURES AND REPRESENTATIONS OF DISCRETE GROUPS

Fanny Kassel

Abstract

We describe recent links between two topics: geometric structures on manifolds in the sense of Ehresmann and Thurston, and dynamics "at infinity" for representations of discrete groups into Lie groups.

1 Introduction

The goal of this survey is to report on recent results relating geometric structures on manifolds to dynamical aspects of representations of discrete groups into Lie groups, thus linking geometric topology to group theory and dynamics.

1.1 Geometric structures. The first topic of this survey is geometric structures on manifolds. Here is a concrete example as illustration (see Figure 1).

Example 1.1. Consider a two-dimensional torus T.

(1) We can view T as the quotient of the Euclidean plane $X = \mathbb{R}^2$ by $\Gamma = \mathbb{Z}^2$, which is a discrete subgroup of the isometry group $G = \mathrm{O}(2) \ltimes \mathbb{R}^2$ of X (acting by linear isometries and translations). Viewing T this way provides it with a Riemannian metric and a notion of parallel lines, length, angles, etc. We say T is endowed with a *Euclidean* (or *flat*) *structure*, or a (G, X)-structure with $(G, X) = (\mathrm{O}(2) \ltimes \mathbb{R}^2, \mathbb{R}^2)$.

(2) Here is a slightly more involved way to view T: we can see it as the quotient of the affine plane $X = \mathbb{R}^2$ by the group Γ generated by the translation of vector $\left(\begin{smallmatrix}1\\0\end{smallmatrix}\right)$ and the affine transformation with linear part $\left(\begin{smallmatrix}1&1\\0&1\end{smallmatrix}\right)$ and translational part $\left(\begin{smallmatrix}0\\1\end{smallmatrix}\right)$. This group Γ is now a discrete subgroup of the affine group $G = \mathrm{GL}(2, \mathbb{R}) \ltimes \mathbb{R}^2$. Viewing T this way still provides it with a notion of parallel lines and even of geodesic, but no longer with a notion

Partially supported by the European Research Council under Starting Grant 715982 (DiGGeS).
MSC2010: primary 57N16; secondary 20H10, 22E40, 37D40, 57M50, 57S30.

of length or angle or speed of geodesic. We say T is endowed with an *affine structure*, or a (G, X)-structure with $(G, X) = (\mathrm{GL}(2, \mathbb{R}) \ltimes \mathbb{R}^2, \mathbb{R}^2)$.

(3) There are many ways to endow T with an affine structure. Here is a different one: we can view T as the quotient of the open subset $\mathcal{U} = \mathbb{R}^2 \smallsetminus \{0\}$ of $X = \mathbb{R}^2$ by the discrete subgroup Γ of $G = \mathrm{GL}(2, \mathbb{R}) \ltimes \mathbb{R}^2$ generated by the homothety $\left(\begin{smallmatrix} 2 & 0 \\ 0 & 2 \end{smallmatrix}\right)$. This still makes T "locally look like" $X = \mathbb{R}^2$, but now the image in T of an affine geodesic of X pointing towards the origin is *incomplete* (it circles around in T with shorter and shorter period and disappears in a finite amount of time).

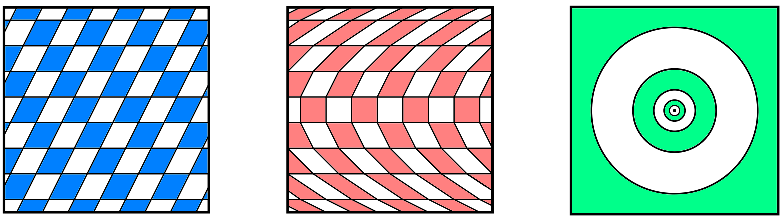

Figure 1: Tilings of $X = \mathbb{R}^2$ showing the three Γ-actions in Example 1.1

As in Example 1.1, a key idea underlying a large part of modern geometry is the existence of *model geometries* which various manifolds may locally carry. By definition, a model geometry is a pair (G, X) where X is a manifold (*model space*) and G a Lie group acting transitively on X (*group of symmetries*). In Example 1.1 we encountered $(G, X) = (\mathrm{O}(n) \ltimes \mathbb{R}^n, \mathbb{R}^n)$ and $(G, X) = (\mathrm{GL}(n, \mathbb{R}) \ltimes \mathbb{R}^n, \mathbb{R}^n)$, corresponding respectively to *Euclidean geometry* and *affine geometry*. Another important example is $X = \mathbb{H}^n$ (the n-dimensional real hyperbolic space) and $G = \mathrm{PO}(n, 1) = \mathrm{O}(n, 1)/\{\pm I\}$ (its group of isometries), corresponding to *hyperbolic geometry*. (For $n = 2$ we can see X as the upper half-plane and G, up to index two, as $\mathrm{PSL}(2, \mathbb{R})$ acting by homographies.) We refer to Table 1 for more examples.

The idea that a manifold M locally carries the geometry (G, X) is formalized by the notion of a (G, X)-*structure* on M: by definition, this is a maximal atlas of coordinate charts on M with values in X such that the transition maps are given by elements of G (see Figure 2). Note that this is quite similar to a manifold structure on M, but we now require the charts to take values in X rather than $\mathbb{R}^n$, and the transition maps to be given by elements of G rather than diffeomorphisms of $\mathbb{R}^n$. Although general (G, X)-structures may display pathological behavior (see Goldman [2018b]), in this survey we will restrict to the two "simple" types of (G, X)-structures appearing in Example 1.1, to which we shall give names to facilitate the discussion:

- **Type C ("complete")**: (G, X)-structures that identify M with a quotient of X by a discrete subgroup Γ of G acting properly discontinuously;

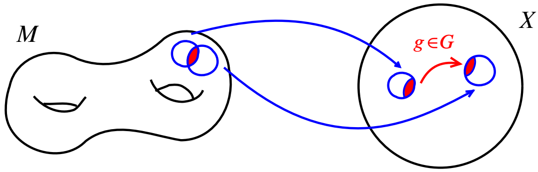

Figure 2: Charts defining a (G, X)-structure on M

- **Type U ("incomplete but still uniformizable")**: (G, X)-structures that identify M with a quotient of some proper open subset $\mathcal{U}$ of X by a discrete subgroup Γ of G acting properly discontinuously.

Setting $\mathcal{V} = X$ or $\mathcal{U}$ as appropriate, we then have coverings $\widetilde{M} \simeq \widetilde{\mathcal{V}} \to \mathcal{V} \to \Gamma\backslash\mathcal{V} \simeq M$ (where $\widetilde{\ }$ denotes universal covers). The charts on M are obtained by taking preimages in $\mathcal{V} \subset X$ of open subsets of M. Moreover, the basic theory of covering groups gives a natural group homomorphism $\mathrm{hol} : \pi_1(M) \to G$ with image Γ and kernel $\pi_1(\mathcal{V})$, called the *holonomy*.

In this survey, we use the phrase *geometric structures* for (G, X)-structures. We shall not detail the rich historical aspects of geometric structures here; instead, we refer to the excellent surveys of Goldman [2010, 2018a,b]. Let us just mention that the notion of model geometry has its origins in ideas of Lie and Klein, formulated in Klein's 1872 Erlangen program. Influenced by these ideas and those of Poincaré, Cartan and others, Ehresmann [1937] initiated a general study of geometric structures in the 1930s. Later, geometric structures were greatly promoted by the revolutionary work of Thurston [1980].

1.2 Classifying geometric structures. The fundamental problem in the theory of geometric structures is their classification, namely:

Problem A. Given a manifold M,
(1) Describe which model geometries (G, X) the manifold M may locally carry;
(2) For a fixed model (G, X), describe all possible (G, X)-structures on M.

We refer to Goldman [2010] for a detailed survey of Problem A with a focus on dimensions two and three, and to Kobayashi and Yoshino [2005] for a special case.

Problem A.(1) asks how the global topology of M determines the geometries that it may locally carry. This has been the object of deep results, among which:

- the classical *uniformization theorem*: a closed Riemann surface may carry a Euclidean, a spherical, or a hyperbolic structure, depending on its genus;

- Thurston's *hyperbolization theorem*: a large class of 3-dimensional manifolds, defined in purely topological terms, may carry a hyperbolic structure;

- more generally, Thurston's *geometrization program* (now Perelman's theorem): any closed orientable 3-dimensional manifold may be decomposed into pieces, each admitting one of eight model geometries (see Bonahon [2002]).

Problem A.(2) asks to describe the *deformation space* of (G, X)-structures on M. In the simple setting of Example 1.1, this space is already quite rich (see Baues [2014]). For hyperbolic structures on a closed Riemann surface of genus ≥ 2 (Example 2.1), Problem A.(2) gives rise to the fundamental and wide-ranging *Teichmüller theory*.

1.3 Representations of discrete groups. The second topic of this survey is representations (i.e. group homomorphisms) of discrete groups (i.e. countable groups) to Lie groups G, and their dynamics "at infinity". We again start with an example.

Example 1.2. Let $\Gamma = \pi_1(S)$ where S is a closed orientable Riemann surface of genus ≥ 2. By the uniformization theorem, S carries a complete ("type C") hyperbolic structure, which yields a holonomy representation $\Gamma \to \mathrm{PSL}(2, \mathbb{R})$ as in Section 1.1. Embedding $\mathrm{PSL}(2, \mathbb{R})$ into $G = \mathrm{PSL}(2, \mathbb{C})$, we obtain a representation $\rho : \Gamma \to G$, called *Fuchsian*, and an associated action of Γ on the hyperbolic space $X = \mathbb{H}^3$ and on its boundary at infinity $\partial_\infty \mathbb{H}^3 = \widehat{\mathbb{C}}$ (the Riemann sphere). The *limit set* of $\rho(\Gamma)$ in $\widehat{\mathbb{C}}$ is the set of accumulation points of $\rho(\Gamma)$-orbits of X; it is a circle in the sphere $\widehat{\mathbb{C}}$. Deforming ρ slightly yields a new representation $\rho' : \Gamma \to G$, called *quasi-Fuchsian*, which is still faithful, with discrete image, and whose limit set in $\widehat{\mathbb{C}}$ is still a topological circle (now "wiggly", see Figure 3). The action of $\rho'(\Gamma)$ is chaotic on the limit set (e.g. all orbits are dense) and properly discontinuous on its complement.

Example 1.2 plays a central role in the theory of Kleinian groups and in Thurston's geometrization program; it was extensively studied by Ahlfors, Beardon, Bers, Marden, Maskit, Minsky, Sullivan, Thurston, and many others.

In this survey we report on various generalizations of Example 1.2, for representations of discrete groups Γ to semisimple Lie groups G which are faithful (or with finite kernel) and whose images are discrete subgroups of G. While in Example 1.2 the group $G = \mathrm{PSL}(2, \mathbb{C})$ has real rank one (meaning that its Riemannian symmetric space $\mathbb{H}^3$ has no flat regions beyond geodesics), we also wish to consider the case that G has *higher real rank*, e.g. $G = \mathrm{PGL}(d, \mathbb{R})$ with $d \geq 3$. In general, semisimple groups G tend to have very different behavior depending on whether their real rank is one or higher; for instance, the *lattices* of G (i.e. the discrete subgroups of finite covolume for the Haar measure) may display some forms of flexibility in real rank one, but exhibit strong rigidity phenomena in higher real rank. Beyond lattices, the landscape of discrete subgroups of G is somewhat understood in real rank one (at least several important classes of discrete subgroups

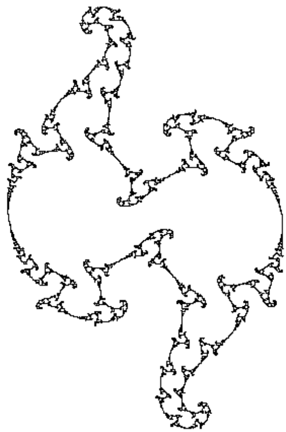

Figure 3: The limit set of a quasi-Fuchsian group in $\partial_\infty \mathbb{H}^3 \simeq \mathbb{C} \cup \{\infty\}$

have been identified for their good geometric, topological, and dynamical properties, see Section 3.1), but it remains very mysterious in higher real rank. We shall explain some recent attempts at understanding it better.

One interesting aspect is that, even when G has higher real rank, discrete subgroups of G of infinite covolume may be nonrigid and in fact admit large deformation spaces. In particular, as part of *higher Teichmüller theory*, there has recently been an active and successful effort to find large deformation spaces of faithful and discrete representations of surface groups $\pi_1(S)$ into higher-rank semisimple G which share some of the rich features of the Teichmüller space of S (see Sections 4.3 and 5, Burger, Iozzi, and Wienhard [2014] and Wienhard [2018]). Such features also include dynamics "at infinity" as in Example 1.2, which are encompassed by a notion of *Anosov representation* (Labourie [2006]), see Section 4.

1.4 Flag varieties and boundary maps. Let us be a bit more precise. Given a representation $\rho : \Gamma \to G$, by dynamics "at infinity" we mean the dynamics of the action of Γ via ρ on some *flag varieties* G/P (where P is a parabolic subgroup), seen as "boundaries" of G or of its Riemannian symmetric space G/K. In Example 1.2 we considered a rank-one situation where $G = \mathrm{PSL}(2, \mathbb{C})$ and $G/P = \partial_\infty \mathbb{H}^3 = \widehat{\mathbb{C}}$. A typical higher-rank situation that we have in mind is $G = \mathrm{PGL}(d, \mathbb{R})$ with $d \geq 3$ and $G/P = \mathrm{Gr}_i(\mathbb{R}^d)$ (the Grassmannian of i-planes in $\mathbb{R}^d$) for some $1 \leq i \leq d-1$.

In the work of Mostow, Margulis, Furstenberg, and others, rigidity results have often relied on the construction of Γ-equivariant measurable maps from or to G/P. More recently, in the context of higher Teichmüller theory (see Burger, Iozzi, and Wienhard [2010b], Fock and Goncharov [2006], Labourie [2006]), it has proved important to study continuous equivariant *boundary maps* which embed the boundary $\partial_\infty\Gamma$ of a Gromov hyperbolic group Γ (i.e. the visual boundary of the Cayley graph of Γ) into G/P. Such boundary maps $\xi : \partial_\infty\Gamma \to G/P$ define a closed invariant subset $\xi(\partial_\infty\Gamma)$ of G/P, the *limit set*, on which the dynamics of the action by Γ accurately reflect the intrinsic chaotic dynamics of Γ on $\partial_\infty\Gamma$. These boundary maps may be used to transfer the Anosov property of the intrinsic geodesic flow of Γ into some uniform contraction/expansion properties for a flow on a natural flat bundle associated to ρ and G/P (see Section 4). They may also define some open subsets $\mathcal{U}$ of G/P on which the action of Γ is properly discontinuous, by removing an "extended limit set" $\mathcal{L}_{\rho(\Gamma)} \supset \xi(\partial_\infty\Gamma)$ (see Sections 3, 5 and 6); this generalizes the domains of discontinuity in the Riemann sphere of Example 1.2.

For finitely generated groups Γ that are not Gromov hyperbolic, one can still define a boundary $\partial_\infty\Gamma$ in several natural settings, e.g. as the visual boundary of some geodesic metric space on which Γ acts geometrically, and the approach considered in this survey can then be summarized by the following general problem.

Problem B. Given a discrete group Γ with a boundary $\partial_\infty\Gamma$, and a Lie group G with a boundary G/P, identify large (e.g. open in $\mathrm{Hom}(\Gamma, G)$) classes of faithful and discrete representations $\rho : \Gamma \to G$ for which there exist continuous ρ-equivariant boundary maps $\xi : \partial_\infty\Gamma \to G/P$. Describe the dynamics of Γ on G/P via ρ.

1.5 Goal of the paper. We survey recent results on (G, X)-structures (Problem A) and on representations of discrete groups (Problem B), making links between the two topics. In one direction, we observe that various types of (G, X)-structures have holonomy representations that are interesting for Problem B. In the other direction, starting with representations that are interesting for Problem B (Anosov representations), we survey recent constructions of associated (G, X)-structures. These results tend to indicate some deep interactions between the geometry of (G, X)-manifolds and the dynamics of their holonomy representations, which largely remain to be explored. We hope that they will continue to stimulate the development of rich theories in the future.

Organization of the paper. In Section 2 we briefly review the notion of a holonomy representation. In Section 3 we describe three important families of (G, X)-structures for which boundary maps into flag varieties naturally appear. In Section 4 we define Anosov representations and give examples and characterizations. In Section 5 we summarize recent constructions of geometric structures associated to Anosov representations. In Section 6 we discuss a situation in which the links between geometric structures and Anosov representations are particularly tight, in the context of convex projective geometry. In Section 7 we examine an instance of (G, X)-structures for a nonreductive Lie group G, corresponding to affine manifolds and giving rise to affine Anosov representations. We conclude with a few remarks.

Acknowledgments. I would like to heartily thank all the mathematicians who helped, encouraged, and inspired me over the past years; the list is too long to include here. I am very grateful to all my coauthors, in particular those involved in the work discussed below: Jeffrey Danciger (Sections 5 to 7), François Guéritaud (Sections 4 to 7), Olivier Guichard (Sections 4 and 5), Rafael Potrie (Section 4), and Anna Wienhard (Sections 4 and 5). I warmly thank J.-P. Burelle, J. Danciger, O. Guichard, and S. Maloni for reading earlier versions of this text and making many valuable comments and suggestions, and R. Canary and W. Goldman for kindly answering my questions.

2 Holonomy representations

Let G be a real Lie group acting transitively, faithfully, analytically on a manifold X, as in Table 1. In Section 1.1 we defined holonomy representations for certain types of (G, X)-structures. We now give a short review of the notion in general.

Type of geometry	X	G	H
Real projective	$\mathbb{P}^n(\mathbb{R})$	$\mathrm{PGL}(n+1, \mathbb{R})$	stab. of line of $\mathbb{R}^{n+1}$
Affine	$\mathbb{R}^n$	$\mathrm{Aff}(\mathbb{R}^n) = \mathrm{GL}(n, \mathbb{R}) \ltimes \mathbb{R}^n$	$\mathrm{GL}(n, \mathbb{R})$
Euclidean	$\mathbb{R}^n$	$\mathrm{Isom}(\mathbb{R}^n) = \mathrm{O}(n) \ltimes \mathbb{R}^n$	$\mathrm{O}(n)$
Real hyperbolic	$\mathbb{H}^n$	$\mathrm{Isom}(\mathbb{H}^n) = \mathrm{PO}(n, 1)$	$\mathrm{O}(n)$
Spherical	$\mathbb{S}^n$	$\mathrm{Isom}(\mathbb{S}^n) = \mathrm{O}(n+1)$	$\mathrm{O}(n)$
Complex projective	$\mathbb{P}^n(\mathbb{C})$	$\mathrm{PGL}(n+1, \mathbb{C})$	stab. of line of $\mathbb{C}^{n+1}$

Table 1: Some examples of model geometries (G, X), where $X \simeq G/H$

Let M be a (G, X)-manifold, i.e. a manifold endowed with a (G, X)-structure. Fix a basepoint $m \in M$ and a chart $\varphi : \mathcal{U} \to X$ with $m \in \mathcal{U}$. We can lift any loop on M starting at m to a path on X starting at $\varphi(m)$, using successive charts of M which coincide on their intersections; the last chart in this analytic continuation process coincides, on an open set, with $g \cdot \varphi$ for some unique $g \in G$; we set $\mathrm{hol}(\gamma) := g$ where $\gamma \in \pi_1(M, m)$ is the homotopy class of the loop (see Figure 4). This defines a representation $\mathrm{hol} : \pi_1(M) \to G$ called the *holonomy* (see Goldman [2010, 2018b] for details); it is unique modulo conjugation by G. This coincides with the notion from Section 1.1; in particular, if $M \simeq \Gamma\backslash\mathcal{V}$ with $\mathcal{V}$ open in X and Γ discrete in G, and if $\mathcal{V}$ is simply connected, then $\mathrm{hol} : \pi_1(M) \to \Gamma$ is just the natural identification of $\pi_1(M)$ with Γ.

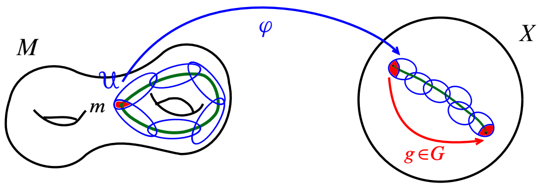

Figure 4: Construction of a holonomy representation

The *deformation space* $\mathrm{Def}_{(G,X)}(M)$ of (G,X)-structures on M is the quotient of the set of (G,X)-structures by the group of diffeomorphisms of M homotopic to the identity, acting by precomposition of the charts. It has a natural topology, see Baues [2014, § 3]. The holonomy defines a map from $\mathrm{Def}_{(G,X)}(M)$ to the space $\mathrm{Hom}(\Gamma, G)/G$ of representations of Γ to G modulo conjugation by G. This map may be injective in some cases, as in Example 2.1 below, but in general it is not. However, when M is closed, the so-called *Ehresmann–Thurston principle* (see Thurston [1980]) states that the map is continuous, open, with discrete fibers; in particular, the set of holonomy representations of (G,X)-structures on M is then stable under small deformations.

Example 2.1. Let $(G,X) = (\mathrm{PO}(2,1), \mathbb{H}^2)$ where $\mathrm{PO}(2,1) \simeq \mathrm{PGL}(2,\mathbb{R})$ is the isometry group of the real hyperbolic plane $\mathbb{H}^2$. Let $M = S$ be a closed orientable connected surface of genus $g \geq 2$. All (G,X)-structures on S are complete. The deformation space $\mathrm{Def}_{(G,X)}(S)$ is the Teichmüller space $\mathrm{Teich}(S)$ of S. The holonomy defines a homeomorphism between $\mathrm{Teich}(S) \simeq \mathbb{R}^{6g-6}$ and the space of Fuchsian (i.e. faithful and discrete) representations from $\pi_1(S)$ to G modulo conjugation by G.

3 Examples of $(\mathbf{G},\mathbf{X})$-structures and their holonomy representations

In this section we introduce three important families of (G,X)-structures, which have been much studied in the past few decades. We observe some structural stability for their holonomy representations, and the existence of continuous equivariant boundary maps together with expansion/contraction properties "at infinity". These phenomena will be captured by the notion of an Anosov representation in Section 4.

3.1 Convex cocompact locally symmetric structures in rank one. Let G be a real semisimple Lie group of real rank one with Riemannian symmetric space $X = G/K$ (i.e. K is a maximal compact subgroup of G), e.g. $(G,X) = (\mathrm{PO}(n,1), \mathbb{H}^n)$ for $n \geq 2$. Convex cocompact groups are an important class of discrete subgroups Γ of G which generalize the uniform lattices. They are special cases of geometrically finite groups, for which no cusps appear; see Bowditch [1993, 1998] for a general theory.

By definition, a discrete subgroup Γ of G is *convex cocompact* if it preserves and acts with compact quotient on some nonempty convex subset $\mathcal{C}$ of $X = G/K$; equivalently, the complete (G, X)-manifold (or orbifold) $\Gamma\backslash X$ has a compact convex subset (namely $\Gamma\backslash\mathcal{C}$) containing all the topology. Such a group Γ is always finitely generated. A representation $\rho : \Gamma \to G$ is called *convex cocompact* if its kernel is finite and its image is a convex cocompact subgroup of G.

For instance, in Example 1.2 the quasi-Fuchsian representations are exactly the convex cocompact representations from $\pi_1(S)$ to $G = \mathrm{PSL}(2, \mathbb{C})$; modulo conjugation, they are parametrized by $\mathrm{Teich}(S) \times \mathrm{Teich}(S)$ (Bers [1960]). Another classical example of convex cocompact groups in rank-one G is Schottky groups, namely free groups defined by the so-called *ping pong* dynamics of their generators in $\partial_\infty X$.

Here $\partial_\infty X$ denotes the visual boundary of X, yielding the standard compactification $\overline{X} = X \sqcup \partial_\infty X$ of X; for $X = \mathbb{H}^n$ we can see $\overline{X}$ in projective space as in Example 3.2.(1) below. The G-action on X extends continuously to $\overline{X}$, and $\partial_\infty X$ identifies with G/P where P is a minimal parabolic subgroup of G.

For a convex cocompact representation $\rho : \Gamma \to G$, the existence of a cocompact invariant convex set $\mathcal{C}$ implies (by the Švarc–Milnor lemma or "fundamental observation of geometric group theory") that ρ is a *quasi-isometric embedding*. This means that the points of any $\rho(\Gamma)$-orbit in $X = G/K$ go to infinity at linear speed for the word length function $|\cdot| : \Gamma \to \mathbb{N}$: for any $x_0 \in X$ there exist $C, C' > 0$ such that $d_{G/K}(x_0, \rho(\gamma) \cdot x_0) \geq C\,|\gamma| - C'$ for all $\gamma \in \Gamma$. (This property does not depend on the choice of finite generating subset of Γ defining $|\cdot|$.) A consequence "at infinity" is that any ρ-orbital map $\Gamma \to X$ extends to a ρ-equivariant embedding $\xi : \partial_\infty\Gamma \to \partial_\infty X \simeq G/P$, where $\partial_\infty\Gamma$ is the boundary of the Gromov hyperbolic group Γ. The image of ξ is the *limit set* $\Lambda_{\rho(\Gamma)}$ of $\rho(\Gamma)$ in $\partial_\infty X$. The dynamics on $\partial_\infty X \simeq G/P$ are decomposed as in Example 1.2: the action of $\rho(\Gamma)$ is "chaotic" on $\Lambda_{\rho(\Gamma)}$ (e.g. all orbits are dense if Γ is nonelementary), and properly discontinuous, with compact quotient, on the complement $\Omega_{\rho(\Gamma)} = \partial_\infty X \smallsetminus \Lambda_{\rho(\Gamma)}$.

Further dynamical properties were described by Sullivan [1979, 1985]: for instance, the action of $\rho(\Gamma)$ on $\partial_\infty X \simeq G/P$ is *expanding* at each point $z \in \Lambda_{\rho(\Gamma)}$, i.e. there exist $\gamma \in \Gamma$ and $C > 1$ such that $\rho(\gamma)$ multiplies all distances by $\geq C$ on a neighborhood of z in $\partial_\infty X$ (for some fixed auxiliary metric on $\partial_\infty X$). This implies that the group $\rho(\Gamma)$ is *structurally stable*, i.e. there is a neighborhood of the natural inclusion in $\mathrm{Hom}(\rho(\Gamma), G)$ consisting entirely of faithful representations. In fact, ρ admits a neighborhood consisting entirely of convex cocompact representations, by a variant of the Ehresmann–Thurston principle. For $G = \mathrm{SL}(2, \mathbb{C})$, a structurally stable subgroup of G is either locally rigid or convex cocompact (Sullivan [1985]).

3.2 Convex projective structures: divisible convex sets. Let G be the projective linear group $\mathrm{PGL}(d,\mathbb{R})$ and X the projective space $\mathbb{P}(\mathbb{R}^d)$, for $d \geq 2$. Recall that a subset of $X = \mathbb{P}(\mathbb{R}^d)$ is said to be *convex* if it is contained and convex in some affine chart, *properly convex* if its closure is convex, and *strictly convex* if it is properly convex and its boundary in X does not contain any nontrivial segment.

Remark 3.1. Any properly convex open subset Ω of $X = \mathbb{P}(\mathbb{R}^d)$ admits a well-behaved (complete, proper, Finsler) metric d_Ω, the *Hilbert metric*, which is invariant under the subgroup of $G = \mathrm{PGL}(d,\mathbb{R})$ preserving Ω (see e.g. Benoist [2008]). In particular, any discrete subgroup of G preserving Ω acts properly discontinuously on Ω.

By definition, a *convex projective structure* on a manifold M is a (G,X)-structure obtained by identifying M with $\Gamma\backslash\Omega$ for some properly convex open subset Ω of X and some discrete subgroup Γ of G. When M is closed, i.e. when Γ acts with compact quotient, we say that Γ *divides* Ω. Such *divisible convex sets* Ω are the objects of a rich theory, see Benoist [ibid.]. The following classical examples are called *symmetric*.

Examples 3.2. (1) For $d = n+1 \geq 3$, let $\langle\cdot,\cdot\rangle_{n,1}$ be a symmetric bilinear form of signature $(n,1)$ on $\mathbb{R}^d$, and let $\Omega = \{[v] \in \mathbb{P}(\mathbb{R}^d) \mid \langle v,v\rangle_{n,1} < 0\}$ be the projective model of the real hyperbolic space $\mathbb{H}^n$. It is a strictly convex open subset of $X = \mathbb{P}(\mathbb{R}^d)$ (an ellipsoid), and any uniform lattice Γ of $\mathrm{PO}(n,1) \subset G = \mathrm{PGL}(d,\mathbb{R})$ divides Ω.

(2) For $d = n(n+1)/2$, let us see $\mathbb{R}^d$ as the space $\mathrm{Sym}(n,\mathbb{R})$ of symmetric $n \times n$ real matrices, and let $\Omega \subset \mathbb{P}(\mathbb{R}^d)$ be the image of the set of positive definite ones. The set Ω is a properly convex open subset of $X = \mathbb{P}(\mathbb{R}^d)$; it is strictly convex if and only if $n = 2$. The group $\mathrm{GL}(n,\mathbb{R})$ acts on $\mathrm{Sym}(n,\mathbb{R})$ by $g \cdot s := gsg^t$, which induces an action of $\mathrm{PGL}(n,\mathbb{R})$ on Ω. This action is transitive and the stabilizer of a point is $\mathrm{PO}(n)$, hence Ω identifies with the Riemannian symmetric space $\mathrm{PGL}(n,\mathbb{R})/\mathrm{PO}(n)$. In particular, any uniform lattice Γ of $\mathrm{PGL}(n,\mathbb{R})$ divides Ω. (A similar construction works over the complex numbers, the quaternions, or the octonions: see Benoist [ibid.].)

Many nonsymmetric strictly convex examples were also constructed since the 1960s by various techniques; see Benoist [2008] and Choi, G.-S. Lee, and Marquis [2016b] for references. Remarkably, there exist irreducible divisible convex sets $\Omega \subset \mathbb{P}(\mathbb{R}^d)$ which are not symmetric and not strictly convex: the first examples were built by Benoist [2006] for $4 \leq d \leq 7$. Ballas, Danciger, and G.-S. Lee [2018] generalized Benoist's construction for $d = 4$ to show that large families of nonhyperbolic closed 3-manifolds admit convex projective structures. Choi, G.-S. Lee, and Marquis [2016a] recently built nonstrictly convex examples of a different flavor for $5 \leq d \leq 7$.

For *strictly convex* Ω, dynamics "at infinity" are relatively well understood: if Γ divides Ω, then Γ is Gromov hyperbolic (Benoist [2004]) and, by cocompactness, any orbital map $\Gamma \to \Omega$ extends continuously to an equivariant homeomorphism ξ from the boundary

$\partial_\infty\Gamma$ of Γ to the boundary of Ω in X. This is similar to Section 3.1, except that now X itself is a flag variety G/P (see Table 1). The image of the boundary map ξ is again a *limit set* Λ_Γ on which the action of Γ is "chaotic", but Λ_Γ is now part of a larger "extended limit set" $\mathcal{L}_\Gamma$, namely the union of all projective hyperplanes tangent to Ω at points of Λ_Γ. The space $X \simeq G/P$ is the disjoint union of $\mathcal{L}_\Gamma$ and Ω. The dynamics of Γ on X are further understood by considering the *geodesic flow* on $\Omega \subset X$, defined using the Hilbert metric of Remark 3.1; for $\Omega = \mathbb{H}^n$ as in Example 3.2.(1), this is the usual geodesic flow. Benoist [ibid.] proved that the induced flow on $\Gamma\backslash\Omega$ is Anosov and topologically mixing; see Crampon [2014] for further properties.

For *nonstrictly convex* Ω, the situation is less understood. Groups Γ dividing Ω are never Gromov hyperbolic (Benoist [2004]); for $d = 4$ they are relatively hyperbolic (Benoist [2006]), but in general they might not be (e.g. if Ω is symmetric), and it is not obvious what type of boundary $\partial_\infty\Gamma$ (defined independently of Ω) might be most useful in the context of Problem B. The geodesic flow on $\Gamma\backslash\Omega$ is not Anosov, but Bray [2017] proved it is still topologically mixing for $d = 4$. Much of the dynamics remains to be explored.

By Koszul [1968], discrete subgroups of G dividing Ω are structurally stable; moreover, for a closed manifold M with fundamental group $\Gamma = \pi_1(M)$, the set $\mathrm{Hom}_M^{\mathrm{conv}}(\Gamma, G)$ of holonomy representations of convex (G, X)-structures on M is open in $\mathrm{Hom}(\Gamma, G)$. This set is also closed in $\mathrm{Hom}(\Gamma, G)$ as soon as Γ does not contain an infinite normal abelian subgroup, by Choi and Goldman [2005] (for $d = 3$) and Benoist [2005] (in general). For $d = 3$, when M is a closed surface of genus $g \geq 2$, Goldman [1990] showed that $\mathrm{Hom}_M^{\mathrm{conv}}(\Gamma, G)/G$ is homeomorphic to $\mathbb{R}^{16g-16}$, via an explicit parametrization generalizing classical (*Fenchel–Nielsen*) coordinates on Teichmüller space.

3.3 AdS quasi-Fuchsian representations. We now discuss the Lorentzian counterparts of Example 1.2, which have been studied by Witten [1988] and others as simple models for $(2+1)$-dimensional gravity. Let $M = S \times (0, 1)$ be as in Example 1.2. Instead of taking $(G, X) = (\mathrm{PO}(3, 1), \mathbb{H}^3)$, we now take $G = \mathrm{PO}(2, 2)$ and

$$X = \mathrm{AdS}^3 = \{[v] \in \mathbb{P}(\mathbb{R}^4) \mid \langle v, v\rangle_{2,2} < 0\}.$$

In other words, we change the signature of the quadratic form defining X from $(3, 1)$ (as in Example 3.2.(1)) to $(2, 2)$. This changes the natural G-invariant metric from Riemannian to Lorentzian, and the topology of X from a ball to a solid torus. The space $X = \mathrm{AdS}^3$ is called the *anti-de Sitter* 3-space.

The manifold $M = S \times (0, 1)$ does not admit (G, X)-structures of type C (terminology of Section 1.1), but it admits some of type U, called *globally hyperbolic maximal Cauchy-compact* (GHMC). In general, a Lorentzian manifold is called globally hyperbolic if it satisfies the intuitive property that "when moving towards the future one does not come back to the past"; more precisely, there is a spacelike hypersurface (*Cauchy hypersurface*) meeting each inextendible causal curve exactly once. Here we also require that the Cauchy surface be compact and that M be maximal (i.e. not isometrically embeddable into a larger globally hyperbolic Lorentzian 3-manifold).

To describe the GHMC (G, X)-structures on M, it is convenient to consider a different model for AdS^3, which leads to beautiful links with 2-dimensional hyperbolic geometry. Namely, we view $\mathbb{R}^4$ as the space $\mathfrak{M}_2(\mathbb{R})$ of real 2×2 matrices, and the quadratic form $\langle\cdot,\cdot\rangle_{2,2}$ as minus the determinant. This induces an identification of $X = \mathrm{AdS}^3$ with $\underline{G} = \mathrm{PSL}(2,\mathbb{R})$ sending $[v] \in X$ to $\left[\frac{1}{|\langle v,v\rangle|}\begin{pmatrix} v_1+v_4 & v_2+v_3 \\ v_2-v_3 & -v_1+v_4 \end{pmatrix}\right] \in \underline{G}$, and a corresponding group isomorphism from the identity component $G_0 = \mathrm{PO}(2,2)_0$ of G acting on $X = \mathrm{AdS}^3$, to $\underline{G} \times \underline{G}$ acting on $\underline{G}$ by right and left multiplication: $(g_1, g_2) \cdot g = g_2 g g_1^{-1}$. It also induces an identification of the boundary $\partial X \subset \mathbb{P}(\mathbb{R}^4)$ with the projectivization of the set of rank-one matrices, hence with $\mathbb{P}^1(\mathbb{R}) \times \mathbb{P}^1(\mathbb{R})$ (by taking the kernel and the image); the action of G_0 on ∂X corresponds to the natural action of $\underline{G} \times \underline{G}$ on $\mathbb{P}^1(\mathbb{R}) \times \mathbb{P}^1(\mathbb{R})$.

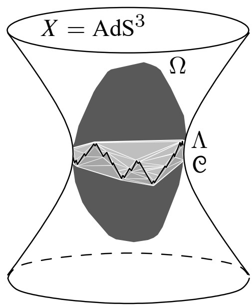

Figure 5: The sets Λ, Ω, $\mathcal{C}$ for an AdS quasi-Fuchsian representation

With these identifications, Mess [2007] proved that all GHMC (G, X)-structures on $M = S \times (0,1)$ are obtained as follows. Let (ρ_L, ρ_R) be a pair of Fuchsian representations from $\Gamma = \pi_1(M) \simeq \pi_1(S)$ to $\underline{G} = \mathrm{PSL}(2,\mathbb{R})$. The group $(\rho_L, \rho_R)(\Gamma) \subset \underline{G} \times \underline{G} \subset G$ preserves a topological circle Λ in ∂X, namely the graph of the homeomorphism of $\mathbb{P}^1(\mathbb{R})$ conjugating the action of ρ_L to that of ρ_R. For any $z \in \Lambda$, the orthogonal $z^\perp$ of z for $\langle\cdot,\cdot\rangle_{2,2}$ is a projective hyperplane tangent to X at z. The complement Ω in $\mathbb{P}(\mathbb{R}^4)$ of the union of all $z^\perp$ for $z \in \Lambda$ is a convex open subset of $\mathbb{P}(\mathbb{R}^4)$ contained in X (see Figure 5) which admits a Γ-invariant Cauchy surface. The action of Γ on Ω via (ρ_L, ρ_R) is properly discontinuous and the convex hull $\mathcal{C}$ of Λ in Ω (called the *convex core*) has compact quotient by Γ. The quotient $(\rho_L, \rho_R)(\Gamma)\backslash\Omega$ is diffeomorphic to $M = S \times (0,1)$, and this yields a GHMC (G, X)-structure on M.

Such (G, X)-structures, or their holonomy representations $\rho = (\rho_L, \rho_R) : \Gamma \to \underline{G} \times \underline{G} \subset G$, are often called *AdS quasi-Fuchsian*, by analogy with Example 1.2. Their deformation space is parametrized by $\mathrm{Teich}(S) \times \mathrm{Teich}(S)$, via (ρ_L, ρ_R) (Mess [ibid.]). Their geometry, especially the geometry of the convex core and the way it determines (ρ_L, ρ_R), is the object of active current research (see Bonsante and Schlenker [2012] and Barbot, Bonsante, Danciger, Goldman, Guéritaud, Kassel, Krasnov, Schlenker, and Zeghib [2012]). Generalizations have recently been worked out in several directions (see Bonsante, Krasnov, and Schlenker [2011], Barbot and Mérigot [2012], Barbot [2015] and Section 6.2).

As in Section 3.1, the compactness of the convex core of an AdS quasi-Fuchsian manifold implies that any orbital map $\Gamma \to \Omega$ extends "at infinity" to an equivariant embedding $\xi : \partial_\infty \Gamma \to \partial X$ with image Λ. Here ∂X is still a flag variety G/P, where P is the stabilizer in $G = \mathrm{PO}(2,2)$ of an isotropic line of $\mathbb{R}^4$ for $\langle \cdot, \cdot \rangle_{2,2}$. Although G has higher rank, the rank-one dynamics of Section 3.1 still appear through the product structure of $G_0 \simeq \underline{G} \times \underline{G}$ acting on $\partial X \simeq \mathbb{P}^1(\mathbb{R}) \times \mathbb{P}^1(\mathbb{R}) \simeq \partial_\infty \mathbb{H}^2 \times \partial_\infty \mathbb{H}^2$.

4 Anosov representations

In this section we define and discuss Anosov representations. These are representations of Gromov hyperbolic groups to Lie groups G with strong dynamical properties, defined using continuous equivariant boundary maps. They were introduced by Labourie [2006] and further investigated by Guichard and Wienhard [2012]. They play an important role in higher Teichmüller theory and in the study of Problem B. As we shall see in Section 4.5, most representations that appeared in Section 3 were in fact Anosov.

4.1 The definition. Let Γ be a Gromov hyperbolic group with boundary $\partial_\infty \Gamma$ (e.g. Γ a surface group and $\partial_\infty \Gamma$ a circle, or Γ a nonabelian free group and $\partial_\infty \Gamma$ a Cantor set). The notion of an Anosov representation of Γ to a reductive Lie group G depends on the choice of a parabolic subgroup P of G up to conjugacy, i.e. on the choice of a flag variety G/P (see Section 1.4). Here, for simplicity, we restrict to $G = \mathrm{PGL}(d, \mathbb{R})$. We choose an integer $i \in [1, d-1]$ and denote by P_i the stabilizer in G of an i-plane of $\mathbb{R}^d$, so that G/P_i identifies with the Grassmannian $\mathrm{Gr}_i(\mathbb{R}^d)$.

By definition, a representation $\rho : \Gamma \to \mathrm{PGL}(d, \mathbb{R})$ is *P_i-Anosov* if there exist two continuous ρ-equivariant maps $\xi_i : \partial_\infty \Gamma \to \mathrm{Gr}_i(\mathbb{R}^d)$ and $\xi_{d-i} : \partial_\infty \Gamma \to \mathrm{Gr}_{d-i}(\mathbb{R}^d)$ which are transverse (i.e. $\xi_i(\eta) + \xi_{d-i}(\eta') = \mathbb{R}^d$ for all $\eta \neq \eta'$ in $\partial_\infty \Gamma$) and satisfy a uniform contraction/expansion condition analogous to the one defining Anosov flows.

Let us state this condition in the original case considered by Labourie [2006], where $\Gamma = \pi_1(M)$ for some closed negatively curved manifold M. We denote by $\widetilde{M}$ the universal cover of M, by T^1 the unit tangent bundle, and by $(\varphi_t)_{t \in \mathbb{R}}$ the geodesic flow on either

$T^1(M)$ or $T^1(\widetilde{M})$. Let
$$E^\rho = \Gamma\backslash(T^1(\widetilde{M}) \times \mathbb{R}^d)$$
be the natural flat vector bundle over $T^1(M) = \Gamma\backslash T^1(\widetilde{M})$ associated to ρ, where Γ acts on $T^1(\widetilde{M})\times\mathbb{R}^d$ by $\gamma\cdot(\tilde{x}, v) = (\gamma\cdot\tilde{x}, \rho(\gamma)\cdot v)$. The geodesic flow $(\varphi_t)_{t\in\mathbb{R}}$ on $T^1(M)$ lifts to a flow $(\psi_t)_{t\in\mathbb{R}}$ on E^ρ, given by $\psi_t \cdot [(\tilde{x}, v)] = [(\varphi_t \cdot \tilde{x}, v)]$. For each $\tilde{x} \in T^1(\widetilde{M})$, the transversality of the boundary maps induces a decomposition $\mathbb{R}^d = \xi_i(\tilde{x}^+) \oplus \xi_{d-i}(\tilde{x}^-)$, where $\tilde{x}^\pm = \lim_{t\to\pm\infty} \varphi_t \cdot \tilde{x}$ are the forward and backward endpoints of the geodesic defined by $\tilde{x}$, and this defines a decomposition of the vector bundle E^ρ into the direct sum of two subbundles $E^\rho_i = \{[(\tilde{x}, v)] \mid v \in \xi_i(\tilde{x}^+)\}$ and $E^\rho_{d-i} = \{[(\tilde{x}, v)] \mid v \in \xi_{d-i}(\tilde{x}^-)\}$. This decomposition is invariant under the flow (ψ_t). By definition, the representation ρ is P_i-Anosov if the following condition is satisfied.

Condition 4.1. *The flow $(\psi_t)_{t\in\mathbb{R}}$ uniformly contracts E^ρ_i with respect to E^ρ_{d-i}, i.e. there exist $C, C' > 0$ such that for any $t \geq 0$, any $x \in T^1(M)$, and any nonzero $w_i \in E^\rho_i(x)$ and $w_{d-i} \in E^\rho_{d-i}(x)$,*
$$\frac{\|\psi_t \cdot w_i\|_{\varphi_t\cdot x}}{\|\psi_t \cdot w_{d-i}\|_{\varphi_t\cdot x}} \leq e^{-Ct+C'} \frac{\|w_i\|_x}{\|w_{d-i}\|_x},$$
where $(\|\cdot\|_x)_{x\in T^1(M)}$ is any fixed continuous family of norms on the fibers $E^\rho(x)$.

See Bridgeman, Canary, Labourie, and Sambarino [2015] for an interpretation in terms of *metric Anosov flows* (or Smale flows).

Condition 4.1 implies in particular that the boundary maps ξ_i, ξ_{d-i} are *dynamics-preserving*, in the sense that the image of the attracting fixed point in $\partial_\infty\Gamma$ of any infinite-order element $\gamma \in \Gamma$ is an attracting fixed point in $\mathrm{Gr}_i(\mathbb{R}^d)$ or $\mathrm{Gr}_{d-i}(\mathbb{R}^d)$ of $\rho(\gamma)$. By density of such fixed points in $\partial_\infty\Gamma$ and by continuity, it follows that ξ_i and ξ_{d-i} are unique, compatible (i.e. $\xi_{\min(i,d-i)}(\eta) \subset \xi_{\max(i,d-i)}(\eta)$ for all $\eta \in \partial_\infty\Gamma$), and injective (using transversality). Since $\partial_\infty\Gamma$ is compact, they are homeomorphisms onto their image.

We note that *P_i-Anosov is equivalent to P_{d-i}-Anosov*, as the integers i and $d-i$ play a similar role in the definition (up to reversing the flow, which switches contraction and expansion). In particular, we may restrict to P_i-Anosov for $1 \leq i \leq d/2$.

Guichard and Wienhard [2012] observed that an analogue of Condition 4.1 can actually be defined for any Gromov hyperbolic group Γ. The idea is to replace $T^1(\widetilde{M})$ by $\partial_\infty\Gamma^{(2)} \times \mathbb{R}$ where $\partial_\infty\Gamma^{(2)}$ is the space of pairs of distinct points in the Gromov boundary $\partial_\infty\Gamma$ of Γ, and the flow φ_t by translation by t along the $\mathbb{R}$ factor. The work of Gromov [1987] (see also Mathéus [1991], Champetier [1994], Mineyev [2005]) yields an appropriate extension of the Γ-action on $\partial_\infty\Gamma^{(2)}$ to $\partial_\infty\Gamma^{(2)} \times \mathbb{R}$, which is properly discontinuous and cocompact.

This leads to a notion of an Anosov representation for any Gromov hyperbolic group Γ, see Guichard and Wienhard [2012].

4.2 Important properties and examples. A fundamental observation motivating the study of Anosov representations is the following: if G is a semisimple Lie group of real rank one, then a representation $\rho : \Gamma \to G$ is Anosov if and only if it is convex cocompact in the sense of Section 3.1.

Moreover, many important properties of convex cocompact representations to rank-one Lie groups generalize to Anosov representations. For instance, Anosov representations $\rho : \Gamma \to G$ are quasi-isometric embeddings, see Labourie [2006] and Guichard and Wienhard [2012]; in particular, they have finite kernel and discrete image. Also by Labourie [2006] and Guichard and Wienhard [2012], any Anosov subgroup (i.e. the image of any Anosov representation $\rho : \Gamma \to G$) is structurally stable; moreover, ρ admits a neighborhood in $\mathrm{Hom}(\Gamma, G)$ consisting entirely of Anosov representations. This is due to the uniform hyperbolicity nature of the Anosov condition.

Kapovich, Leeb, and Porti, in a series of papers (see Kapovich, Leeb, and Porti [2016, 2017], Kapovich and Leeb [2017] and Guichard [2017]), have developed a detailed analogy between Anosov representations to higher-rank semisimple Lie groups and convex cocompact representations to rank-one simple groups, from the point of view of dynamics (e.g. extending the expansion property at the limit set of Section 3.1 and other classical characterizations) and topology (e.g. compactifications).

Here are some classical examples of Anosov representations in higher real rank.

Examples 4.2. Let $\Gamma = \pi_1(S)$ where S is a closed orientable surface of genus ≥ 2.

(1) (Labourie [2006]) For $d \geq 2$, let $\tau_d : \mathrm{PSL}(2,\mathbb{R}) \to G = \mathrm{PGL}(d,\mathbb{R})$ be the irreducible representation (unique up to conjugation by G). For any Fuchsian representation $\rho_0 : \Gamma \to \mathrm{PSL}(2,\mathbb{R})$, the composition $\tau_d \circ \rho_0 : \Gamma \to G$ is P_i-Anosov for all $1 \leq i \leq d-1$. Moreover, any representation in the connected component of $\tau_d \circ \rho_0$ in $\mathrm{Hom}(\Gamma, G)$ is still P_i-Anosov for all $1 \leq i \leq d-1$. These representations were first studied by Hitchin [1992] and are now known as *Hitchin representations*.

(2) (Burger, Iozzi, Labourie, and Wienhard [2005] and Burger, Iozzi, and Wienhard [2010a]) If a representation of Γ to $G = \mathrm{PSp}(2n,\mathbb{R}) \subset \mathrm{PGL}(2n,\mathbb{R})$ (resp. $G = \mathrm{PO}(2,q) \subset \mathrm{PGL}(2+q,\mathbb{R})$) is *maximal*, then it is P_n-Anosov (resp. P_1-Anosov).

(3) (Barbot [2010] for $d = 3$) Let $d \geq 2$. Any Fuchsian representation $\Gamma \to \mathrm{SL}(2,\mathbb{R})$, composed with the standard embedding $\mathrm{SL}(2,\mathbb{R}) \hookrightarrow \mathrm{SL}(d,\mathbb{R})$ (given by the direct sum of the standard action on $\mathbb{R}^2$ and the trivial action on $\mathbb{R}^{d-2}$), defines a P_1-Anosov representation $\Gamma \to G = \mathrm{PSL}(d,\mathbb{R})$.

In (2), we say that $\rho : \Gamma \to G$ is *maximal* if it maximizes a topological invariant, the *Toledo number* $T(\rho)$, defined for any simple Lie group G of Hermitian type. If $X = G/K$

is the Riemannian symmetric space of G, then the imaginary part of the G-invariant Hermitian form on X defines a real 2-form ω_X, and by definition $T(\rho) = \frac{1}{2\pi} \int_S f^* \omega_X$ where $f : \widetilde{S} \to X$ is any ρ-equivariant smooth map. For $G = \mathrm{PSL}(2, \mathbb{R})$, this coincides with the Euler number of ρ. In general, $T(\rho)$ takes discrete values and $|T(\rho)| \leq \mathrm{rank}_{\mathbb{R}}(G)\, |\chi(S)|$ where $\chi(S)$ is the Euler characteristic of S (see Burger, Iozzi, and Wienhard [2014]).

While (1) and (3) provide Anosov representations in two of the three connected components of $\mathrm{Hom}(\Gamma, \mathrm{PSL}(3, \mathbb{R}))$ for $\Gamma = \pi_1(S)$, it is currently not known whether Anosov representations appear in the third component.

See Benoist [1996], Guichard and Wienhard [2012], Kapovich, Leeb, and Porti [2014a], Canary, M. Lee, Sambarino, and Stover [2017], Burelle and Treib [2018] for higher-rank Anosov generalizations of Schottky groups.

4.3 Higher Teichmüller spaces of Anosov representations. Anosov representations play an important role in *higher Teichmüller theory*, a currently very active theory whose goal is to find deformation spaces of faithful and discrete representations of discrete groups Γ into higher-rank semisimple Lie groups G which share some of the remarkable properties of Teichmüller space. Although various groups Γ may be considered, the foundational case is when $\Gamma = \pi_1(S)$ for some closed connected surface S of genus ≥ 2 (see Burger, Iozzi, and Wienhard [2014] and Wienhard [2018]); then one can use rich features of Riemann surfaces, explicit topological considerations, and powerful techniques based on Higgs bundles as in the pioneering work of Hitchin [1992].

Strikingly similar properties to $\mathrm{Teich}(S)$ have been found for two types of *higher Teichmüller spaces*: the space of *Hitchin representations* of Γ into a real split simple Lie group G such as $\mathrm{PGL}(d, \mathbb{R})$, modulo conjugation by G; and the space of *maximal representations* of Γ into a simple Lie group G of Hermitian type such as $\mathrm{PSp}(2n, \mathbb{R})$ or $\mathrm{PO}(2, q)$, modulo conjugation by G. Both these spaces are unions of connected components of $\mathrm{Hom}(\Gamma, G)/G$, consisting entirely of Anosov representations (see Examples 4.2). Similarities of these spaces to $\mathrm{Teich}(S)$ include:

(1) the proper discontinuity of the action of the mapping class group $\mathrm{Mod}(S)$ (Wienhard [2006], Labourie [2008]);

(2) for Hitchin components: the topology of $\mathbb{R}^{\dim(G)\,|\chi(S)|}$ (Hitchin [1992]);

(3) good systems of coordinates generalizing those on $\mathrm{Teich}(S)$ (Goldman [1990], Fock and Goncharov [2006], Bonahon and Dreyer [2014], Strubel [2015], Zhang [2015]);

(4) an analytic $\mathrm{Mod}(S)$-invariant Riemannian metric, the *pressure metric* (Bridgeman, Canary, Labourie, and Sambarino [2015] and Pollicott and Sharp [2017]);

(5) versions of the collar lemma for associated locally symmetric spaces (G.-S. Lee and Zhang [2017], Burger and Pozzetti [2017]).

Other higher Teichmüller spaces of Anosov representations of $\pi_1(S)$ are also being explored, see Guichard and Wienhard [2016]. We refer to Section 5 for geometric structures associated to such spaces.

4.4 Characterizations. Various characterizations of Anosov representations have been developed in the past few years, by Labourie [2006], Guichard and Wienhard [2012], Kapovich, Leeb, and Porti [2014a,b], Kapovich and Leeb [2017], Guéritaud, Guichard, Kassel, and Wienhard [2017a], and others. Here are some characterizations that do not involve any flow. They hold for any reductive Lie group G, but for simplicity we state them for $G = \mathrm{PGL}(d,\mathbb{R})$. For $1 \leq i \leq d$ and $g \in \mathrm{GL}(d,\mathbb{R})$, we denote by $\mu_i(g)$ (resp. $\lambda_i(g)$) the logarithm of the i-th singular value (resp. eigenvalue) of g.

Theorem 4.3. *For a Gromov hyperbolic group Γ, a representation $\rho : \Gamma \to G = \mathrm{PGL}(d,\mathbb{R})$, and an integer $1 \leq i \leq d/2$, the following are equivalent:*

(1) ρ is P_i-Anosov (or equivalently P_{d-i}-Anosov, see Section 4.1);

(2) there exist continuous, ρ-equivariant, transverse, dynamics-preserving boundary maps $\xi_i : \partial_\infty\Gamma \to \mathrm{Gr}_i(\mathbb{R}^d)$ and $\xi_{d-i} : \partial_\infty\Gamma \to \mathrm{Gr}_{d-i}(\mathbb{R}^d)$, and $(\mu_i - \mu_{i+1})(\rho(\gamma)) \to +\infty$ as $|\gamma| \to +\infty$;

(3) there exist continuous, ρ-equivariant, transverse, dynamics-preserving boundary maps $\xi_i : \partial_\infty\Gamma \to \mathrm{Gr}_i(\mathbb{R}^d)$ and $\xi_{d-i} : \partial_\infty\Gamma \to \mathrm{Gr}_{d-i}(\mathbb{R}^d)$, and $(\lambda_i - \lambda_{i+1})(\rho(\gamma)) \to +\infty$ as $\ell_\Gamma(\gamma) \to +\infty$;

(4) there exist $C, C' > 0$ such that $(\mu_i - \mu_{i+1})(\rho(\gamma)) \geq C\,|\gamma| - C'$ for all $\gamma \in \Gamma$;

(5) there exist $C, C' > 0$ such that $(\lambda_i - \lambda_{i+1})(\rho(\gamma)) \geq C\,\ell_\Gamma(\gamma) - C'$ for all $\gamma \in \Gamma$.

Here we denote by $|\cdot| : \Gamma \to \mathbb{N}$ the word length with respect to some fixed finite generating subset of Γ, and by $\ell_\Gamma : \Gamma \to \mathbb{N}$ the translation length in the Cayley graph of Γ for that subset, i.e. $\ell_\Gamma(\gamma) = \min_{\beta\in\Gamma} |\beta\gamma\beta^{-1}|$. In a Gromov hyperbolic group Γ the translation length $\ell_\Gamma(\gamma)$ is known to differ only by at most a uniform additive constant from the stable length $|\gamma|_\infty = \lim_{n\to+\infty} |\gamma^n|/n$, and so we may replace $\ell_\Gamma(\gamma)$ by $|\gamma|_\infty$ in Conditions (3) and (5).

The equivalence (1) ⇔ (2) is proved in Guéritaud, Guichard, Kassel, and Wienhard [ibid.] and Kapovich, Leeb, and Porti [2014b], the equivalence (2) ⇔ (3) in Guéritaud, Guichard, Kassel, and Wienhard [2017a], the equivalence (1) ⇔ (4) in Kapovich, Leeb, and Porti [2014a] and Bochi, Potrie, and Sambarino [2018], and the equivalence (4) ⇔ (5) in Kassel and Potrie [2018].

Condition (4) is a refinement of the condition of being a quasi-isometric embedding, which for $G = \mathrm{PGL}(d,\mathbb{R})$ is equivalent to the existence of $C, C' > 0$ such that $\sqrt{\sum_k (\mu_k - \mu_{k+1})}$ $C\,|\gamma| - C'$ for all $\gamma \in \Gamma$. We refer to Guéritaud, Guichard, Kassel, and Wienhard [2017a] (*CLI condition*) and Kapovich, Leeb, and Porti [2014a] (*Morse condition*) for further refinements satisfied by Anosov representations.

By Kapovich, Leeb, and Porti [ibid.] and Bochi, Potrie, and Sambarino [2018], if Γ is any finitely generated group, then the existence of a representation $\rho : \Gamma \to \mathrm{PGL}(d,\mathbb{R})$ satisfying Condition (4) implies that Γ is Gromov hyperbolic. The analogue for (5) is more subtle: e.g. the Baumslag–Solitar group $\mathrm{BS}(1,2)$, which is not Gromov hyperbolic, still admits a faithful representation into $\mathrm{PSL}(2,\mathbb{R})$ satisfying Condition (5) for the stable length $|\cdot|_\infty$, see Kassel and Potrie [2018].

The original proof of (1) ⇔ (4) by Kapovich, Leeb, and Porti [2014a] uses the geometry of higher-rank Riemannian symmetric spaces and asymptotic cones. The alternative proof given by Bochi, Potrie, and Sambarino [2018] is based on an interpretation of (1) and (4) in terms of partially hyperbolic dynamics, and more specifically of dominated splittings for locally constant linear cocycles over certain subshifts. Pursuing this point of view further, it is shown in Kassel and Potrie [2018] that the equivalence (4) ⇔ (5) of Theorem 4.3 implies the equivalence between nonuniform hyperbolicity (i.e. all invariant measures are hyperbolic) and uniform hyperbolicity for a certain cocycle naturally associated with ρ on the space of biinfinite geodesics of Γ. In general in smooth dynamics, nonuniform hyperbolicity does not imply uniform hyperbolicity.

4.5 Revisiting the examples of Section 3. The boundary maps and dynamics "at infinity" that appeared in the examples of Section 3 are explained for the most part by the notion of an Anosov representation:

- convex cocompact representations to rank-one simple Lie groups as in Section 3.1 are all Anosov (see Section 4.2);

- if S is a closed orientable connected surface of genus ≥ 2, then by Goldman [1990] and Choi and Goldman [2005] the holonomy representations of convex projective structures on S as in Section 3.2 are exactly the Hitchin representations of $\pi_1(S)$ into $\mathrm{PSL}(3,\mathbb{R})$; they are all P_1-Anosov (Example 4.2.(1));

- for general $d \geq 3$, the work of Benoist [2004] shows that if Γ is a discrete subgroup of $\mathrm{PGL}(d,\mathbb{R})$ dividing a *strictly convex* open subset Ω of $\mathbb{P}(\mathbb{R}^d)$, then Γ is Gromov hyperbolic and the inclusion $\Gamma \hookrightarrow \mathrm{PGL}(d,\mathbb{R})$ is P_1-Anosov;

- The work of Mess [2007] implies that a representation $\rho : \pi_1(S) \to \mathrm{PO}(2,2) \subset \mathrm{PGL}(4,\mathbb{R})$ is AdS quasi-Fuchsian if and only if it is P_1-Anosov.

5 Geometric structures for Anosov representations

We just saw in Section 4.5 that various (G, X)-structures described in Section 3 give rise (via the holonomy) to Anosov representations; these (G, X)-structures are of type C or type U (terminology of Section 1.1). In this section, we study the converse direction. Namely, given an Anosov representation $\rho : \Gamma \to G$, we wish to find:

- homogeneous spaces $X = G/H$ on which Γ acts properly discontinuously via ρ; this will yield (G, X)-manifolds (or orbifolds) $M = \rho(\Gamma)\backslash X$ of type C;
- proper open subsets $\mathcal{U}$ (*domains of discontinuity*) of homogeneous spaces $X = G/H$ on which Γ acts properly discontinuously via ρ; this will yield (G, X)-manifolds (or orbifolds) $M = \rho(\Gamma)\backslash\mathcal{U}$ of type U.

We discuss type U in Sections 5.1 and 5.2 and type C in Section 5.3. One motivation is to give a geometric meaning to the higher Teichmüller spaces of Section 4.3.

5.1 Cocompact domains of discontinuity. Domains of discontinuity with compact quotient have been constructed in several settings in the past ten years.

Barbot [2010] constructed such domains in the space X of flags of $\mathbb{R}^3$, for the Anosov representations to $G = \mathrm{PSL}(3,\mathbb{R})$ of Example 4.2.(3) and their small deformations.

Guichard and Wienhard [2012] developed a more general construction of cocompact domains of discontinuity in flag varieties X for Anosov representations to semisimple Lie groups G. Here is one of their main results. For $p \geq q \geq i \geq 1$, we denote by $\mathfrak{F}_i^{p,q}$ the closed subspace of the Grassmannian $\mathrm{Gr}_i(\mathbb{R}^{p+q})$ consisting of i-planes that are totally isotropic for the standard symmetric bilinear form $\langle\cdot,\cdot\rangle_{p,q}$ of signature (p, q).

Theorem 5.1 (Guichard and Wienhard [ibid.]). *Let $G = \mathrm{PO}(p,q)$ with $p \geq q$ and $X = \mathfrak{F}_q^{p,q}$. For any P_1-Anosov representation $\rho : \Gamma \to G \subset \mathrm{PGL}(\mathbb{R}^{p+q})$ with boundary map $\xi_1 : \partial_\infty\Gamma \to \mathfrak{F}_1^{p,q} \subset \mathbb{P}(\mathbb{R}^{p+q})$, the group $\rho(\Gamma)$ acts properly discontinuously with compact quotient on $\mathcal{U}_\rho := X \smallsetminus \mathcal{L}_\rho$, where*

$$\mathcal{L}_\rho := \bigcup_{\eta\in\partial_\infty\Gamma} \{W \in X = \mathfrak{F}_q^{p,q} \mid \xi_1(\eta) \in W\}.$$

We have $\mathcal{U}_\rho \neq \varnothing$ as soon as $\dim(\partial_\infty\Gamma) < p-1$. The homeomorphism type of $\rho(\Gamma)\backslash\mathcal{U}_\rho$ is constant as ρ varies continuously among P_1-Anosov representations of Γ to G.

For $q = 1$, we recover the familiar picture of Section 3.1: the set $\mathcal{L}_\rho$ is the limit set $\Lambda_{\rho(\Gamma)} \subset \partial_\infty \mathbb{H}^p$, and $\mathcal{U}_\rho$ is the domain of discontinuity $\Omega_{\rho(\Gamma)} = \partial_\infty \mathbb{H}^p \smallsetminus \Lambda_{\rho(\Gamma)}$.

For $q = 2$, Theorem 5.1 fits into the theory of *Lorentzian Kleinian groups* acting on the Einstein universe $X = \mathrm{Ein}^p = \mathfrak{F}_1^{p,2}$, as developed by Frances [2005].

Guichard and Wienhard [2012] used Theorem 5.1 to describe domains of discontinuity for various families of Anosov representations to other semisimple Lie groups G. Indeed, they proved that an Anosov representation $\rho : \Gamma \to G$ can always be composed with a representation of G to some $\mathrm{PO}(p,q)$ so as to become P_1-Anosov in $\mathrm{PO}(p,q)$.

Kapovich, Leeb, and Porti [2018] developed a more systematic approach to the construction of domains of discontinuity in flag varieties. They provided sufficient conditions (expressed in terms of a notion of *balanced* ideal in the Weyl group for the Bruhat order) on triples (G, P, Q) consisting of a semisimple Lie group G and two parabolic subgroups P and Q, so that P-Anosov representations to G admit cocompact domains of discontinuity in G/Q. These domains are obtained by removing an explicit "extended limit set" $\mathcal{L}_\rho$ as in Theorem 5.1. The approach of Kapovich–Leeb–Porti is intrinsic: it does not rely on an embedding of G into some $\mathrm{PO}(p,q)$.

5.2 Geometric structures for Hitchin and maximal representations. Let $\Gamma = \pi_1(S)$ where S is a closed orientable surface of genus ≥ 2. Recall (Examples 4.2) that Hitchin representations from Γ to $G = \mathrm{PSL}(d,\mathbb{R})$ are P_i-Anosov for all $1 \leq i \leq d-1$; maximal representations from Γ to $G = \mathrm{PO}(2,q) \subset \mathrm{PGL}(2+q,\mathbb{R})$ are P_1-Anosov.

For $G = \mathrm{PSL}(2,\mathbb{R}) \simeq \mathrm{PO}(2,1)_0$, Hitchin representations and maximal representations of Γ to G both coincide with the Fuchsian representations; they are the holonomy representations of hyperbolic structures on S (Example 2.1). In the setting of higher Teichmüller theory (see Section 4.3), one could hope that Hitchin or maximal representations of Γ to higher-rank Lie groups G might also parametrize certain geometric structures on a manifold related to S. We saw in Section 4.5 that this is indeed the case for $G = \mathrm{PSL}(3,\mathbb{R})$: Hitchin representations of Γ to $\mathrm{PSL}(3,\mathbb{R})$ parametrize the convex projective structures on S (Goldman [1990], Choi and Goldman [2005]). In an attempt to generalize this picture, we now outline constructions of domains of discontinuity for Hitchin representations to $\mathrm{PSL}(d,\mathbb{R})$ with $d > 3$, and maximal representations to $\mathrm{PO}(2,q)$ with $q > 1$. By classical considerations of cohomological dimension, such domains cannot be both cocompact and contractible; in Sections 5.2.2 and 5.2.3 below, we will prefer to forgo compactness to favor the nice geometry of convex domains.

5.2.1 Hitchin representations for even $d = 2n$. Let $(G, X) = (\mathrm{PSL}(2n,\mathbb{R}), \mathbb{P}(\mathbb{R}^{2n}))$. Hitchin representations into G do not preserve any properly convex open set Ω in X (see Danciger, Guéritaud, and Kassel [2017], Zimmer [2017]). However, Guichard and Wienhard [2008, 2012] associated to them nonconvex (G, X)-structures on a closed manifold: if $\rho : \Gamma \to G$ is Hitchin with boundary map $\xi_n : \partial_\infty \Gamma \to \mathrm{Gr}_n(\mathbb{R}^{2n})$, then $\mathcal{U} = X \smallsetminus \bigcup_{\eta \in \partial_\infty \Gamma} \xi_n(\eta)$ is a cocompact domain of discontinuity for ρ. For $n = 2$ the quotient has two connected components which both fiber in circles over S; considering one of them, the Hitchin representations parametrize projective structures on $T^1(S)$ with a natural foliation by 2-dimensional convex sets (Guichard and Wienhard [2008]). For $3 \le n \le 63$, Alessandrini and Li [2018] recently used Higgs bundle techniques to describe a fibration of $\rho(\Gamma)\backslash\mathcal{U}$ over S with fiber $\mathrm{O}(n)/\mathrm{O}(n-2)$.

5.2.2 Hitchin representations for odd $d = 2n + 1$. Hitchin representations into $G = \mathrm{PSL}(2n + 1, \mathbb{R})$ give rise to (G, X)-manifolds for at least two choices of X.

One choice for X is the space of partial flags $(V_1 \subset V_{2n})$ of $\mathbb{R}^{2n+1}$ with V_1 a line and V_{2n} a hyperplane: Guichard and Wienhard [2012] again constructed explicit cocompact domains of discontinuity in X in this setting.

Another choice is $X = \mathbb{P}(\mathbb{R}^{2n+1})$: Hitchin representations in odd dimension are the holonomies of convex projective manifolds, which are noncompact for $n > 1$.

Theorem 5.2 (Danciger, Guéritaud, and Kassel [2017], Zimmer [2017])**.** *For any Hitchin representation $\rho : \Gamma \to \mathrm{PSL}(2n + 1, \mathbb{R})$, there is a $\rho(\Gamma)$-invariant properly convex open subset Ω of $\mathbb{P}(\mathbb{R}^{2n+1})$ and a nonempty closed convex subset $\mathcal{C}$ of Ω which has compact quotient by $\rho(\Gamma)$.*

More precisely, if ρ has boundary maps $\xi_1 : \partial_\infty \Gamma \to \mathrm{Gr}_1(\mathbb{R}^{2n+1}) = \mathbb{P}(\mathbb{R}^{2n+1})$ and $\xi_{2n} : \partial_\infty \Gamma \to \mathrm{Gr}_{2n}(\mathbb{R}^{2n+1})$, we may take $\Omega = \mathbb{P}(\mathbb{R}^{2n+1}) \smallsetminus \bigcup_{\eta \in \partial_\infty \Gamma} \xi_{2n}(\eta)$ and $\mathcal{C}$ to be the convex hull of $\xi_1(\partial_\infty \Gamma)$ in Ω. The group $\rho(\Gamma)$ acts properly discontinuously on Ω (Remark 3.1), and so $\rho(\Gamma)\backslash\Omega$ is a convex projective manifold, with a compact convex core $\rho(\Gamma)\backslash\mathcal{C}$. In other words, $\rho(\Gamma)$ is *convex cocompact in* $\mathbb{P}(\mathbb{R}^{2n+1})$, see Section 6.

5.2.3 Maximal representations. Maximal representations into $G = \mathrm{PO}(2, q)$ give rise to (G, X)-manifolds for at least two choices of X.

One choice is $X = \mathcal{F}_2^{2,q}$ (also known as the space of *photons* in the Einstein universe Ein^q): Theorem 5.1 provides cocompact domains of discontinuity for ρ in X. Collier, Tholozan, and Toulisse [2017] recently studied the geometry of the associated quotient (G, X)-manifolds, and showed that they fiber over S with fiber $\mathrm{O}(q)/\mathrm{O}(q-2)$.

Another choice is $X = \mathbb{P}(\mathbb{R}^{2+q})$: by Danciger, Guéritaud, and Kassel [2018a], maximal representations $\rho : \Gamma \to G$ are the holonomy representations of convex projective manifolds $\rho(\Gamma)\backslash\Omega$, which are noncompact for $q > 1$ but still convex cocompact as in Section 5.2.2. In fact Ω can be taken inside $\mathbb{H}^{2,q-1} = \{[v] \in \mathbb{P}(\mathbb{R}^{2+q}) \mid \langle v, v \rangle_{2,q} < 0\}$ (see also Collier, Tholozan, and Toulisse [2017]), which is a pseudo-Riemannian analogue of the real hyperbolic space in signature $(2, q-1)$, and $\rho(\Gamma)$ is $\mathbb{H}^{2,q-1}$-convex cocompact in the sense of Section 6.2 below.

5.3 Proper actions on full homogeneous spaces. In Sections 5.1 and 5.2, we mainly considered *compact* homogeneous spaces $X = G/H$ (flag varieties); these spaces cannot admit proper actions by infinite discrete groups, but we saw that sometimes they can contain domains of discontinuity $\mathcal{U} \subsetneq X$, yielding (G, X)-manifolds of type U (terminology of Section 1.1).

We now consider *noncompact* homogeneous spaces $X = G/H$. Then Anosov representations $\rho : \Gamma \to G$ may give proper actions of Γ on the whole of $X = G/H$, yielding (G, X)-manifolds $\rho(\Gamma)\backslash X$ of type C. When H is compact, this is not very interesting since all faithful and discrete representations to G give proper actions on X. However, when H is noncompact, it may be remarkably difficult in general to find such representations giving proper actions on X, which led to a rich literature (see Kobayashi and Yoshino [2005] and Kassel [2009, Intro]).

One construction for proper actions on X was initiated by Guichard and Wienhard [2012] and developed further in Guéritaud, Guichard, Kassel, and Wienhard [2017b]. Starting from an Anosov representation $\rho : \Gamma \to G$, the idea is to embed G into some larger semisimple Lie group G' so that $X = G/H$ identifies with a G-orbit in some flag variety $\mathcal{F}'$ of G', and then to find a cocompact domain of discontinuity $\mathcal{U} \supset X$ for ρ in $\mathcal{F}'$ by using a variant of Theorem 5.1. The action of $\rho(\Gamma)$ on X is then properly discontinuous, and $\rho(\Gamma)\backslash(\mathcal{U} \cap \overline{X})$ provides a compactification of $\rho(\Gamma)\backslash X$, which in many cases can be shown to be well-behaved. Here is one of the applications of this construction given in Guéritaud, Guichard, Kassel, and Wienhard [ibid.].

Example 5.3. Let $G = \mathrm{PO}(p, q)$ and $H = \mathrm{O}(p, q-1)$ where $p > q \geq 1$. For any P_q-Anosov representation $\rho : \Gamma \to G \subset \mathrm{PGL}(p+q, \mathbb{R})$, the group $\rho(\Gamma)$ acts properly discontinuously on $X = \mathbb{H}^{p,q-1} = \{[v] \in \mathbb{P}(\mathbb{R}^{p+q}) \mid \langle v, v\rangle_{p,q} < 0\} \simeq G/H$, and for torsion-free Γ the complete (G, X)-manifold $\rho(\Gamma)\backslash X$ is topologically tame.

By *topologically tame* we mean homeomorphic to the interior of a compact manifold with boundary. For other compactifications of quotients of homogeneous spaces by Anosov representations, yielding topological tameness, see Guichard, Kassel, and Wienhard [2015], Kapovich and Leeb [2015], and Kapovich, Leeb, and Porti [2018].

Another construction of complete (G, X)-manifolds for Anosov representations to reductive Lie groups G was given in Guéritaud, Guichard, Kassel, and Wienhard [2017a], based on a properness criterion of Benoist [1996] and Kobayashi [1996]. For simplicity we discuss it for $G = \mathrm{PGL}(d, \mathbb{R})$. As in Section 4.4, let $\mu_i(g)$ be the logarithm of the i-th singular value of a matrix $g \in \mathrm{GL}(d, \mathbb{R})$; this defines a map $\mu = (\mu_1, \dots, \mu_d) : \mathrm{PGL}(d, \mathbb{R}) \to \mathbb{R}^d/\mathbb{R}(1, \dots, 1) \simeq \mathbb{R}^{d-1}$. The properness criterion of Benoist and Kobayashi states that for two closed subgroups H, Γ of $G = \mathrm{PGL}(d, \mathbb{R})$, the action of Γ on G/H is properly discontinuous if and only if the set $\mu(\Gamma)$ "drifts away at infinity from $\mu(H)$", in the sense that for any $R > 0$ we have $d_{\mathbb{R}^{d-1}}(\mu(\gamma), \mu(H)) \geq R$ for all but finitely many $\gamma \in \Gamma$. If Γ is the image of an Anosov representation, then we can apply the implication (1) $\Rightarrow$ (2) of Theorem 4.3 to see that the properness criterion is satisfied for many examples of H.

Example 5.4. For $i = 1$ (resp. n), the image of any P_i-Anosov representation to $G = \mathrm{PSL}(2n, \mathbb{R})$ acts properly discontinuously on $X = G/H$ for $H = \mathrm{SL}(n, \mathbb{C})$ (resp. $\mathrm{SO}(n+1, n-1)$).

6 Convex cocompact projective structures

In Sections 3 and 4.5 we started from (G, X)-structures to produce Anosov representations, and in Section 5 we started from Anosov representations to produce (G, X)-structures. We now discuss a situation, in the setting of convex projective geometry, in which the links between (G, X)-structures and Anosov representations are particularly tight and go in both directions, yielding a better understanding of both sides. In Section 6.4 we will also encounter generalizations of Anosov representations, for finitely generated groups that are not necessarily Gromov hyperbolic.

6.1 Convex cocompactness in higher real rank. The results presented here are part of a quest to generalize the notion of rank-one convex cocompactness of Section 3.1 to higher real rank.

The most natural generalization, in the setting of Riemannian symmetric spaces, turns out to be rather restrictive: Kleiner and Leeb [2006] and Quint [2005] proved that if G is a real simple Lie group of real rank ≥ 2 and K a maximal compact subgroup of G, then any Zariski-dense discrete subgroup of G acting with compact quotient on some nonempty convex subset of G/K is a uniform lattice in G.

Meanwhile, we have seen in Section 4.2 that Anosov representations to higher-rank semisimple Lie groups G have strong dynamical properties which nicely generalize those of rank-one convex cocompact representations (see Kapovich, Leeb, and Porti [2016, 2017], Kapovich and Leeb [2017] and Guichard [2017]). However, in general Anosov representations to G do not act with compact quotient on any nonempty convex subset of G/K, and it is not clear that Anosov representations should come with any geometric notion of convexity at all (see e.g. Section 5.2.1).

In this section, we shall see that Anosov representations in fact do come with convex structures. We shall introduce several generalizations of convex cocompactness to higher real rank (which we glimpsed in Sections 5.2.2 and 5.2.3) and relate them to Anosov representations.

6.2 Convex cocompactness in pseudo-Riemannian hyperbolic spaces. We start with a generalization of the hyperbolic quasi-Fuchsian manifolds of Example 1.2 or the AdS quasi-Fuchsian manifolds of Section 3.3, where we replace the real hyperbolic space $\mathbb{H}^3$ or its Lorentzian analogue AdS^3 by their general pseudo-Riemannian analogue in signature $(p, q-1)$ for $p, q \geq 1$, namely

$$X = \mathbb{H}^{p,q-1} = \big\{[v] \in \mathbb{P}(\mathbb{R}^{p+q}) \mid \langle v, v\rangle_{p,q} < 0\big\}.$$

The symmetric bilinear form $\langle\cdot,\cdot\rangle_{p,q}$ of signature (p,q) induces a pseudo-Riemannian structure of signature $(p, q-1)$ on X, with isometry group $G = \mathrm{PO}(p,q)$ and constant negative sectional curvature (see e.g. Danciger, Guéritaud, and Kassel [2018a, § 2.1]). The following is not our original definition, but an equivalent one from Danciger, Guéritaud, and Kassel [2017, Th. 1.25].

Definition 6.1. A discrete subgroup Γ of $G = \mathrm{PO}(p,q)$ is $\mathbb{H}^{p,q-1}$*-convex cocompact* if it preserves a properly convex open subset Ω of $X = \mathbb{H}^{p,q-1} \subset \mathbb{P}(\mathbb{R}^{p+q})$ and if it acts with compact quotient on some closed convex subset $\mathcal{C}$ of Ω with nonempty interior, whose ideal boundary $\partial_{\mathrm{i}}\mathcal{C} := \overline{\mathcal{C}} \smallsetminus \mathcal{C} = \overline{\mathcal{C}} \cap \partial X$ does not contain any nontrivial projective segment. A representation $\rho : \Gamma \to G$ is $\mathbb{H}^{p,q-1}$*-convex cocompact* if its kernel is finite and its image is an $\mathbb{H}^{p,q-1}$-convex cocompact subgroup of G.

Here $\overline{\mathcal{C}}$ is the closure of $\mathcal{C}$ in $\mathbb{P}(\mathbb{R}^{p+q})$ and ∂X the boundary of $X = \mathbb{H}^{p,q-1}$ in $\mathbb{P}(\mathbb{R}^{p+q})$. For $\Gamma, \Omega, \mathcal{C}$ as in Definition 6.1, the quotient $\Gamma\backslash\Omega$ is a (G, X)-manifold (or orbifold) (see Remark 3.1), which we shall call *convex cocompact*; the subset $\Gamma\backslash\mathcal{C}$ is compact, convex, and contains all the topology, as in Sections 3.1 and 3.3.

There is a rich world of examples of convex cocompact (G, X)-manifolds, including direct generalizations of the quasi-Fuchsian manifolds of Sections 3.1 and 3.3 (see Barbot and Mérigot [2012] and Danciger, Guéritaud, and Kassel [2018a, 2017]) but also more exotic examples where the fundamental group is not necessarily realizable as a discrete subgroup of $\mathrm{PO}(p,1)$ (see Danciger, Guéritaud, and Kassel [2018a] and G.-S. Lee and Marquis [2018]).

The following result provides links with Anosov representations.

Theorem 6.2 (Danciger, Guéritaud, and Kassel [2018a, 2017])**.** *For $p, q \geq 1$, let Γ be an infinite discrete group and $\rho : \Gamma \to G = \mathrm{PO}(p,q) \subset \mathrm{PGL}(p+q, \mathbb{R})$ a representation.*

(1) If ρ is $\mathbb{H}^{p,q-1}$-convex cocompact, then Γ is Gromov hyperbolic and ρ is P_1-Anosov.

(2) *Conversely, if* Γ *is Gromov hyperbolic, if* ρ *is* P_1*-Anosov, and if* $\rho(\Gamma)$ *preserves a properly convex open subset of* $\mathbb{P}(\mathbb{R}^{p+q})$*, then* ρ *is* $\mathbb{H}^{p,q-1}$*-convex cocompact or* $\mathbb{H}^{q,p-1}$*-convex cocompact.*

(3) *If* Γ *is Gromov hyperbolic with* connected *boundary* $\partial_\infty\Gamma$ *and if* ρ *is* P_1*-Anosov, then* ρ *is* $\mathbb{H}^{p,q-1}$*-convex cocompact or* $\mathbb{H}^{q,p-1}$*-convex cocompact.*

In (2)–(3), the phrase "$\mathbb{H}^{q,p-1}$-convex cocompact" is understood after identifying $\mathrm{PO}(p,q)$ with $\mathrm{PO}(q,p)$ and $\mathbb{P}(\mathbb{R}^{p,q}) \smallsetminus \overline{\mathbb{H}^{p,q-1}}$ with $\mathbb{H}^{q,p-1}$ under multiplication of $\langle\cdot,\cdot\rangle_{p,q}$ by -1. The case that $q = 2$ and Γ is isomorphic to a uniform lattice of $\mathrm{PO}(p,1)$ is due to Barbot and Mérigot [2012].

The links between $\mathbb{H}^{p,q-1}$-convex cocompactness and Anosov representations in Theorem 6.2 have several applications.

Applications to (G, X)-structures, see Danciger, Guéritaud, and Kassel [2018a, 2017].
• $\mathbb{H}^{p,q-1}$-convex cocompactness is stable under small deformations, because being Anosov is; thus the set of holonomy representations of convex cocompact (G, X)-structures on a given manifold M is open in $\mathrm{Hom}(\pi_1(M), G)$.
• Examples of convex cocompact (G, X)-manifolds can be obtained using classical families of Anosov representations: e.g. Hitchin representations into $\mathrm{PO}(n+1,n)$ are $\mathbb{H}^{n+1,n-1}$-convex cocompact for odd n and $\mathbb{H}^{n,n}$-convex cocompact for even n, and Hitchin representations into $\mathrm{PO}(n+1,n+1)$ are $\mathbb{H}^{n+1,n}$-convex cocompact. Maximal representations into $\mathrm{PO}(2,q)$ are $\mathbb{H}^{2,q-1}$-convex cocompact, see Section 5.2.3.

Applications to Anosov representations:
• New examples of Anosov representations can be constructed from convex cocompact (G, X)-manifolds: e.g. this approach is used in Danciger, Guéritaud, and Kassel [2018a] to prove that any Gromov hyperbolic right-angled Coxeter group in d generators admits P_1-Anosov representations to $\mathrm{PGL}(d,\mathbb{R})$. This provides a large new class of hyperbolic groups admitting Anosov representations; these groups can have arbitrary large cohomological dimension, and exotic boundaries (see Dani [2017] for references). (Until now most known examples of Anosov representations were for surface groups or free groups.)
• For $q = 2$ and Γ a uniform lattice of $\mathrm{PO}(p,1)_0$, Barbot [2015] used convex cocompact (G, X)-structures to prove that the connected component $\mathcal{T}$ of $\mathrm{Hom}(\Gamma, \mathrm{PO}(p,2))$ containing the natural inclusion $\Gamma \hookrightarrow \mathrm{PO}(p,1)_0 \hookrightarrow \mathrm{PO}(p,2)$ consists entirely of Anosov representations. This is interesting in the framework of Section 4.3.

6.3 Strong projective convex cocompactness. We now consider a broader notion of convex cocompactness, not involving any quadratic form. Let $d \geq 2$.

Definition 6.3. A discrete subgroup Γ of $G = \mathrm{PGL}(d,\mathbb{R})$ is *strongly* $\mathbb{P}(\mathbb{R}^d)$*-convex cocompact* if it preserves a strictly convex open subset Ω of $X = \mathbb{P}(\mathbb{R}^d)$ with C^1 boundary and if it acts with compact quotient on some nonempty closed convex subset $\mathcal{C}$ of Ω. A representation $\rho : \Gamma \to G$ is *strongly* $\mathbb{P}(\mathbb{R}^d)$*-convex cocompact* if its kernel is finite and its image is a strongly $\mathbb{P}(\mathbb{R}^d)$-convex cocompact subgroup of G.

The action of Γ on Ω in Definition 6.3 is a special case of a class of *geometrically finite actions* introduced by Crampon and Marquis [2014]. We use the adverb "strongly" to emphasize the strong regularity assumptions made on Ω. In Definition 6.3 we say that the quotient $\Gamma\backslash\Omega$ is a *strongly convex cocompact* projective manifold (or orbifold); the subset $\Gamma\backslash\mathcal{C}$ is again compact, convex, and contains all the topology.

Strongly $\mathbb{P}(\mathbb{R}^d)$-convex cocompact representations include $\mathbb{H}^{p,q-1}$-convex cocompact representations as in Section 6.2 (see Danciger, Guéritaud, and Kassel [2018a]), and the natural inclusion of groups dividing strictly convex open subsets of $\mathbb{P}(\mathbb{R}^d)$ as in Section 3.2. The following result generalizes Theorem 6.2, and improves on earlier results of Benoist [2004] and Crampon and Marquis [2014].

Theorem 6.4 (Danciger, Guéritaud, and Kassel [2017]). *Let Γ be an infinite discrete group and $\rho : \Gamma \to G = \mathrm{PGL}(d,\mathbb{R})$ a representation such that $\rho(\Gamma)$ preserves a nonempty properly convex open subset of $X = \mathbb{P}(\mathbb{R}^d)$. Then ρ is strongly $\mathbb{P}(\mathbb{R}^d)$-convex cocompact if and only if Γ is Gromov hyperbolic and ρ is P_1-Anosov.*

Another generalization of Theorem 6.2 was independently obtained by Zimmer [2017]: it is similar to Theorem 6.4, but involves a slightly different notion of convex cocompactness and assumes $\rho(\Gamma)$ to act irreducibly on $\mathbb{P}(\mathbb{R}^d)$.

Applications of Theorem 6.4 include:

• Examples of strongly convex cocompact projective manifolds using classical Anosov representations (e.g. Hitchin representations into $\mathrm{PSL}(2n+1,\mathbb{R})$ as in Section 5.2.2).

• In certain cases, a better understanding of the set of Anosov representations of a Gromov hyperbolic group Γ inside a given connected component of $\mathrm{Hom}(\Gamma, G)$: e.g. for an irreducible hyperbolic right-angled Coxeter group Γ on k generators, it is proved in Danciger, Guéritaud, and Kassel [2018c], using Theorem 6.4 and the work of Vinberg [1971], that P_1-Anosov representations form the full interior of the space of faithful and discrete representations of Γ as a reflection group in $G = \mathrm{PGL}(d,\mathbb{R})$ when $d \geq k$.

For a Gromov hyperbolic group Γ and a P_1-Anosov representation $\rho : \Gamma \to G = \mathrm{PGL}(d,\mathbb{R})$, the group $\rho(\Gamma)$ does not always preserve a properly convex open subset of $X = \mathbb{P}(\mathbb{R}^d)$: see Section 5.2.1. However, as observed by Zimmer [2017], ρ can always be composed with the embedding $\iota : G \hookrightarrow \mathrm{PGL}(V)$ described in Example 3.2.(2), for $V = \mathrm{Sym}(d,\mathbb{R}) \simeq \mathbb{R}^{d(d+1)}$; then $\iota \circ \rho(\Gamma)$ preserves a properly convex open subset in $\mathbb{P}(V)$. The composition $\iota\circ\rho : \Gamma \to \mathrm{PGL}(V)$ is still P_1-Anosov by Guichard and Wienhard [2012], and it is strongly $\mathbb{P}(V)$-convex cocompact by Theorem 6.4. More generally, using Guichard and Wienhard [ibid.], any Anosov representation to any semisimple Lie group can always be composed with an embedding into some $\mathrm{PGL}(V)$ so as to become strongly $\mathbb{P}(V)$-convex cocompact.

6.4 Projective convex cocompactness in general. We now introduce an even broader notion of convex cocompactness, where we remove the strong regularity assumptions on Ω in Definition 6.3. This yields a large class of convex projective manifolds, whose fundamental groups are not necessarily Gromov hyperbolic. Their holonomy representations are generalizations of Anosov representations, sharing some of their desirable properties (Theorem 6.7). This shows that Anosov representations are not the only way to successfully generalize rank-one convex cocompactness to higher real rank.

Definition 6.5 (Danciger, Guéritaud, and Kassel [2017]). A discrete subgroup Γ of $G = \mathrm{PGL}(d, \mathbb{R})$ is $\mathbb{P}(\mathbb{R}^d)$-*convex cocompact* if it preserves a properly convex open subset Ω of $X = \mathbb{P}(\mathbb{R}^d)$ and if it acts with compact quotient on some "large enough" closed convex subset $\mathcal{C}$ of Ω. A representation $\rho : \Gamma \to G$ is $\mathbb{P}(\mathbb{R}^d)$-*convex cocompact* if its kernel is finite and its image is a $\mathbb{P}(\mathbb{R}^d)$-convex cocompact subgroup of G.

In Definition 6.5, by "$\mathcal{C}$ large enough" we mean that all accumulation points of all Γ-orbits of Ω are contained in the boundary of $\mathcal{C}$ in $X = \mathbb{P}(\mathbb{R}^d)$. If we did not impose this (even if we asked $\mathcal{C}$ to have nonempty interior), then the notion of $\mathbb{P}(\mathbb{R}^d)$-convex cocompactness would not be stable under small deformations: see Danciger, Guéritaud, and Kassel [2017, 2018b]. In Definition 6.5 we call $\Gamma\backslash\Omega$ a *convex cocompact* projective manifold (or orbifold).

The class of $\mathbb{P}(\mathbb{R}^d)$-convex cocompact representations includes all strongly $\mathbb{P}(\mathbb{R}^d)$-convex cocompact representations as in Section 6.3, hence all $\mathbb{H}^{p,q-1}$-convex cocompact representations as in Section 6.2. In fact, the following holds.

Proposition 6.6 (Danciger, Guéritaud, and Kassel [2017]). *Let Γ be an infinite discrete group. A representation $\rho : \Gamma \to G = \mathrm{PGL}(d, \mathbb{R})$ is strongly $\mathbb{P}(\mathbb{R}^d)$-convex cocompact (Definition 6.3) if and only if it is $\mathbb{P}(\mathbb{R}^d)$-convex cocompact (Definition 6.5) and Γ is Gromov hyperbolic.*

This generalizes a result of Benoist [2004] on divisible convex sets. Together with Theorem 6.4, Proposition 6.6 shows that $\mathbb{P}(\mathbb{R}^d)$-convex cocompact representations are generalizations of Anosov representations, to a larger class of finitely generated groups Γ which are not necessarily Gromov hyperbolic. These representations still enjoy the following good properties.

Theorem 6.7 (Danciger, Guéritaud, and Kassel [2017]). *Let Γ be an infinite discrete group and $\rho : \Gamma \to G = \mathrm{PGL}(d, \mathbb{R})$ a $\mathbb{P}(\mathbb{R}^d)$-convex cocompact representation. Then*

(1) ρ is a quasi-isometric embedding;

(2) *there is a neighborhood of* ρ *in* $\mathrm{Hom}(\Gamma, G)$ *consisting entirely of* $\mathbb{P}(\mathbb{R}^d)$*-convex cocompact representations;*

(3) ρ *is* $\mathbb{P}((\mathbb{R}^d)^*)$*-convex cocompact;*

(4) ρ *induces a* $\mathbb{P}(\mathbb{R}^D)$*-convex cocompact representation for any* $D \geq d$ *(by lifting* ρ *to a representation to* $\mathrm{SL}^{\pm}(d, \mathbb{R})$ *and composing it with the natural inclusion* $\mathrm{SL}^{\pm}(d, \mathbb{R}) \hookrightarrow \mathrm{SL}^{\pm}(D, \mathbb{R})$*).*

In order to prove (2), we show that the representations of Theorem 6.7 are exactly the holonomy representations of compact convex projective manifolds with strictly convex boundary; this allows to apply the deformation theory of Cooper, Long, and Tillmann [2018].

Groups that are $\mathbb{P}(\mathbb{R}^d)$-convex cocompact but not strongly $\mathbb{P}(\mathbb{R}^d)$-convex cocompact include all groups dividing a properly convex, but not strictly convex, open subset of $X = \mathbb{P}(\mathbb{R}^d)$ as in Section 3.2, as well as their small deformations in $\mathrm{PGL}(D, \mathbb{R})$ for $D \geq d$ (Theorem 6.7.(2)–(4)). Such nontrivial deformations exist: e.g. for $d = 4$ we can always bend along tori or Klein bottle subgroups, see Benoist [2006]. There seems to be a rich world of examples beyond this, which is just starting to be unveiled, see Danciger, Guéritaud, and Kassel [2017, 2018b,c]. It would be interesting to understand the precise nature of the corresponding abstract groups Γ, and how the dynamics of $\mathbb{P}(\mathbb{R}^d)$-convex cocompact representations generalize that of Anosov representations.

7 Complete affine structures

In Sections 3 to 6 we always considered semisimple, or more generally reductive, Lie groups G. We now discuss links between (G, X)-structures and representations of discrete groups into G in an important case where G is not reductive: namely G is the group $\mathrm{Aff}(\mathbb{R}^d) = \mathrm{GL}(d, \mathbb{R}) \ltimes \mathbb{R}^d$ of invertible affine transformations of $X = \mathbb{R}^d$. We shall see in Section 7.3 that for $d = 3$ the holonomy representations of certain complete (i.e. type C in Section 1.1) (G, X)-structures are characterized by a uniform contraction condition, which is also an *affine Anosov* condition; we shall briefly mention partial extensions to $d > 3$, which are currently being explored.

7.1 Brief overview: understanding complete affine manifolds. Let $(G, X) = (\mathrm{Aff}(\mathbb{R}^d), \mathbb{R}^d)$. This section is centered around *complete affine manifolds*, i.e. (G, X)-manifolds of the form $M = \rho(\Gamma)\backslash X$ where $\Gamma \simeq \pi_1(M)$ is a discrete group and $\rho : \Gamma \to G$ a faithful representation through which Γ acts properly discontinuously and freely on $X = \mathbb{R}^d$. The study of such representations has a rich history through the interpretation of their images as *affine crystallographic groups*, i.e. symmetry groups of affine tilings of $\mathbb{R}^d$, possibly with noncompact tiles; see Abels [2001] for a detailed survey. The compact and noncompact cases are quite different.

For a compact complete affine manifold M, Auslander [1964] conjectured that $\pi_1(M)$ must always be virtually (i.e. up to finite index) polycyclic. This extends a classical theorem of Bieberbach on affine Euclidean isometries. The conjecture is proved for $d \leq 6$ (Fried and Goldman [1983], Abels, Margulis, and Soifer [2012]), but remains wide open for $d \geq 7$, despite partial results (see Abels [2001]).

In contrast, in answer to a question of Milnor [1977], there exist noncompact complete affine manifolds M for which $\pi_1(M)$ is *not* virtually polycyclic. The first examples were constructed by Margulis [1984] for $d = 3$, with $\pi_1(M)$ a nonabelian free group. In these examples the holonomy representation takes values in $\mathrm{O}(2,1) \ltimes \mathbb{R}^3$ (this is always the case for $d = 3$ when $\pi_1(M)$ is not virtually polycyclic, see Fried and Goldman [1983]), hence M inherits a flat Lorentzian structure. Such manifolds are called *Margulis spacetimes*. They have a rich geometry and have been much studied since the 1990s, most prominently by Charette, Drumm, Goldman, Labourie, and Margulis. In particular, the questions of the topological tameness of Margulis spacetimes and of the existence of nice fundamental domains in $X = \mathbb{R}^3$ (bounded by piecewise linear objects called *crooked planes*) have received much attention: see e.g. Drumm [1992], Drumm and Goldman [1999], Charette, Drumm, and Goldman [2016], Choi and Goldman [2017], Danciger, Guéritaud, and Kassel [2016a,b]. See also Goldman, Labourie, and Margulis [2009], Abels, Margulis, and Soifer [2012], and Smilga [2016] for higher-dimensional analogues M with $\pi_1(M)$ a free group.

Following Danciger, Guéritaud, and Kassel [2016a,b] (see also Schlenker [2016]), a convenient point of view for understanding Margulis spacetimes is to regard them as "infinitesimal analogues" of complete AdS manifolds. In order to describe this point of view, we first briefly discuss the AdS case.

7.2 Complete AdS manifolds. As in Section 3.3, let $(G, X) = (\mathrm{PO}(2,2), \mathrm{AdS}^3)$, and view X as the group $\underline{G} = \mathrm{PSL}(2,\mathbb{R})$ and the identity component G_0 of G as $\underline{G} \times \underline{G}$ acting on $X \simeq \underline{G}$ by right and left multiplication. We consider (G, X)-manifolds of the form $M = \rho(\Gamma)\backslash X$ where $\Gamma \simeq \pi_1(M)$ is an infinite discrete group and $\rho = (\rho_L, \rho_R) : \Gamma \to \underline{G} \times \underline{G} \subset G$ a faithful representation through which Γ acts properly discontinuously and freely on X. Not all faithful and discrete $\rho = (\rho_L, \rho_R)$ yield properly discontinuous actions on X: e.g. if $\rho_L = \rho_R$, then ρ has a global fixed point, precluding properness. However, the following properness criteria hold. We denote by $\lambda(g) := \inf_{x \in \mathbb{H}^2} d_{\mathbb{H}^2}(x, g \cdot x) \geq 0$ the translation length of $g \in \underline{G}$ in $\mathbb{H}^2$.

Theorem 7.1 (Kassel [2009], Guéritaud, Guichard, Kassel, and Wienhard [2017a]). *Let $G = \mathrm{PO}(2,2)$ and $\underline{G} = \mathrm{PSL}(2,\mathbb{R})$. Consider a discrete group Γ and a representation*

$\rho = (\rho_L, \rho_R) : \Gamma \to \underline{G} \times \underline{G} \subset G$ with ρ_L convex cocompact. The following are equivalent, up to switching ρ_L and ρ_R in both (2) and (3):

(1) the action of Γ on $X = \mathrm{AdS}^3 \simeq \underline{G}$ via ρ is properly discontinuous;

(2) there exists $C < 1$ such that $\lambda(\rho_R(\gamma)) \le C\lambda(\rho_L(\gamma))$ for all $\gamma \in \Gamma$;

(3) there is a (ρ_L, ρ_R)-equivariant Lipschitz map $f : \mathbb{H}^2 \to \mathbb{H}^2$ with $\mathrm{Lip}(f) < 1$;

(4) Γ is Gromov hyperbolic and $\rho : \Gamma \to G \subset \mathrm{PGL}(4, \mathbb{R})$ is P_2-Anosov.

The equivalences (1) ⇔ (2) ⇔ (3), proved in Kassel [2009], have been generalized in Guéritaud and Kassel [2017] to $\underline{G} = \mathrm{PO}(n, 1)$ for any $n \ge 2$, allowing ρ_L to be geometrically finite instead of convex cocompact. These equivalences state that $\rho = (\rho_L, \rho_R)$ acts properly discontinuously on $X = \mathrm{AdS}^3 \simeq \underline{G}$ if and only if, up to switching the two factors, ρ_L is faithful and discrete and ρ_R is "uniformly contracting" with respect to ρ_L. The equivariant map f in (3) provides an explicit fibration in circles of $\rho(\Gamma)\backslash X$ over the hyperbolic surface $\rho_L(\Gamma)\backslash\mathbb{H}^2$, see Guéritaud and Kassel [ibid.]. We refer to Salein [2000], Guéritaud and Kassel [2017], Guéritaud, Kassel, and Wolff [2015], Deroin and Tholozan [2016], Danciger, Guéritaud, and Kassel [2018d], Lakeland and Leininger [2017] for many examples, to Tholozan [2017] for a classification in the compact AdS case, and to Kassel [2009] and Guéritaud and Kassel [2017] for links with the asymmetric metric on Teichmüller space introduced by Thurston [1986].

The equivalences (1) ⇔ (2) ⇔ (4), proved in Guéritaud, Guichard, Kassel, and Wienhard [2017a], generalize to $\underline{G} = \mathrm{PO}(n, 1)$, $\mathrm{PU}(n, 1)$, or $\mathrm{Sp}(n, 1)$; the Anosov condition is then expressed in $\mathrm{PGL}(2n+2, \mathbb{K})$ where $\mathbb{K}$ is $\mathbb{R}$, $\mathbb{C}$, or the quaternions. As an application, the set of holonomy representations of *complete* $(\underline{G} \times \underline{G}, \underline{G})$-structures on a compact manifold M is open in the set of holonomy representations of all possible $(\underline{G} \times \underline{G}, \underline{G})$-structures on M. By Tholozan [2015], it is also closed, which gives evidence for an open conjecture stating that all $(\underline{G} \times \underline{G}, \underline{G})$-structures on M should be complete (i.e. obtained as quotients of $\widetilde{\underline{G}}$).

7.3 Complete affine manifolds. We now go back to $(G, X) = (\mathrm{Aff}(\mathbb{R}^d), \mathbb{R}^d)$, looking for characterizations of holonomy representations of complete affine manifolds, i.e. representations to G yielding properly discontinuous actions on X.

We first note that any representation from a group Γ to the nonreductive Lie group $G = \mathrm{GL}(d, \mathbb{R}) \ltimes \mathbb{R}^d$ is of the form $\rho = (\rho_L, u)$ where $\rho_L : \Gamma \to \mathrm{GL}(d, \mathbb{R})$ (linear part) is a representation to $\mathrm{GL}(d, \mathbb{R})$ and $u : \Gamma \to \mathbb{R}^d$ (translational part) a ρ_L-cocycle, meaning $u(\gamma_1\gamma_2) = u(\gamma_1) + \rho_L(\gamma_1) \cdot u(\gamma_2)$ for all $\gamma_1, \gamma_2 \in \Gamma$.

We focus on the case $d = 3$ and ρ_L with values in $\mathrm{O}(2, 1)$. Let us briefly indicate how, following Danciger, Guéritaud, and Kassel [2016a,b], the Margulis spacetimes of

Section 7.1 are "infinitesimal versions" of the complete AdS manifolds of Section 7.2. Let $\underline{G} = \mathrm{O}(2,1)_0 \simeq \mathrm{PSL}(2,\mathbb{R})$ be the group of orientation-preserving isometries of $\mathbb{H}^2$. Its Lie algebra $\underline{\mathfrak{g}} \simeq \mathbb{R}^3$ is the set of "infinitesimal isometries" of $\mathbb{H}^2$, i.e. Killing vector fields on $\mathbb{H}^2$. Here are some properness criteria.

Theorem 7.2 (Goldman, Labourie, and Margulis [2009], Danciger, Guéritaud, and Kassel [2016a]). *Let $G = \mathrm{Aff}(\mathbb{R}^3)$ and $\underline{G} = \mathrm{O}(2,1)_0 \simeq \mathrm{PSL}(2,\mathbb{R})$. Consider a discrete group Γ and a representation $\rho = (\rho_L, u) : \Gamma \to \underline{G} \ltimes \underline{\mathfrak{g}} \subset G$ with ρ_L convex cocompact. The following are equivalent, up to replacing u by $-u$ in both (2) and (3):*

(1) the action of Γ on $X = \mathbb{R}^3 \simeq \underline{\mathfrak{g}}$ via $\rho = (\rho_L, u)$ is properly discontinuous;

(2) there exists $c < 0$ such that $\frac{\mathrm{d}}{\mathrm{d}t}|_{t=0}\, \lambda(e^{u(\gamma)}\rho_L(\gamma)) \leq c\, \lambda(\rho_L(\gamma))$ for all $\gamma \in \Gamma$;

(3) there is a (ρ_L, u)-equivariant vector field Y on $\mathbb{H}^2$ with "lipschitz" constant < 0.

The equivalence (1) ⇔ (2) is a reinterpretation, based on Goldman and Margulis [2000], of a celebrated result of Goldman, Labourie, and Margulis [2009]. The equivalence (1) ⇔ (3) is proved in Danciger, Guéritaud, and Kassel [2016a].

These equivalences are "infinitesimal versions" of the equivalences (1) ⇔ (2) ⇔ (3) of Theorem 7.1. Indeed, as explained in Danciger, Guéritaud, and Kassel [ibid.], we can see the ρ_L-cocycle $u : \Gamma \to \underline{\mathfrak{g}}$ as an "infinitesimal deformation" of the holonomy representation ρ_L of the hyperbolic surface (or orbifold) $S = \rho_L(\Gamma)\backslash\mathbb{H}^2$; Condition (2) states that closed geodesics on S get uniformly shorter under this infinitesimal deformation. We can see a (ρ_L, u)-equivariant vector field Y on $\mathbb{H}^2$ as an "infinitesimal deformation" of the developing map of the hyperbolic surface S; Condition (3), which involves an unconventional notion of "lipschitz" constant, states that any two points of $\mathbb{H}^2$ get uniformly closer compared to their initial distance. Thus Theorem 7.2 states that $\rho = (\rho_L, u)$ acts properly discontinuously on $X = \mathbb{R}^3 \simeq \underline{\mathfrak{g}}$ if and only if the infinitesimal deformation u, up to replacing it by $-u$, is "uniformly contracting".

The vector field Y in (3) provides an explicit fibration in lines of the Margulis spacetime $\rho(\Gamma)\backslash X$ over the hyperbolic surface S, and this can be used to define a *geometric transition* from complete AdS manifolds to Margulis spacetimes, see Danciger, Guéritaud, and Kassel [ibid.].

In Theorem 7.1, the "uniform contraction" characterizing properness was in fact an Anosov condition, encoding strong dynamics on a certain flag variety. It is natural to expect that something similar should hold in the setting of Theorem 7.2. For this, a notion of *affine Anosov representation* to $\mathrm{O}(2,1) \ltimes \mathbb{R}^3$ was recently introduced by Ghosh [2017] and extended to $\mathrm{O}(n+1,n) \ltimes \mathbb{R}^d \subset \mathrm{Aff}(\mathbb{R}^d) = G$ for any $d = 2n+1 \geq 3$ by Ghosh and Treib [2017]; the definition is somewhat analogous to Section 4.1 but uses affine bundles and their sections. By Ghosh [2017] and Ghosh and Treib [2017], given a P_n-Anosov representation $\rho_L : \Gamma \to \mathrm{O}(n+1,n)$ and a ρ_L-cocycle $u : \Gamma \to \mathbb{R}^d$, the action of Γ on $X = \mathbb{R}^d$ via $\rho = (\rho_L, u)$ is properly discontinuous if and only if ρ is affine Anosov.

Theorem 7.2 was recently generalized in Danciger, Guéritaud, and Kassel [2018d] as follows: for $\underline{G} = \mathrm{O}(p,q)$ with $p,q \geq 1$, consider a discrete group Γ, a faithful and discrete representation $\rho_L : \Gamma \to \underline{G}$, and a ρ_L-cocycle $u : \Gamma \to \underline{\mathfrak{g}}$; then the action of Γ on $\underline{\mathfrak{g}}$ via $\rho = (\rho_L, u) : \Gamma \to \mathrm{Aff}(\underline{\mathfrak{g}})$ is properly discontinuous as soon as u satisfies a uniform contraction property in the pseudo-Riemannian hyperbolic space $\mathbb{H}^{p,q-1}$ of Section 6.2. This allowed for the construction of the first examples of irreducible complete affine manifolds M such that $\pi_1(M)$ is neither virtually polycyclic nor virtually free: $\pi_1(M)$ can in fact be any irreducible right-angled Coxeter group. It would be interesting to understand the links with a notion of affine Anosov representation in this setting.

8 Concluding remarks

By investigating the links between the geometry of (G,X)-structures on manifolds and the dynamics of their holonomy representations, we have discussed only a small part of a very active area of research.

We have described partial answers to Problem A for several types of model geometries (G,X). However, Problem A is still wide open in many contexts. As an illustration, let us mention two major open conjectures on closed affine manifolds (in addition to the Auslander conjecture of Section 7.1): the Chern conjecture states that if a closed d-manifold M admits an $(\mathrm{Aff}(\mathbb{R}^d), \mathbb{R}^d)$-structure, then its Euler characteristic must be zero; the Markus conjecture states that an $(\mathrm{Aff}(\mathbb{R}^d), \mathbb{R}^d)$-structure on M is complete if and only if its holonomy representation takes values in $\mathrm{SL}(d,\mathbb{R}) \ltimes \mathbb{R}^d$. See Klingler [2017] and references therein for recent progress on this.

We have seen that Anosov representations from Gromov hyperbolic groups to semisimple Lie groups provide a large class of representations answering Problem B. However, not much is known beyond them. One further class, generalizing Anosov representations to finitely generated groups Γ which are not necessarily Gromov hyperbolic, is the class of $\mathbb{P}(\mathbb{R}^d)$-convex cocompact representations to $\mathrm{PGL}(d,\mathbb{R})$ of Section 6.4; it would be interesting to understand this class better in the framework of Problem B, see Section 6.4 and Danciger, Guéritaud, and Kassel [2017, Appendix]. As another generalization of Anosov representations, it is natural to look for a class of representations of relatively hyperbolic groups to higher-rank semisimple Lie groups which would bear similarities to geometrically finite representations to rank-one groups, with cusps allowed: see Kapovich and Leeb [2017, § 5] for a conjectural picture. Partial work in this direction has been done in the convex projective setting, see Crampon and Marquis [2014].

To conclude, here are two open questions which we find particularly interesting.

Structural stability. Sullivan [1985] proved that a structurally stable, nonrigid subgroup of $G = \mathrm{PSL}(2, \mathbb{C})$ is always Gromov hyperbolic and convex cocompact in G. It is natural to ask if this may be extended to subgroups of higher-rank semisimple Lie groups G such as $\mathrm{PGL}(d, \mathbb{R})$ for $d \geq 3$, for instance with "convex cocompact" replaced by "Anosov". In Section 6.4 we saw that there exist nonrigid, structurally stable subgroups of $G = \mathrm{PGL}(d, \mathbb{R})$ which are *not* Gromov hyperbolic, namely groups that are $\mathbb{P}(\mathbb{R}^d)$-convex cocompact but not strongly $\mathbb{P}(\mathbb{R}^d)$-convex cocompact (Definitions 6.3 and 6.5). However, does a Gromov hyperbolic, nonrigid, structurally stable, discrete subgroup of G always satisfy some Anosov property?

Abstract groups admitting Anosov representations. Which linear hyperbolic groups admit Anosov representations to some semisimple Lie group? Classical examples include surface groups, free groups, and more generally rank-one convex cocompact groups, see Section 4.2. By Danciger, Guéritaud, and Kassel [2018a], all Gromov hyperbolic right-angled Coxeter groups (and all groups commensurable to them) admit Anosov representations, see Section 6.2. On the other hand, if a hyperbolic group admits an Anosov representation, then its Gromov flow (see Section 4.1) must satisfy strong dynamical properties, which may provide an obstruction: see Bridgeman, Canary, Labourie, and Sambarino [2015, end of § 1]. It would be interesting to have further concrete examples of groups admitting or not admitting Anosov representations.

SPATIAL REFINEMENTS AND KHOVANOV HOMOLOGY

Robert Lipshitz and Sucharit Sarkar

Abstract

We review the construction and context of a stable homotopy refinement of Khovanov homology.

1 Introduction

While studying critical points and geodesics, Morse [1925, 1930, 1996] introduced what is now called *Morse theory*—using functions for which the second derivative test does not fail (*Morse functions*) to decompose manifolds into simpler pieces. The finite-dimensional case was further developed by many authors (see Bott [1980] for a survey of the history), and an infinite-dimensional analogue introduced by Palais and Smale [1964], Palais [1963], and Smale [1964]. In both cases, a Morse function f on M leads to a chain complex $C_*(f)$ generated by the critical points of f. This chain complex satisfies the *fundamental theorem of Morse homology*: its homology $H_*(f)$ is isomorphic to the singular homology of M. This is both a feature and a drawback: it means that one can use information about the topology of M to deduce the existence of critical points of f, but also implies that $C_*(f)$ does not see the smooth topology of M. (See Milnor [1963, 1965] for an elegant account of the subject's foundations and some of its applications.)

Much later, Floer [1988c,a,b] introduced some new examples of infinite-dimensional, Morse-like theories. Unlike Palais-Smale's Morse theory, in which the descending manifolds of critical points are finite-dimensional, in Floer's setting both ascending and descending manifolds are infinite-dimensional. Also unlike Palais-Smale's setting, Floer's homology groups are not isomorphic to singular homology of the ambient space (though the singular homology acts on them). Indeed, most Floer (co)homology theories seem to have no intrinsic cup product operation, and so are unlikely to be the homology of any natural space.

RL was supported by NSF DMS-1642067. SS was supported by NSF DMS-1643401.
MSC2010: primary 57M25; secondary 55P42.
Keywords: Framed flow categories, Cohen-Jones-Segal construction, Khovanov stable homotopy type, Burnside category.

Cohen, J. Jones, and Segal [1995] proposed that although Floer homology is not the homology of a space, it could be the homology of some associated spectrum (or pro-spectrum), and outlined a construction, under restrictive hypotheses, of such an object. While they suggest that these spectra might be determined by the ambient, infinite-dimensional manifold together with its polarization (a structure which seems ubiquitous in Floer theory), their construction builds a CW complex cell-by-cell, using the moduli spaces appearing in Floer theory. (We review their construction in Section 2.4. Steps towards describing Floer homology in terms of a polarized manifold have been taken by Lipyanskiy [n.d.].) Although the Cohen-Jones-Segal approach has been stymied by analytic difficulties, it has inspired other constructions of stable homotopy refinements of various Floer homologies and related invariants; see Furuta [2001], Bauer and Furuta [2004], Bauer [2004], Manolescu [2003], Kronheimer and Manolescu [n.d.], Douglas [n.d.], Cohen [2010, 2009], Kragh [n.d., 2013], Abouzaid and Kragh [2016], Khandhawit [2015a,b], Sasahira [n.d.], and Khandhawit, Lin, and Sasahira [n.d.].

From the beginning, Floer homologies have been used to define invariants of objects in low-dimensional topology—3-manifolds, knots, and so on. In a slightly different direction, Khovanov [2000] defined another knot invariant, which he calls $\mathfrak{sl}_2$ *homology* and everyone else calls *Khovanov homology*, whose graded Euler characteristic is the Jones polynomial from V. Jones [1985]. (See Bar-Natan [2002] for a friendly introduction.) While it looks formally similar to Floer-type invariants, Khovanov homology is defined combinatorially. No obvious infinite-dimensional manifold or functional is present. Still, Seidel and Smith [2006] (inspired by earlier work of Khovanov and Seidel [2002] and others) gave a conjectural reformulation of Khovanov homology via Floer homology. Over $\mathbb{Q}$, the isomorphism between Seidel-Smith's and Khovanov's invariants was recently proved by Abouzaid and Smith [n.d.]. Manolescu [2007] gave an extension of the reformulation to $\mathfrak{sl}_n$ homology constructed by Khovanov and Rozansky [2008].

Inspired by this history, Lipshitz and Sarkar [2014a,c,b] gave a combinatorial definition of a spectrum refining Khovanov homology, and studied some of its properties. This circle of ideas was further developed in Lipshitz, Ng, and Sarkar [2015] and in Lawson, Lipshitz, and Sarkar [n.d.(a),(b)], and extended in many directions by other authors (see Section 3.3). Another approach to a homotopy refinement was given by Everitt and Turner [2014], though it turns out their invariant is determined by Khovanov homology, cf. Everitt, Lipshitz, Sarkar, and Turner [2016]. Inspired by a different line of inquiry, Hu, D. Kriz, and I. Kriz [2016] also gave a construction of a Khovanov stable homotopy type. Lawson, Lipshitz, and Sarkar [n.d.(a)] show that the two constructions give homotopy equivalent spectra, perhaps suggesting some kind of uniqueness.

Most of this note is an outline of a construction of a Khovanov homotopy type, following Lawson, Lipshitz, and Sarkar [ibid.] and Hu, D. Kriz, and I. Kriz [2016], with an emphasis on the general question of stable homotopy refinements of chain complexes. In the last two sections, we briefly outline some of the structure and uses of the homotopy type (Section 3.3) and some questions and speculation (Section 3.4). Another exposition of some of this material can be found in Lawson, Lipshitz, and Sarkar [2017].

Acknowledgments. We are deeply grateful to our collaborator Tyler Lawson, whose contributions and perspective permeate the account below. We also thank Mohammed Abouzaid, Ciprian Manolescu, and John Pardon for comments on a draft of this article.

2 Spatial refinements

The spatial refinement problem can be summarized as follows.

Start with a chain complex C_* with a distinguished, finite basis, arising in some interesting setting. Incorporating more information from the setting, construct a based CW complex (or spectrum) whose reduced cellular chain complex, after a shift, is isomorphic to C_* with cells corresponding to the given basis.

A result of Carlsson [1981] implies that there is no universal solution to the spatial refinement problem, i.e., no functor S from chain complexes (supported in large gradings, say) to CW complexes so that the composition of S and the reduced cellular chain complex functor is the identity (cf. Prasma et al. [n.d.]). Specifically, for $G = \mathbb{Z}/2\times\mathbb{Z}/2$ he defines a module P over $\mathbb{Z}[G]$ so that there is no G-equivariant Moore space $M(P,n)$ for any n. If C_* is a free resolution of P over $\mathbb{Z}[G]$ then $S(C_*)$ would be such a Moore space, a contradiction.

Thus, spatially refining C_* requires context-specific work. This section gives general frameworks for such spatial refinements, and the next section has an interesting example of one.

2.1 Linear and cubical diagrams. Let C_* be a freely and finitely generated chain complex with a given basis. After shifting we may assume C_* is supported in gradings $0,\dots,n$. Let $[n+1]$ be the category with objects $0,1,\dots,n$ and a unique morphism $i\to j$ if $i\geq j$. Let $\mathcal{B}(\mathbb{Z})$ denote the category of finitely generated free abelian groups, with objects finite sets and $\operatorname{Hom}_{\mathcal{B}(\mathbb{Z})}(S,T)$ the set of linear maps $\mathbb{Z}\langle S\rangle\to\mathbb{Z}\langle T\rangle$ or, equivalently, $T\times S$ matrices of integers. Then C_* may be viewed as a functor F from $[n+1]$ to $\mathcal{B}(\mathbb{Z})$ subject to the condition that F sends any length two arrow (that is, a morphism $i\to j$ with $i-j=2$) to the zero map. Given such a functor $F\colon [n+1]\to\mathcal{B}(\mathbb{Z})$, that is, a *linear diagram*

$$\mathbb{Z}\langle F(n)\rangle\to\mathbb{Z}\langle F(n-1)\rangle\to\cdots\to\mathbb{Z}\langle F(1)\rangle\to\mathbb{Z}\langle F(0)\rangle \tag{2-1}$$

with every composition the zero map, we obtain a chain complex C_* by shifting the gradings, $C_i = \mathbb{Z}\langle F(i)\rangle[i]$, and letting $\partial_i = F(i \to i-1)$. This construction is functorial. That is, if $\mathscr{B}(\mathbb{Z})^{[n+1]}_{\bullet}$ denotes the full subcategory of the functor category $\mathscr{B}(\mathbb{Z})^{[n+1]}$ generated by those functors which send every length two arrow to the zero map, and if Kom denotes the category of chain complexes, then the above construction is a functor $\mathsf{ch}\colon \mathscr{B}(\mathbb{Z})^{[n+1]}_{\bullet} \to \mathsf{Kom}$. Indeed, it would be reasonable to call an element of $\mathscr{B}(\mathbb{Z})^{[n+1]}_{\bullet}$ a *chain complex in* $\mathscr{B}(\mathbb{Z})$.

A linear diagram $F \in \mathscr{B}(\mathbb{Z})^{[n+1]}_{\bullet}$ may also be viewed as a *cubical diagram* $G\colon [2]^n \to \mathscr{B}(\mathbb{Z})$ by setting

$$G(v) = \begin{cases} F(i) & \text{if } v = (\underbrace{0,\dots,0}_{n-i},\underbrace{1,\dots,1}_{i}) \\ \varnothing & \text{otherwise.} \end{cases} \tag{2-2}$$

On morphisms, G is either zero or induced from F, as appropriate. Conversely, a cubical diagram $G \in \mathscr{B}(\mathbb{Z})^{[2]^n}$ gives a linear diagram $F \in \mathscr{B}(\mathbb{Z})^{[n+1]}_{\bullet}$ by setting $F(i) = \coprod_{|v|=i} G(v)$, where $|v|$ denotes the number of 1's in v. The component of $F(i+1 \to i)$ from $\mathbb{Z}\langle G(u)\rangle \subset \mathbb{Z}\langle F(i+1)\rangle$ to $\mathbb{Z}\langle G(v)\rangle \subset \mathbb{Z}\langle F(i)\rangle$ is

$$\begin{cases} (-1)^{u_1+\dots+u_{k-1}} G(u \to v) & \text{if } u - v = \widehat{e}_k, \text{ the } k^{\text{th}} \text{ unit vector,} \\ 0 & \text{if } u - v \text{ is not a unit vector.} \end{cases} \tag{2-3}$$

These give functors $\mathscr{B}(\mathbb{Z})^{[n+1]}_{\bullet} \underset{\beta}{\overset{\alpha}{\rightleftarrows}} \mathscr{B}(\mathbb{Z})^{[2]^n}$ with $\beta \circ \alpha = \mathrm{Id}$.

The composition $\mathsf{ch} \circ \beta\colon \mathscr{B}(\mathbb{Z})^{[2]^n} \to \mathsf{Kom}$ is the *totalization* Tot, and may be viewed as an iterated mapping cone. Up to chain homotopy equivalence, one can also construct Tot using homotopy colimits. Define a category $[2]_+$ by adjoining a single object $*$ to $[2]$ and a single morphism $1 \to *$; let $[2]^n_+ = ([2]_+)^n$. Given $G \in \mathscr{B}(\mathbb{Z})^{[2]^n}$, by treating abelian groups as chain complexes supported in homological grading zero, we get an associated cubical diagram $A\colon [2]^n \to \mathsf{Kom}$. Extend A to a diagram $A_+\colon [2]^n_+ \to \mathsf{Kom}$ by setting

$$A_+(v) = \begin{cases} A(v) & \text{if } v \in [2]^n \\ 0 & \text{otherwise.} \end{cases} \tag{2-4}$$

Then the totalization of G is the *homotopy colimit* of A_+. (See Segal [1974], Bousfield and Kan [1972], and Vogt [1973].)

2.2 Spatial refinements of diagrams of abelian groups. As a next step, given a finitely generated chain complex represented by a functor $F\colon [n+1] \to \mathscr{B}(\mathbb{Z})$ we wish to construct a based cell complex with cells in dimensions $N, \dots, N+n$ whose reduced cellular complex—with distinguished basis given by the cells—is isomorphic to the given complex shifted up by N.

Let $\mathcal{T}(S^N)$ be the category with objects finite sets and morphisms $\mathrm{Hom}_{\mathcal{T}(S^N)}(S,T)$ the set of all based maps $\bigvee_S S^N \to \bigvee_T S^N$ between wedges of N-dimensional spheres; applying reduced N^{th} homology to the morphisms produces a functor, also denoted $\widetilde{H}_N$, from $\mathcal{T}(S^N)$ to $\mathscr{B}(\mathbb{Z})$. A *strict N-dimensional spatial lift* of F is a functor $P\colon [n+1] \to \mathcal{T}(S^N)$ satisfying $\widetilde{H}_N \circ P = F$ and P is the constant map on any length two arrow in $[n+1]$, i.e., a *strict chain complex in $\mathcal{T}(S^N)$ lifting F*. Just as morphisms in $\mathscr{B}(\mathbb{Z})$ are matrices, if we replace S^N by the sphere spectrum $\mathbb{S}$, we may view a morphism in $\mathcal{T}(\mathbb{S})$ as a matrix of maps $\mathbb{S} \to \mathbb{S}$ by viewing $\bigvee_S \mathbb{S}$ as a coproduct and $\bigvee_T \mathbb{S}$ as a product.

Given such a linear diagram P, we can construct a based cell complex by taking mapping cones and suspending sequentially, cf. Cohen, J. Jones, and Segal [1995, §5]. If CW denotes the category of based cell complexes, then P induces a diagram $X\colon [n+1] \to \mathsf{CW}$,

$$X(n) \xrightarrow{f_n} X(n-1) \xrightarrow{f_{n-1}} \cdots \xrightarrow{f_2} X(1) \xrightarrow{f_1} X(0) \tag{2-5}$$

with every composition the constant map. Since $f_1 \circ f_2$ is the constant map, there is an induced map $g_1\colon \Sigma X(2) \to \mathrm{Cone}(f_1)$ from the reduced suspension to the reduced cone. Then we get a diagram $Y\colon [n] \to \mathsf{CW}$,

$$Y(n-1) = \Sigma X(n) \xrightarrow{\Sigma f_n} \cdots \xrightarrow{\Sigma f_3} Y(1) = \Sigma X(2) \xrightarrow{g_1} Y(0) = \mathrm{Cone}(f_n). \tag{2-6}$$

Take the mapping cone of g_1 and suspend to get a diagram $Z\colon [n-1] \to \mathsf{CW}$ and so on. The reduced cellular chain complex of the final CW complex is the original chain complex, shifted up by N. This construction is also functorial: if $\mathcal{T}(S^N)^{[n+1]}_{\bullet}$ is the full subcategory generated by the functors which send every length two arrow to the constant map, then the construction is a functor $\mathcal{T}(S^N)^{[n+1]}_{\bullet} \to \mathsf{CW}$. The construction can also be carried out in a single step. Construct a category $[n+1]_+$ by adjoining a single object $*$ and a unique morphism $i \to *$ for all $i \neq 0$. Extend $X\colon [n+1] \to \mathsf{CW}$ to $X_+\colon [n+1]_+ \to \mathsf{CW}$ by sending $*$ to a point and take the homotopy colimit of X_+.

A linear diagram $P \in \mathcal{T}(S^N)^{[n+1]}_{\bullet}$ produces a cubical diagram $Q\colon [2]^n \to \mathcal{T}(S^N)$ by the analogue of Equation (2-2). There is a *totalization* functor $\mathsf{Tot}\colon \mathcal{T}(S^N)^{[2]^n} \to \mathsf{CW}$

extending the functor $\mathscr{T}(S^N)_\bullet^{[n+1]} \to \mathsf{CW}$ so that

$$\begin{array}{ccccc} \mathscr{T}(S^N)_\bullet^{[n+1]} & \longrightarrow & \mathscr{T}(S^N)^{[2]^n} & \longrightarrow & \mathsf{CW} \\ \downarrow & & \downarrow & & \downarrow \widetilde{C}_*^{\mathrm{cell}}[-N] \\ \mathscr{B}(\mathbb{Z})_\bullet^{[n+1]} & \longrightarrow & \mathscr{B}(\mathbb{Z})^{[2]^n} & \longrightarrow & \mathsf{Kom}. \end{array} \tag{2-7}$$

commutes. The totalization functor is defined as an iterated mapping cone or as a homotopy colimit of an extension of Q analogous to Equation (2-4).

2.3 Lax spatial refinements. Instead of working with strict functors as in the previous section, sometimes is it more convenient to work with lax functors. A *lax* or *homotopy coherent* or $(\infty, 1)$ *functor* $F: \mathscr{C} \to \mathsf{Top}$ is a diagram that commutes up to homotopies which are specified, and the homotopies themselves commute up to higher homotopies which are also specified, and so on; for details see Vogt [1973], Cordier [1982], and Lurie [2009a]. More precisely, F consists of based topological spaces $F(x)$ for $x \in \mathscr{C}$, and higher homotopy maps $F(f_n, \dots, f_1)\colon [0,1]^{n-1} \times F(x_0) \to F(x_n)$ for composable morphisms $x_0 \xrightarrow{f_1} \cdots \xrightarrow{f_n} x_n$ with certain boundary conditions and restrictions involving basepoints and identity morphisms; the case $n = 1$ is maps corresponding to the arrows in the diagram, $n = 2$ is homotopies corresponding to pairs of composable arrows, etc. A strict functor may be viewed as a lax functor. Let $\mathfrak{h}\mathsf{Top}^{\mathscr{C}}$ denote the category of lax functors $\mathscr{C} \to \mathsf{Top}$, with morphisms given by lax functors $\mathscr{C} \times [2] \to \mathsf{Top}$. (There are also higher morphisms corresponding to lax functors $\mathscr{C} \times [n] \to \mathsf{Top}$.)

There is a notion of a lax functor to $\mathscr{T}(S^N)$ induced from the notion of lax functors to Top. Let $\mathfrak{h}\mathscr{T}(S^N)_\bullet^{[n+1]}$ be the subcategory of $\mathfrak{h}\mathscr{T}(S^N)^{[n+1]}$ consisting of those objects (respectively, morphisms) F such that $F\big(x_0 \xrightarrow{f_1} \cdots \xrightarrow{f_n} x_n\big)$ is the constant map to the basepoint for any string of morphisms in $[n+1]$ (respectively, $[n+1] \times [2]$) with some f_i of length ≥ 2 in $[n+1]$ (respectively, $[n+1] \times \{0,1\}$). We call such functors *chain complexes in* $\mathscr{T}(S^N)$. (In Cohen-Jones-Segal's language, chain complexes in $\mathscr{T}(S^N)$ are functors $\mathscr{J}_0^n \to \mathscr{T}_*$.)

If one starts with a chain complex $F \in \mathscr{B}(\mathbb{Z})_\bullet^{[n+1]}$ and wishes to refine it to a based cell complex, instead of constructing a strict N-dimensional spatial lift in $\mathscr{T}(S^N)_\bullet^{[n+1]}$, it is enough to construct a *lax* N*-dimensional spatial lift*, that is, a functor $P \in \mathfrak{h}\mathscr{T}(S^N)_\bullet^{[n+1]}$ with $\widetilde{H}_N \circ P = F$. Such a P produces a cell complex by adjoining a basepoint to get a lax diagram $[n+1]_+ \to \mathsf{CW}$ and then taking homotopy colimits. Alternatively, we may convert P to a lax cubical diagram $Q \in \mathfrak{h}\mathscr{T}(S^N)^{[2]^n}$ and proceed as before. The iterated mapping cone construction becomes intricate since the associated diagram $X\colon [2]^n \to \mathsf{CW}$ is lax. So, extend to a lax diagram $X_+\colon [2]^n_+ \to \mathsf{CW}$ as before and then take its homotopy colimit. This generalization to the lax set-up remains functorial and the analogue of Diagram (2-7) still commutes.

2.4 Framed flow categories. Cohen, J. Jones, and Segal [1995] first proposed lax spatial refinements of diagrams $F\colon [n+1] \to \mathscr{B}(\mathbb{Z})$ via framed flow categories, using the Pontryagin-Thom construction. A *framed flow category* is an abstraction of the gradient flows of a Morse-Smale function. Concretely, a framed flow category $\mathscr{C}$ consists of:

1. A finite set of *objects* $\mathrm{Ob}(\mathscr{C})$ and a *grading* $\mathrm{gr}\colon \mathrm{Ob}(\mathscr{C}) \to \mathbb{Z}$. After translating, we may assume the gradings lie in $[0,n]$.
2. For $x, y \in \mathscr{C}$ with $\mathrm{gr}(x) - \mathrm{gr}(y) - 1 = k$, a *morphism set* $\mathfrak{M}(x,y)$ which is a k-dimensional $\langle k\rangle$-manifold. A *$\langle k\rangle$-manifold M* is a smooth manifold with corners so that each codimension-c corner point lies in exactly c facets (closure of a codimension-1 component), equipped with a decomposition of its boundary $\partial M = \cup_{i=1}^{k} \partial_i M$ so that each $\partial_i M$ is a *multifacet* of M (union of disjoint facets), and $\partial_i M \cap \partial_j M$ is a multifacet of $\partial_i M$ and $\partial_j M$, cf. Jänich [1968] and Laures [2000].
3. An associative *composition* map $\mathfrak{M}(y,z) \times \mathfrak{M}(x,y) \hookrightarrow \partial_{\mathrm{gr}(y)-\mathrm{gr}(z)} \mathfrak{M}(x,z) \subset \mathfrak{M}(x,z)$. Setting

   (2-8) $$\mathfrak{M}(i,j) = \coprod_{\substack{x,y \\ \mathrm{gr}(x)=i, \mathrm{gr}(y)=j}} \mathfrak{M}(x,y),$$

   the composition is required to induce an isomorphism of $\langle i-j-2\rangle$-manifolds

   (2-9) $$\partial_{j-k} \mathfrak{M}(i,k) \cong \mathfrak{M}(j,k) \times \mathfrak{M}(i,j).$$

4. *Neat embeddings* $\iota_{i,j}\colon \mathfrak{M}(i,j) \hookrightarrow [0,1)^{i-j-1} \times (-1,1)^{D(i-j)}$ for some large $D \in \mathbb{N}$, namely, smooth embeddings satisfying

   (2-10) $$\iota_{i,k}^{-1}([0,1)^{j-k-1} \times \{0\} \times [0,1)^{i-j-1} \times (-1,1)^{D(i-k)}) = \partial_{j-k} \mathfrak{M}(i,k)$$

   and certain orthogonality conditions near boundaries. These embeddings are required to be coherent with respect to composition. The space of such collections of neat embeddings is $(D-2)$-connected.
5. *Framings* of the normal bundles of $\iota_{i,j}$, also coherent with respect to composition, which give extensions $\bar{\iota}_{i,j}\colon \mathfrak{M}(i,j) \times [-1,1]^{D(i-j)} \hookrightarrow [0,1)^{i-j-1} \times (-1,1)^{D(i-j)}$.

A framed flow category produces a lax linear diagram $P \in \mathfrak{h}\mathscr{T}(S^N)_{\bullet}^{[n+1]}$ with $N = nD$. On objects, set $P(i) = \{x \in \mathscr{C} \mid \mathrm{gr}(x) = i\}$. On morphisms, define the map

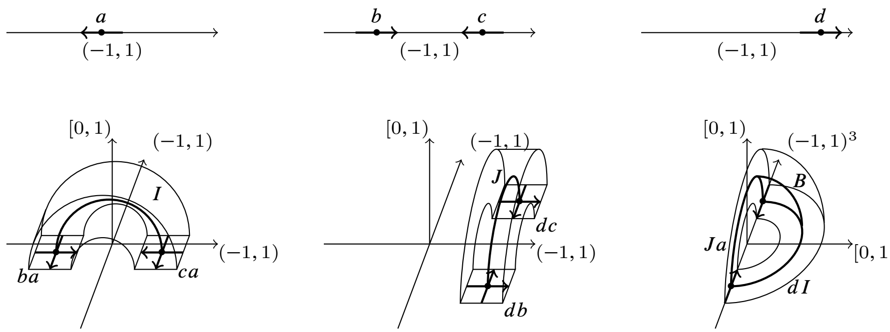

Figure 2.1: **A framed flow category $\mathscr{C}$.** $\mathrm{Ob}(\mathscr{C}) = \{x, y, z, w\}$ *in gradings* $3, 2, 1, 0$*, respectively. The* 0*-dimensional morphism spaces are:* $\mathfrak{M}(x, y) = \{a\}$, $\mathfrak{M}(y, z) = \{b, c\}$*, and* $\mathfrak{M}(z, w) = \{d\}$*, each embedded in* $(-1, 1)$*. The* 1*-dimensional morphism spaces are:* $\mathfrak{M}(x, z) = I$ *(resp.* $\mathfrak{M}(y, w) = J$*) an interval, embedded in* $[0, 1) \times (-1, 1)^2$*, with endpoints* $\{ba, ca\}$ *(resp.* $\{db, dc\}$*) embedded in* $\{0\} \times (-1, 1)^2$ *by the product embedding. The* 2*-dimensional morphism space is a disk* B*, embedded in* $[0, 1)^2 \times (-1, 1)^3$*; it is a* $\langle 2\rangle$*-manifold with boundary decomposed as a union of two arcs,* $\partial_1 B = dI \subset \{0\} \times [0, 1) \times (-1, 1)^3$ *and* $\partial_2 B = Ja \subset [0, 1) \times \{0\} \times (-1, 1)^3$*. Coherent framings of all the normal bundles are represented by the tubular neighborhoods* $\bar{\iota}_{i,j}$*. In the last subfigure,* $(-1, 1)^3$ *is drawn as an interval by projecting to the middle* $(-1, 1)$.

associated to the sequence $m_0 \to m_1 \to \cdots \to m_k$ to be the constant map unless all the arrows are length one. To a sequence of length one arrows, $i \to i - 1 \to \cdots \to j$, associate a map

$$
\begin{aligned}
[0,1]^{i-j-1} \times \bigvee_{x \in P(i)} S^N = [0,1]^{i-j-1} \times \coprod_{x \in P(i)} [-1,1]^{nD}/\partial \\
\to \bigvee_{y \in P(j)} S^N = \coprod_{y \in P(j)} [-1,1]^{nD}/\partial
\end{aligned}
\tag{2-11}
$$

using $\bar{\iota}_{i,j}$ and the Pontryagin-Thom construction.

We can then apply the totalization functor to P to get a cell complex with cells in dimensions $N, N+1, \ldots, N+n$. As Cohen, J. Jones, and Segal [1995] sketch, for a flow category coming from a generic gradient flow of a Morse function, the cell complex produced by the totalization functor is the N^{th} reduced suspension of the Morse cell complex built from the unstable disks of the critical points.

Much of the above data can also be reformulated in the language of S-modules from Pardon [n.d., §4.3]. Let $S[n+1]$ be the (non-symmetric) multicategory with objects pairs

(j,i) of integers with $0 \le j \le i \le n$, unique multimorphisms $(i_0,i_1),(i_1,i_2),\dots,(i_{k-1},i_k) \to (i_0,i_k)$ when $k \ge 1$, and no other multimorphisms (cf. *shape multicategories* from Lawson, Lipshitz, and Sarkar [n.d.(b)]). Let $\underline{\mathsf{Top}}$ be the multicategory of based topological spaces whose multimorphisms $X_1,\dots,X_k \to Y$ are maps $X_1 \wedge \cdots \wedge X_k \to Y$. An S*-module* is a multifunctor $S[n+1] \to \underline{\mathsf{Top}}$.

Given $\mathscr{C}$, define S-modules $\mathbf{S}, \mathbf{J}$ by setting $\mathbf{S}(j,i) = \vee_{y\in P(j)} S^{D(i-j)}$ and $\mathbf{J}(j,i) = (\vee_{x\in P(i)} S^{D(i-j)}) \wedge \mathcal{J}(i,j)$ where $\mathcal{J}$ is the category with objects integers and morphisms $\mathcal{J}(i,j)$ the one-point compactification of $[0,1)^{i-j-1}$ if $i \ge j$ (which is a point if $i = j$) and composition $\mathcal{J}(j,k) \wedge \mathcal{J}(i,j) \to \mathcal{J}(i,k)$ induced by the inclusion map $[0,1)^{j-k-1} \times \{0\} \times [0,1)^{i-j-1} \hookrightarrow \partial[0,1)^{i-k-1}$, cf. Cohen, J. Jones, and Segal [1995, §5]. On a multimorphism $(i_0,i_1),\dots,(i_{k-1},i_k) \to (i_0,i_k)$, $\mathbf{S}$ sends the $(y_0,\dots,y_{k-1}) \in P(i_0) \times \cdots \times P(i_{k-1})$ summand $S^{D(i_1-i_0)} \wedge \cdots \wedge S^{D(i_k-i_{k-1})}$ homeomorphically to the y_0 summand $S^{D(i_k-i_0)}$, and $\mathbf{J}$ sends the $(x_1,\dots,x_k) \in P(i_1)\times\cdots\times P(i_k)$ summand $(S^{D(i_1-i_0)} \wedge \cdots \wedge S^{D(i_k-i_{k-1})}) \wedge (\mathcal{J}(i_1,i_0) \wedge \cdots \wedge \mathcal{J}(i_k,i_{k-1}))$ to the x_k summand $S^{D(i_k-i_0)} \wedge \mathcal{J}(i_k,i_0)$, homeomorphically on the first factor, and using the composition in $\mathcal{J}$ on the second factor. Given a neat embedding of $\mathscr{C}$, we can define another S-module $\mathbf{N}$ by setting $\mathbf{N}(j,i) = \iota^{\nu}_{i,j}$, the Thom space of the normal bundle of $\iota_{i,j}$, if $i > j$. (When $i = j$, $\mathbf{N}(j,j)$ is a point.) On multimorphisms, $\mathbf{N}$ is induced from the inclusion maps $\operatorname{im}(\bar{\iota}_{i_1,i_0})\times\cdots\times\operatorname{im}(\bar{\iota}_{i_k,i_{k-1}}) \to \operatorname{im}(\bar{\iota}_{i_k,i_0})$. The Pontryagin-Thom collapse map is a natural transformation—an S*-module map*—from $\mathbf{J}$ to $\mathbf{N}$, which sends the $x \in P(i)$ summand of $\mathbf{J}(j,i)$ to the Thom-space summand $\cup_{y\in P(j)} \iota^{\nu}_{x,y}$ in $\mathbf{N}(j,i)$. A framing of $\mathscr{C}$ produces another S-module map $\mathbf{N} \to \mathbf{S}$ which sends the summand $\iota^{\nu}_{x,y}$ in $\mathbf{N}(j,i)$ to the y summand of $\mathbf{S}(j,i)$. Composing we get an S-module map $\mathbf{J} \to \mathbf{S}$, which is precisely the data needed to recover a lax diagram in $\mathfrak{h}\mathcal{T}(S^N)^{[n+1]}_{\bullet}$.

Finally, as popularized by Abouzaid, note that since the (smooth) framings of $\iota_{i,j}$ were only used to construct maps $\iota^{\nu}_{i,j} \to \vee_{y\in P(j)} S^{D(i-j)}$, a weaker structure on the flow category—namely, coherent trivializations of the Thom spaces $\iota^{\nu}_{i,j}$ as spherical fibrations—might suffice.

2.5 Speculative digression: matrices of framed cobordisms. Perhaps it would be tidy to reformulate the notion of stably framed flow categories as chain complexes in some category $\mathscr{B}(\mathsf{Cob})$ equipped with a functor $\mathscr{B}(\mathsf{Cob}) \to \mathcal{T}(\mathbb{S})$. It is clear how such a definition would start. Objects in $\mathscr{B}(\mathsf{Cob})$ should be finite sets. By the Pontryagin-Thom construction, a map $\mathbb{S} \to \mathbb{S}$ is determined by a framed 0-manifold; therefore, a morphism in $\mathscr{B}(\mathsf{Cob})$ should be a matrix of framed 0-manifolds. To account for the homotopies in $\mathcal{T}(\mathbb{S})$, $\mathscr{B}(\mathsf{Cob})$ should have higher morphisms. For instance, given two $(T \times S)$-matrices A, B of framed 0-manifolds, a 2-morphism from A to B should be a $(T \times S)$-matrix of framed 1-dimensional cobordisms. Given two such $(T \times S)$-matrices

M, N of framed 1-dimensional cobordisms, a 3-morphism from M to N should be a $(T \times S)$-matrix of framed 2-dimensional cobordisms with corners, and so on. That is, the target category Cob seems to be the extended cobordism category, an (∞, ∞)-category studied, for instance, by Lurie [2009b].

Since matrix multiplication requires only addition and multiplication, the construction $\mathscr{B}(\mathscr{C})$ makes sense for any *rig* or *symmetric bimonoidal* category $\mathscr{C}$ and, presumably, for a rig (∞, ∞)-category, for some suitable definition; and perhaps the framed cobordism category Cob is an example of a rig (∞, ∞)-category. Maybe the Pontryagin-Thom construction gives a functor $\mathscr{B}(\mathsf{Cob}) \to \mathscr{T}(\mathbb{S})$, and that a stably framed flow category is just a functor $[n+1] \to \mathscr{B}(\mathsf{Cob})$.

Rather than pursuing this, we will focus on a tiny piece of Cob, in which all 0-manifolds are framed positively, all 1-dimensional cobordisms are trivially-framed intervals and, more generally, all higher cobordisms are trivially-framed disks. In this case, all of the information is contained in the objects, 1-morphisms, and 2-morphisms, and this tiny piece equals $\mathscr{B}(\mathsf{Sets})$ with Sets being viewed as a rig category via disjoint union and Cartesian product.

2.6 The cube and the Burnside category. The *Burnside category* $\mathscr{B}$ (associated to the trivial group) is the following weak 2-category. The objects are finite sets. The 1-morphisms $\mathrm{Hom}(S, T)$ are $T \times S$ matrices of finite sets; composition is matrix multiplication, using the disjoint union and product of sets in place of $+$ and $\times$ of real numbers. The 2-morphisms are matrices of entrywise bijections between matrices of sets.

(The category $\mathscr{B}$ is denoted $\mathcal{S}_2$ by Hu, D. Kriz, and I. Kriz [2016], and is an example of what they call a *$\star$-category*. The realization procedure below is a concrete analogue of the Elmendorf and Mandell [2006] infinite loop space machine; see also Lawson, Lipshitz, and Sarkar [n.d.(a), §8].)

There is an abelianization functor $\mathsf{Ab}\colon \mathscr{B} \to \mathscr{B}(\mathbb{Z})$ which is the identity on objects and sends a morphism $(A_{t,s})_{s \in S, t \in T}$ to the matrix $(\# A_{t,s})_{s \in S, t \in T} \in \mathbb{Z}^{T \times S}$. We are given a diagram $G \in \mathscr{B}(\mathbb{Z})^{[2]^n}$ which we wish to lift to a diagram $Q \in \mathfrak{h}\mathscr{T}(S^N)^{[2]^n}$. As we will see, it suffices to lift G to a diagram $D\colon [2]^n \to \mathscr{B}$.

Since $\mathscr{B}$ is a weak 2-category, we should first clarify what we mean by a diagram in $\mathscr{B}$. A *strictly unital lax 2-functor*—henceforth just called a lax functor—$D\colon [2]^n \to \mathscr{B}$ consists of the following data:

1. A finite set $F(x) \in \mathscr{B}$ for each $v \in [2]^n$.

2. An $F(v) \times F(u)$-matrix of finite sets $F(u \to v) \in \mathrm{Hom}_{\mathscr{B}}(F(u), F(v))$ for each $u > v \in [2]^n$.

3. A 2-isomorphism $F_{u,v,w}\colon F(v \to w) \circ_1 F(u \to v) \to F(u \to w)$ for each $u > v > w \in [2]^n$ so that for each $u > v > w > z$, $F_{u,w,z} \circ_2 (\mathrm{Id} \circ_1 F_{u,v,w}) = (F_{v,w,z} \circ_1 \mathrm{Id}) \circ_2 F_{u,v,z}$, where $\circ_i$ denotes composition of i-morphisms ($i = 1, 2$).

Next we turn such a lax diagram $D\colon [2]^n \to \mathscr{B}$ into a lax diagram $Q \in \mathfrak{h}\mathscr{T}(S^N)^{[2]^n}$, $N \geq n+1$, satisfying $\widetilde{H}_N \circ Q = \mathsf{Ab} \circ D$. Associate a *box* $B_x = [-1,1]^N$ to each $x \in D(v)$, $v \in [2]^n$. For each $u > v$, let $D(u \to v) = (A_{y,x})_{x \in D(u), y \in D(v)}$ and let $E(u \to v)$ be the space of embeddings $\iota_{u,v} = \{\iota_{u,v,x}\}_{x \in D(u)}$ where

$$\iota_{u,v,x}\colon \coprod_y A_{y,x} \times B_y \hookrightarrow B_x \tag{2-12}$$

whose restriction to each copy of B_y is a sub-box inclusion, i.e., composition of a translation and dilation. The space $E(A)$ is $(N-2)$-connected.

For any such data $\iota_{u,v}$, a collapse map and a fold map give a *box map*

$$\widehat{\iota}_{u,v}\colon \bigvee_{x \in D(u)} S^N = \coprod_{x \in D(u)} B_x/\partial \to \coprod_{\substack{x \in D(u)\\ y \in D(v)\\ a \in A_{y,x}}} B_y/\partial \to \coprod_{y \in D(v)} B_y/\partial = \bigvee_{y \in D(v)} S^N. \tag{2-13}$$

Given $u > v > w$ and data $\iota_{u,v}$, $\iota_{v,w}$, the composition $\widehat{\iota}_{v,w} \circ \widehat{\iota}_{u,v}$ is also a box map corresponding to some induced embedding data.

The construction of the lax diagram $Q \in \mathfrak{h}\mathscr{T}(S^N)^{[2]^n}$ is inductive. On objects, Q agrees with D. For (non-identity) morphisms $u \to v$, choose a box map $Q(u \to v) = \widehat{\iota}_{u,v}\colon \bigvee_{x \in D(u)} S^N \to \bigvee_{y \in D(v)} S^N$ refining $D(u \to v)$. Staying in the space of box maps, the required homotopies exist and are unique up to homotopy because each $E(A)$ is $N-2 \geq n-1$ connected, and there are no sequences of composable morphisms of length $> n-1$. (See Lawson, Lipshitz, and Sarkar [ibid.] for details.)

The above construction closely follows the Pontryagin-Thom procedure from Section 2.4. Indeed, functors from the cube to the Burnside category correspond to certain kinds of flow categories (*cubical* ones), and the realizations in terms of box maps and cubical flow categories agree.

3 Khovanov homology

3.1 The Khovanov cube. Khovanov homology was defined by Khovanov [2000] using the Frobenius algebra $V = H^*(S^2)$. Let $x_- \in H^0(S^2)$ and $x_+ \in H^2(S^2)$ be the positive generators. (Our labeling is opposite Khovanov's convention, as the maps in our cube go from 1 to 0.) Via the equivalence of Frobenius algebras and $(1+1)$-dimensional topological field theories (cf. Abrams [1996]), we can reinterpret V as a functor from the $(1+1)$-dimensional bordism category Cob^{1+1} to $\mathscr{B}(\mathbb{Z})$ that assigns $\{x_+, x_-\}$ to circle, and hence $\prod_{\pi_0(C)}\{x_+, x_-\}$ to a one-manifold C. For $x \in V(C)$, let $\|x\|_+$ (respectively, $\|x\|_-$) denote the number of circles in C labeled x_+ (respectively, x_-) by x. For a cobordism $\Sigma\colon C_1 \to C_0$, the map $V(\Sigma)\colon \mathbb{Z}\langle V(C_1)\rangle = \otimes_{\pi_0(C_1)}\mathbb{Z}\langle x_+, x_-\rangle \to \mathbb{Z}\langle V(C_0)\rangle = \otimes_{\pi_0(C_0)}\mathbb{Z}\langle x_+, x_-\rangle$ is the tensor product of the maps induced by the connected components of Σ; and if $\Sigma\colon C_1 \to C_0$ is a connected, genus-g cobordism, then the (y, x)-entry of the matrix representing the map, $x \in V(C_1)$, $y \in V(C_0)$, is

$$\begin{cases} 1 & \text{if } g = 0,\ \|x\|_+ + \|y\|_- = 1,\\ 2 & \text{if } g = 1,\ \|x\|_+ = \|y\|_- = 0,\\ 0 & \text{otherwise} \end{cases} \tag{3-1}$$

(cf. Bar-Natan [2005] and Hu, D. Kriz, and I. Kriz [2016]).

Now, given a link diagram L with n crossings numbered $c_1, \dots, c_n$, Khovanov [2000] constructs a cubical diagram $G_{Kh} = V \circ \mathbb{L} \in \mathscr{B}(\mathbb{Z})^{[2]^n}$ where $\mathbb{L}\colon [2]^n \to \mathsf{Cob}^{1+1}$ is the *cube of resolutions* (extending Kauffman [1987]) defined as follows. For $v \in [2]^n$, let $\mathbb{L}(v)$ be the complete resolution of the link diagram L formed by resolving the i^{th} crossing c_i $\times$ by the 0-*resolution* $)($ if $v_i = 0$ and by the 1-*resolution* $\asymp$ if $v_i = 1$. For a morphism $u \to v$, $\mathbb{L}(u \to v)$ is the cobordism which is an elementary saddle from the 1-resolution to the 0-resolution near crossings c_i for each i with $u_i > v_i$, and is a product cobordism elsewhere.

The dual of the resulting total complex, shifted by n_-, the number of negatives crossings $\times$ in L, is usually called the Khovanov complex

$$\mathcal{C}^*_{Kh}(L) = \mathsf{Dual}(\mathsf{Tot}(G_{Kh}))[n_-], \tag{3-2}$$

and its cohomology $Kh^*(L)$ the Khovanov homology, which is a link invariant. There is an internal grading, the *quantum grading*, that comes from placing the two symbols x_+ and x_- in two different quantum gradings, and the entire complex decomposes along this grading, so Khovanov homology inherits a second grading $Kh^i(L) = \oplus_j Kh^{i,j}(L)$, and its quantum-graded Euler characteristic

$$\sum_{i,j}(-1)^i q^j \operatorname{rank}(Kh^{i,j}(L)) \tag{3-3}$$

recovers the unnormalized Jones polynomial of L. The quantum grading persists in the space-level refinement but, for brevity, we suppress it.

3.2 The stable homotopy type. Following Section 2.6, to give a space-level refinement of Khovanov homology it suffices to lift G_{Kh} to a lax functor $[2]^n \to \mathscr{B}$.

Hu, D. Kriz, and I. Kriz [2016, §3.2] shows that the TQFT $V\colon \mathsf{Cob}^{1+1} \to \mathscr{B}(\mathbb{Z})$ does not lift to a functor $\mathsf{Cob}^{1+1} \to \mathscr{B}$. However, we may instead work with the *embedded* cobordism category Cob_e^{1+1}, which is a weak 2-category whose objects are closed 1-manifolds embedded in S^2, morphisms are compact cobordisms embedded in $S^2 \times [0,1]$, and 2-morphisms are isotopy classes of isotopies in $S^2 \times [0,1]$ rel boundary. The cube $\mathbb{L}\colon [2]^n \to \mathsf{Cob}^{1+1}$ factors through a functor $\mathbb{L}_e\colon [2]^n \to \mathsf{Cob}_e^{1+1}$. (This functor $\mathbb{L}_e$ is lax, similar to what we had for functors to the Burnside category except without strict unitarity.) So it remains to lift V to a (lax) functor $V_e\colon \mathsf{Cob}_e^{1+1} \to \mathscr{B}$

(3-4)
$$\begin{array}{ccccc} & \overset{\mathbb{L}_e}{\nearrow} & \mathsf{Cob}_e^{1+1} & \overset{V_e}{\dashrightarrow} & \mathscr{B}. \\ [2]^n & & \downarrow & & \downarrow \\ & \underset{\mathbb{L}}{\searrow} & \mathsf{Cob}^{1+1} & \xrightarrow{V} & \mathscr{B}(\mathbb{Z}) \end{array}$$

On an embedded one-manifold C, we must set

(3-5)
$$V_e(C) = \prod_{\pi_0(C)} \{x_+, x_-\}.$$

For an embedded cobordism $\Sigma\colon C_1 \to C_0$ with C_i embedded in $S^2 \times \{i\}$, the matrix $V_e(\Sigma)$ is a tensor product over the connected components of Σ, i.e., if $\Sigma = \amalg_{j=1}^m (\Sigma_j\colon C_{1,j} \to C_{0,j})$ and $(y^j, x^j) \in V_e(C_{0,j}) \times V_e(C_{1,j})$, then the $(\Pi_{j=1}^m y^j, \Pi_{j=1}^m x^j)$ entry of $V_e(\Sigma)$ equals

(3-6)
$$V_e(\Sigma_1)_{y^1,x^1} \times \cdots \times V_e(\Sigma_m)_{y^m,x^m}.$$

And finally, if $\Sigma\colon C_1 \to C_0$ is a connected genus-g cobordism, then for $x \in V_e(C_1)$ and $y \in V_e(C_0)$, the (y,x)-entry of $V_e(\Sigma)$ must be a

(3-7)
$$\begin{cases} \text{1-element set} & \text{if } g = 0,\ \|x\|_+ + \|y\|_- = 1, \\ \text{2-element set} & \text{if } g = 1,\ \|x\|_+ = \|y\|_- = 0, \\ \varnothing & \text{otherwise.} \end{cases}$$

One-element sets do not have any non-trivial automorphisms, so we may set all the one-element sets to $\{\mathrm{pt}\}$. The two-element sets must be chosen carefully: they have to behave naturally under isotopy of cobordisms (the 2-morphisms in Cob_e^{1+1}) and must admit natural isomorphisms $V_e(\Sigma \circ \Sigma') \cong V_e(\Sigma) \circ V_e(\Sigma')$ when composing cobordisms $\Sigma'\colon C_2 \to C_1$ and $\Sigma\colon C_1 \to C_0$.

Decompose $S^2 \times [0,1]$ as a union of two compact 3-manifolds glued along Σ, $A \cup_\Sigma B$. Set $V_e(\Sigma)$ to be the (cardinality two) set of unordered bases $\{\alpha, \beta\}$ for $\ker(H^1(\Sigma) \to$

$H^1(\partial\Sigma)) \cong \mathbb{Z}^2$ so that α (respectively, β) is the restriction of a generator of $\ker(H^1(A) \to H^1(A \cap (S^2 \times \{0,1\}))) \cong \mathbb{Z}$ (respectively, $\ker(H^1(B) \to H^1(B \cap (S^2 \times \{0,1\}))) \cong \mathbb{Z}$), and so that, if we orient Σ as the boundary of A then $\langle \alpha \cup \beta, [\Sigma] \rangle = 1$ (or equivalently, if we orient Σ as the boundary of B then $\langle \beta \cup \alpha, [\Sigma] \rangle = 1$). This assignment is clearly natural.

Given cobordisms $\Sigma' \colon C_2 \to C_1$ and $\Sigma \colon C_1 \to C_0$, we need to construct a natural 2-isomorphism $V_e(\Sigma) \circ V_e(\Sigma') \to V_e(\Sigma \circ \Sigma')$. The only non-trivial case is when Σ and Σ' are genus-0 cobordisms gluing to form a connected, genus-1 cobordism. In that case, letting $x \in V_e(C_2)$ (respectively, $y \in V_e(C_0)$) denote the generator that labels all circles of C_2 by x_- (respectively, all circles of C_0 by x_+), we need to construct a bijection between the (y,x)-entry $M_{y,x}$ of $V_e(\Sigma) \circ V_e(\Sigma')$ and the (y,x)-entry $N_{y,x}$ of $V_e(\Sigma \circ \Sigma')$. Consider an element Z of $M_{y,x}$; Z specifies an element $z \in V(C_1)$. There is a unique circle C in C_1 that is non-separating in $\Sigma \circ \Sigma'$ and is labeled x_+ by z. Choose an orientation o of $\Sigma \circ \Sigma'$, orient C as the boundary of Σ, and let $[C]$ denote the image of C in $H_1(\Sigma \circ \Sigma', \partial(\Sigma \circ \Sigma'))$. Assign to Z the unique basis in $N_{y,x}$ that contains the Poincaré dual of $[C]$. It is easy to check that this map is well-defined, independent of the choice of o, natural, and a bijection.

This concludes the definition of the functor $V_e \colon \mathsf{Cob}_e^{1+1} \to \mathscr{B}$. The spatial lift $Q_{Kh} \in \mathfrak{h}\mathcal{T}(S^N)^{[2]^n}$ is then induced from the composition $V_e \circ \mathbb{L}_e \colon [2]^n \to \mathscr{B}$. Totalization produces a cell complex $\mathsf{Tot}(Q_{Kh})$ with

$$\widetilde{C}^*_{\mathrm{cell}}(\mathsf{Tot}(Q_{Kh}))[N+n_-] = \mathcal{C}^*_{Kh}(L). \tag{3-8}$$

We define the Khovanov spectrum $\mathcal{X}_{Kh}(L)$ to be the formal $(N+n_-)^{\text{th}}$ desuspension of $\mathsf{Tot}(Q_{Kh})$. The stable homotopy type of $\mathcal{X}_{Kh}(L)$ is a link invariant; see Lipshitz and Sarkar [2014a], Hu, D. Kriz, and I. Kriz [2016], and Lawson, Lipshitz, and Sarkar [n.d.(a)]. The spectrum decomposes as a wedge sum over quantum gradings, $\mathcal{X}_{Kh}(L) = \bigvee_j \mathcal{X}^j_{Kh}(L)$. There is also a reduced version of the Khovanov stable homotopy type, $\widetilde{\mathcal{X}}_{Kh}(L)$, refining the reduced Khovanov chain complex.

3.3 Properties and applications. In order to apply the Khovanov homotopy type to knot theory, one needs to extract some concrete information from it beyond Khovanov homology. Doing so, one encounters three difficulties:

☹1. The number of vertices of the Khovanov cube is 2^n, where n is the number of crossings of L, so the number of cells in the CW complex $\mathcal{X}_{Kh}(L)$ grows at least that fast. So, direct computation must be by computer, and for relatively low crossing number links.

☹2. For low crossing number links, $Kh^{i,j}(L)$ is supported near the diagonal $2i - j = \sigma(L)$, so each $\mathcal{X}^j_{Kh}(L)$ has nontrivial homology only in a small number of adjacent gradings, and these $Kh^{i,j}(L)$ have no p-torsion for $p > 2$. If X is a spectrum so that $\widetilde{H}^i(X)$ is nontrivial only for $i \in \{k, k+1\}$ then the homotopy type of X is determined by $\widetilde{H}^*(X)$, while if $\widetilde{H}^*(X)$ is nontrivial in only three adjacent gradings and has no p-torsion ($p > 2$) then the homotopy type of X is determined by $\widetilde{H}^*(X)$ and the Steenrod operations Sq^1 and Sq^2 (see Baues [1995, Theorems 11.2, 11.7]).

☹3. There are no known formulas for most algebro-topological invariants of a CW complex. (The situation is a bit better for simplicial complexes.)

Lipshitz and Sarkar [2014c] found an explicit formula for the operation $\mathrm{Sq}^2\colon Kh^{i,j}(L;\mathbb{F}_2) \to Kh^{i+2,j}(L;\mathbb{F}_2)$. The operation Sq^1 is the Bockstein, and hence easy to compute. Using these, one can determine the spectra $\mathcal{X}^j_{Kh}(L)$ for all prime links up to 11 crossings. All these spectra are wedge sums of (de)suspensions of 6 basic pieces (cf. ☹2), and all possible basic pieces except $\mathbb{C}P^2$ occur (see ?1). The first knot for which $\mathcal{X}^{i,j}_{Kh}(K)$ is not a Moore space is also the first non-alternating knot: $T(3,4)$. Extending these computations:

Theorem 1 (Seed [n.d.]). *There are pairs of knots with isomorphic Khovanov cohomologies but non-homotopy equivalent Khovanov spectra.*

The first such pair is 11^n_{70} and 13^n_{2566}. D. Jones, Lobb, and Schütz [n.d.(b)] introduced moves and simplifications allowing them to give a by-hand computation of Sq^2 for $T(3,4)$ and some other knots.

Theorem 2 (Lawson, Lipshitz, and Sarkar [n.d.(a)]). *Given links L, L', $\mathcal{X}_{Kh}(L \amalg L') \simeq \mathcal{X}_{Kh}(L) \wedge \mathcal{X}_{Kh}(L')$ and, if L and L' are based, $\widetilde{\mathcal{X}}_{Kh}(L\#L') \simeq \widetilde{\mathcal{X}}_{Kh}(L) \wedge \widetilde{\mathcal{X}}_{Kh}(L')$ and $\mathcal{X}_{Kh}(L\#L') \simeq \mathcal{X}_{Kh}(L) \wedge_{\mathcal{X}_{Kh}(U)} \mathcal{X}_{Kh}(L')$. Finally, if $m(L)$ is the mirror of L then $\mathcal{X}_{Kh}(m(L))$ is the Spanier-Whitehead dual to $\mathcal{X}_{Kh}(L)$.*

Corollary 3.1. *For any integer k there is a knot K so that the operation $\mathrm{Sq}^k\colon Kh^{*,*}(K) \to Kh^{*+k,*}(K)$ is nontrivial. (Compare ?3.)*

Proof. Choose a knot K_0 so that in some quantum grading, $\widetilde{Kh}(K_0)$ has 2-torsion but $\widetilde{Kh}(K_0;\mathbb{F}_2)$ has vanishing Sq^i for $i > 1$. (For instance, $K_0 = 13^n_{3663}$ works, Shumakovitch [2014].) Let $K = \overbrace{K_0\#\cdots\#K_0}^{k}$. By the Cartan formula, $\mathrm{Sq}^k(\alpha) \neq 0$ for some $\alpha \in \widetilde{Kh}(K;\mathbb{F}_2)$. The short exact sequence

$$0 \to \widetilde{Kh}(K;\mathbb{F}_2) \to Kh(K;\mathbb{F}_2) \to \widetilde{Kh}(K;\mathbb{F}_2) \to 0$$

from Rasmussen [2005, §4.3] is induced by a cofiber sequence of Khovanov spectra from Lipshitz and Sarkar [2014a, §8], so if $\beta \in Kh(K;\mathbb{F}_2)$ is any preimage of α then by naturality, $\mathrm{Sq}^k(\beta) \neq 0$, as well. □

Plamenevskaya [2006] defined an invariant of links L in S^3 transverse to the standard contact structure, as an element of the Khovanov homology of L.

Theorem 3 (Lipshitz, Ng, and Sarkar [2015]). *Given a transverse link L in S^3 there is a well-defined cohomotopy class of $\mathcal{X}_{Kh}(L)$ lifting Plamenevskaya's invariant.*

While Lipshitz, Ng, and Sarkar [ibid.] show that Plamenevskaya's class is known to be invariant under flypes, the homotopical refinement is not presently known to be. It remains open whether either invariant is effective (i.e., stronger than the self-linking number).

The Steenrod squares on Khovanov homology was used by Lipshitz and Sarkar [2014b] to tweak the concordance invariant and slice-genus bound s by Rasmussen [2010] to give potentially new concordance invariants and slice genus bounds. In the simplest case, Sq^2, these concordance invariants are, indeed, different from Rasmussen's invariants. They can be used to give some new results on the 4-ball genus for certain families of knots, see Lawson, Lipshitz, and Sarkar [n.d.(a)]. More striking, Feller, Lewark, and Lobb [n.d.] used these operations to resolve whether certain knots are *squeezed*, i.e., occur in a minimal-genus cobordism between positive and negative torus knots.

In a different direction, the Khovanov homotopy type admits a number of extensions. Lobb, Orson, and Schütz [2017] and, independently, Willis [n.d.] proved that the Khovanov homotopy type stabilizes under adding twists, and used this to extend it to a colored Khovanov stable homotopy type; further stabilization results were proved by Willis [ibid.] and Islambouli and Willis [n.d.]. D. Jones, Lobb, and Schütz [n.d.(a)] proposed a homotopical refinement of the $\mathfrak{sl}_n$ Khovanov-Rozansky homology for a large class of knots and there is also work in progress in this direction by Hu, I. Kriz, and Somberg [n.d.]. Sarkar, Scaduto, and Stoffregen [n.d.] gave a homotopical refinement of the odd Khovanov homology of Ozsváth, Rasmussen, and Szabó [2013].

The construction of the functor V_e is natural enough that it was used by Lawson, Lipshitz, and Sarkar [n.d.(b)] to give a space-level refinement of the arc algebras and tangle invariants from Khovanov [2002]. In the refinement, the arc algebras are replaced by ring spectra (or, if one prefers, spectral categories), and the tangle invariants by module spectra.

3.4 Speculation.

We conclude with some open questions:

Ⓠ1. Does $\mathbb{C}P^2$ occur as a wedge summand of the Khovanov spectrum associated to some link? (Cf. Section 3.3.) More generally, are there non-obvious restrictions on the spectra which occur in the Khovanov homotopy types?

Ⓠ2. Is the obstruction to amphichirality coming from the Khovanov spectrum stronger than the obstruction coming from Khovanov homology? Presumably the answer is "yes," but verifying this might require interesting new computational techniques.

?3. Are there prime knots with arbitrarily high Steenrod squares? Other power operations? Again, we expect that the answer is "yes."

?4. How can one compute Steenrod operations, or stable homotopy invariants beyond homology, from a flow category? (Compare Lipshitz and Sarkar [2014c].)

?5. Is the refined Plamenevskaya invariant from Lipshitz, Ng, and Sarkar [2015] effective? Alternatively, is it invariant under negative flypes / SZ moves?

?6. Is there a well-defined homotopy class of maps of Khovanov spectra associated to an isotopy class of link cobordisms $\Sigma \subset [0,1] \times \mathbb{R}^3$? Given such a cobordism Σ in general position with respect to projection to $[0,1]$, there is an associated map, but it is not known if this map is an isotopy invariant. More generally, one could hope to associate an $(\infty, 1)$-functor from a quasicategory of links and embedded cobordisms to a quasicategory of spectra, allowing one to study families of cobordisms. If not, this is a sense in which Khovanov homotopy, or perhaps homology, is *un*natural. Applications of these cobordism maps would also be interesting (cf. Swann [2010]).

?7. If analytic difficulties are resolved, applying the Cohen-Jones-Segal construction to the symplectic Khovanov homology of Seidel and Smith [2006] should also give a Khovanov spectrum. Is that symplectic Khovanov spectrum homotopy equivalent to the combinatorial Khovanov spectrum? (Cf. Abouzaid and Smith [n.d.].)

?8. The (symplectic) Khovanov complex admits, in some sense, an $O(2)$-action, cf. Manolescu [2006], Seidel and Smith [2010], Hendricks, Lipshitz, and Sarkar [n.d.], and Sarkar, Seed, and Szabó [2017]. Does the Khovanov stable homotopy type?

?9. Is there a homotopical refinement of the Lee [2005] or Bar-Natan [2005] deformation of Khovanov homology? Perhaps no genuine spectrum exists, but one can hope to find a lift of the theory to a module over *ku* or *ko* or another ring spectrum (cf. Cohen [2009]). Exactly how far one can lift the complex might be predicted by the polarization class of a partial compactification of the symplectic Khovanov setting from Seidel and Smith [2006].

?10. Can one make the discussion in Section 2.5 precise? Are there other rig (or ∞-rig) categories, beyond Sets, useful in refining chain complexes in categorification or Floer theory to get modules over appropriate ring spectra?

?11. Is there an intrinsic, diagram-free description of $\mathcal{X}_{Kh}(K)$ or, for that matter, for Khovanov homology or the Jones polynomial?

HOMOLOGY COBORDISM AND TRIANGULATIONS

CIPRIAN MANOLESCU

Abstract

The study of triangulations on manifolds is closely related to understanding the three-dimensional homology cobordism group. We review here what is known about this group, with an emphasis on the local equivalence methods coming from Pin(2)-equivariant Seiberg-Witten Floer spectra and involutive Heegaard Floer homology.

1 Triangulations of manifolds

A *triangulation* of a topological space X is a homeomorphism $f : |K| \to X$, where $|K|$ is the geometric realization of a simplicial complex K. If X is a smooth manifold, we say that the triangulation is smooth if its restriction to every closed simplex of $|K|$ is a smooth embedding. By the work of Cairns [1935] and Whitehead [1940], every smooth manifold admits a smooth triangulation. Furthermore, this triangulation is unique, up to pre-compositions with piecewise linear (PL) homeomorphisms.

The question of classifying triangulations for *topological* manifolds is much more difficult. Research in this direction was inspired by the following two conjectures.

Hauptvermutung (Steinitz [1908], Tietze [1908]): *Any two triangulations of a space X admit a common refinement (i.e., another triangulation that is a subdivision of both).*

Triangulation Conjecture (based on a remark by Kneser [1926]): *Any topological manifold admits a triangulation.*

Both of these conjectures turned out to be false. The Hauptvermutung was disproved by Milnor [1961], who used Reidemeister torsion to distinguish two triangulations of a space X that is not a manifold. Counterexamples on manifolds came out of the work of Kirby and Siebenmann [1977]. (For a nice survey of the mathematics surrounding the

Keywords: manifold, gauge theory, Seiberg-Witten, Heegaard Floer.

Hauptvermutung, see Ranicki [1996].) With regard to the triangulation conjecture, counterexamples were shown to exist in dimension 4 by Casson (cf. Akbulut and McCarthy [1990]), and in all dimensions ≥ 5 by Manolescu [2016].

When studying triangulations on manifolds, a natural condition that one can impose is that the link of every vertex is PL homeomorphic to a sphere. Such triangulations are called *combinatorial*, and (up to subdivision) they are equivalent to PL structures on the manifold.

In dimensions ≤ 3, every topological manifold admits a unique smooth and a unique PL structure; cf. Radó [1925] and Moise [1952]. In dimensions ≥ 5, PL structures on topological manifolds were classified in the 1960's. Specifically, building on work of Sullivan [1996] and Casson [1996], Kirby and Siebenmann [1977] proved the following:

- A topological manifold M of dimension $d \geq 5$ admits a PL structure if and only if a certain obstruction class $\Delta(M) \in H^4(M;\mathbb{Z}/2)$ vanishes;
- For every $d \geq 5$, there exists a d-dimensional manifold M such that $\Delta(M) \neq 0$, that is, one without a PL structure;
- If $\Delta(M) = 0$ for a d-dimensional manifold M with $d \geq 5$, then the PL structures on M are classified by elements of $H^3(M;\mathbb{Z}/2)$. (This shows the failure of the Hauptvermutung for manifolds.)

Finally, in dimension four, PL structures are the same as smooth structures, and the classification of smooth structures is an open problem—although much progress has been made using gauge theory, starting with the work of Donaldson [1983]. Note that Freedman [1982] constructed non-smoothable topological four-manifolds, such as the E_8-manifold.

We can also ask about arbitrary triangulations of topological manifolds, not necessarily combinatorial. It is not at all obvious that non-combinatorial triangulations of manifolds exist, but they do.

Example 1.1. Start with a triangulation of a non-trivial homology sphere M^d with $\pi_1(M) \neq 1$; such homology spheres exist in dimensions $d \geq 3$. Take two cones on each simplex, to obtain a triangulation of the suspension ΣM. Repeat the procedure, to get a triangulation of the double suspension $\Sigma^2 M$. By the double suspension theorem of Edwards [2006] and Cannon [1979], the space $\Sigma^2 M$ is homeomorphic to S^{d+2}. However, the link of one of the final cone points is ΣM, which is not even a manifold. Thus, S^{d+2} admits a non-combinatorial triangulation.

Remark 1.2. One can show that any triangulation of a manifold of dimension ≤ 4 is combinatorial.

In general, if we triangulate a d-dimensional manifold, the link of a k-dimensional simplex has the homology of the $(d-k-1)$-dimensional sphere. (However, the link may not be a manifold, as in the example above.) In the 1970's, Galewski and Stern [1980] and Matumoto [1978] developed the theory of triangulations of high-dimensional manifolds by considering homology cobordism relations between the links of simplices. Their theory involves the n-dimensional *homology cobordism group* $\Theta^n_{\mathbb{Z}}$, which we now proceed to define.

Let us first define a d-dimensional *combinatorial homology manifold* M to be a simplicial complex such that the links of k-dimensional simplices have the homology of S^{d-k-1}. We can extend this definition to combinatorial homology manifolds M with boundary, by requiring the links of simplices on the boundary to have the homology of a disk (and so that ∂M is a combinatorial homology manifold). We let

$$\Theta^n_{\mathbb{Z}} = \{Y^n \text{ oriented combinatorial homology manifolds, } H_*(Y) \cong H_*(S^n)\}/\sim$$

where the equivalence relation is given by $Y_0 \sim Y_1 \iff$ there exists a compact, oriented, combinatorial homology manifold W^{n+1} with $\partial W = (-Y_0) \cup Y_1$ and $H_*(W, Y_i; \mathbb{Z}) = 0$. If $Y_0 \sim Y_1$, we say that Y_0 and Y_1 are *homology cobordant*. Summation in $\Theta^n_{\mathbb{Z}}$ is given by connected sum, the standard sphere S^n gives the zero element, and $-[Y]$ is the class of Y with the orientation reversed. This turns $\Theta^n_{\mathbb{Z}}$ into an Abelian group.

It follows from the work of Kervaire [1969] that $\Theta^n_{\mathbb{Z}} = 0$ for $n \neq 3$. On the other hand, the three-dimensional homology cobordism group $\Theta^3_{\mathbb{Z}}$ is nontrivial. To study $\Theta^3_{\mathbb{Z}}$, note that in dimension three, every homology sphere is a manifold. Also, a four-dimensional homology cobordism can be replaced by a PL one, between the same homology spheres, cf. Martin [1973, Theorem A]. Furthermore, in dimensions three and four, the smooth and PL categories are equivalent. This shows that we can define $\Theta^3_{\mathbb{Z}}$ in terms of smooth homology spheres and smooth cobordisms.

The easiest way to see that $\Theta^3_{\mathbb{Z}} \neq 0$ is to consider the *Rokhlin homomorphism*

$$\mu : \Theta^3_{\mathbb{Z}} \to \mathbb{Z}/2, \quad \mu(Y) = \sigma(W)/8 \pmod 2, \tag{1}$$

where W is any compact, smooth, spin 4-manifold with boundary Y, and $\sigma(W)$ denotes the signature of W. For example, the Poincaré sphere P bounds the negative definite plumbing $-E_8$ of signature -8, and therefore has $\mu(P) = 1$. This implies that P is not homology cobordant to S^3, and hence $\Theta^3_{\mathbb{Z}} \neq 0$.

Let us introduce the exact sequence:

$$0 \longrightarrow \ker(\mu) \longrightarrow \Theta^3_{\mathbb{Z}} \xrightarrow{\mu} \mathbb{Z}/2 \longrightarrow 0. \tag{2}$$

We are now ready to state the results of Galewski and Stern [1980], Galewski and Stern [1979] and Matumoto [1978] about triangulations of high-dimensional manifolds.

They mostly parallel those of Kirby-Siebenmann on combinatorial triangulations. One difference is that, when studying arbitrary triangulations, the natural equivalence relation to consider is *concordance*: Two triangulations of the same manifold M are concordant if there exists a triangulation on $M \times [0,1]$ that restricts to the two triangulations on the boundaries $M \times \{0\}$ and $M \times \{1\}$.

- A d-dimensional manifold M (for $d \geq 5$) is triangulable if and only if $\delta(\Delta(M)) = 0 \in H^5(M; \ker(\mu))$. Here, $\Delta(M) \in H^4(M; \mathbb{Z}/2)$ is the Kirby-Siebenmann obstruction to the existence of PL structures, and $\delta : H^4(M; \mathbb{Z}/2) \to H^5(M; \ker(\mu))$ is the Bockstein homomorphism coming from the exact sequence (2).

- There exist non-triangulable manifolds in dimensions ≥ 5 if and only if the exact sequence (2) does not split. (In Manolescu [2016], the author proved that it does not split.)

- If they exist, triangulations on a manifold M of dimension ≥ 5 are classified (up to concordance) by elements in $H^4(M; \ker(\mu))$.

The above results provide an impetus for further studying the group $\Theta^3_{\mathbb{Z}}$, together with the Rokhlin homomorphism.

2 The homology cobordism group

Since $\Theta^3_{\mathbb{Z}}$ can be defined in terms smooth four-dimensional cobordisms, it is not surprising that the tools used to better understand it came from gauge theory. Indeed, beyond the existence of the Rokhlin epimorphism, the first progress was made by Fintushel and Stern [1985], using Yang-Mills theory:

Theorem 2.1 (Fintushel and Stern [ibid.])**.** *The group $\Theta^3_{\mathbb{Z}}$ is infinite. For example, it contains a $\mathbb{Z}$ subgroup, generated by the Poincaré sphere $\Sigma(2,3,5)$.*

Their proof involved associating to a Seifert fibered homology sphere $\Sigma(a_1, \dots, a_k)$ a numerical invariant $R(a_1, \dots, a_k)$, the expected dimension of a certain moduli space of self-dual connections. By combining these methods with Taubes' work on end-periodic four-manifolds (cf. Taubes [1987]), one obtains a stronger result:

Theorem 2.2 (Fintushel and Stern [1990], Furuta [1990])**.** *The group $\Theta^3_{\mathbb{Z}}$ contains a $\mathbb{Z}^\infty$ subgroup. For example, the classes $[\Sigma(2,3,6k-1)]$, $k \geq 1$, are linearly independent in $\Theta^3_{\mathbb{Z}}$.*

When Y is a homology three-sphere, the Yang-Mills equations on $\mathbb{R} \times Y$ were used by Floer [1988] to construct his celebrated *instanton homology*. From the equivariant structure on instanton homology, Frøyshov [2002] defined a homomorphism

$$h : \Theta^3_{\mathbb{Z}} \to \mathbb{Z},$$

with the property that $h(\Sigma(2,3,5)) = 1$ (and therefore h is surjective). This implies the following:

Theorem 2.3 (Frøyshov [ibid.]). *The group $\Theta^3_{\mathbb{Z}}$ has a $\mathbb{Z}$ summand, generated by the Poincaré sphere $P = \Sigma(2,3,5)$.*

Since then, further progress on homology cobordism was made using Seiberg-Witten theory and its symplectic-geometric replacement, Heegaard Floer homology. These will be discussed in Sections 3 and 4, respectively.

In spite of this progress, the following structural questions about $\Theta^3_{\mathbb{Z}}$ remain unanswered:

Questions: *Does $\Theta^3_{\mathbb{Z}}$ have any torsion? Does it have a $\mathbb{Z}^\infty$ summand? Is it in fact $\mathbb{Z}^\infty$?*

We remark that the existence of a $\mathbb{Z}^\infty$ summand could be established by constructing an epimorphism $\Theta^3_{\mathbb{Z}} \to \mathbb{Z}^\infty$. In the context of knot concordance, a result of this type was proved by Hom [2015]: Using knot Floer homology, she showed the existence of a $\mathbb{Z}^\infty$ summand in the smooth knot concordance group generated by topologically slice knots.

3 Seiberg-Witten theory

The Seiberg-Witten equations, introduced in Seiberg and Witten [1994] and Witten [1994] are a prominent tool for studying smooth four-manifolds. They form a system of nonlinear partial differential equations with a $U(1)$ gauge symmetry; the system is elliptic modulo the gauge action. In dimension three, the information coming from these equations can be packaged into an invariant called *Seiberg-Witten Floer homology* (or *monopole Floer homology*). This was defined in full generality, for all three-manifolds, by Kronheimer and Mrowka [2007] in their book. For rational homology spheres, alternate constructions were given in Marcolli and B.-L. Wang [2001], Manolescu [2003], Frøyshov [2010]. Lidman and Manolescu [2016] showed that the definitions in Manolescu [2003] and Kronheimer and Mrowka [2007] are equivalent.

In many settings, the Seiberg-Witten equations can be used as a replacement for the Yang-Mills equations. For example, from the S^1-equivariant structure on Seiberg-Witten Floer homology one can extract an epimorphism

$$\delta : \Theta^3_{\mathbb{Z}} \to \mathbb{Z},$$

and give a new proof of Theorem 2.3; see Frøyshov [2010] and Kronheimer and Mrowka [2007]. It is not known whether δ coincides with the invariant h coming from instanton homology. Note that Frøyshov [2010] and Kronheimer and Mrowka [2007] use the same notation h for the invariant coming from Seiberg-Witten theory; to prevent confusion with the instanton one, we write δ here. We use the normalization that $\delta(P) = 1$ for the Poincaré sphere P.

The construction of Seiberg-Witten Floer homology in Manolescu [2003] actually gives a refined invariant: an S^1-equivariant Floer stable homotopy type, SWF, which can be associated to rational homology spheres equipped with spin^c structures. The definition of SWF was recently generalized to all three-manifolds (in an "unfolded" version) by Khandhawit, J. Lin, and Sasahira [2016].

When the spin^c structure comes from a spin structure, the S^1 symmetry of the Seiberg-Witten equations (given by constant gauge transformations) can be expanded to a symmetry by the group $\mathrm{Pin}(2)$, where

$$\mathrm{Pin}(2) = S^1 \cup jS^1 \subset \mathbb{C} \oplus j\mathbb{C} = \mathbb{H}.$$

As observed in Manolescu [2016], this turns SWF into a $\mathrm{Pin}(2)$-equivariant stable homotopy type, and allows us to define a $\mathrm{Pin}(2)$-equivariant Seiberg-Witten Floer homology. By imitating the construction of the Frøyshov invariant δ in this setting, we obtain three new maps

$$\alpha, \beta, \gamma : \Theta^3_{\mathbb{Z}} \dashrightarrow \mathbb{Z}. \tag{3}$$

These are not homomorphisms (we use the dotted arrow to indicate that), but on the other hand they are related to the Rokhlin homomorphism from (1):

$$\alpha \equiv \beta \equiv \gamma \equiv \mu \pmod 2.$$

Under orientation reversal, the three invariants behave as follows:

$$\alpha(-Y) = -\gamma(Y), \ \beta(-Y) = -\beta(Y).$$

The properties of β suffice to prove the following.

Theorem 3.1 (Manolescu [ibid.]). *There are no 2-torsion elements $[Y] \in \Theta^3_{\mathbb{Z}}$ with $\mu(Y) = 1$. Hence, the short exact sequence (2) does not split and, as a consequence of the work of Galewski and Stern [1980] and Matumoto [1978], non-triangulable manifolds exist in every dimension ≥ 5.*

Indeed, if Y were a homology sphere with $2[Y] = 0 \in \Theta^3_{\mathbb{Z}}$, then Y would be homology cobordant to $-Y$, which would imply that

$$\beta(Y) = \beta(-Y) = -\beta(Y) \ \Rightarrow\ \beta(Y) = 0 \ \Rightarrow\ \mu(Y) = 0.$$

An alternate construction of Pin(2)-equivariant Seiberg-Witten Floer homology, in the spirit of Kronheimer and Mrowka [2007] and applicable to all three-manifolds, was given by F. Lin [2014]. In particular, this gives an alternate proof of Theorem 3.1. Lin's theory was further developed in F. Lin [2015], F. Lin [2016a], F. Lin [2016b], Dai [2016].

The invariants α, β, γ were computed for Seifert fibered spaces by Stoffregen [2015b] and by F. Lin [2015]. One application of their calculations is the following result (a proof of which was also announced earlier by Frøyshov, using instanton homology).

Theorem 3.2 (Frøyshov [n.d.], Stoffregen [2015b], F. Lin [2015]). *There exist homology spheres that are not homology cobordant to any Seifert fibered space.*

This should be contrasted with a result of Myers [1983], which says that every element of $\Theta^3_{\mathbb{Z}}$ can be represented by a hyperbolic three-manifold.

In Stoffregen [2015a], Stoffregen studied the behavior of the invariants α, β, γ under taking connected sums, and used it to give a new proof of the infinite generation of $\Theta^3_{\mathbb{Z}}$. He found a subgroup $\mathbb{Z}^\infty \subset \Theta^3_{\mathbb{Z}}$ generated by the Brieskorn spheres $\Sigma(p, 2p-1, 2p+1)$ for $p \geq 3$ odd. (Compare Theorem 2.2.)

In fact, the information in $\alpha, \beta, \gamma, \delta$, and much more, can be obtained from a stronger invariant, a class in the *local equivalence group* $\mathfrak{LE}$ defined by Stoffregen [2015b]. To define $\mathfrak{LE}$, we first define a *space of type SWF* to be a pointed finite Pin(2)-CW complex X such that

- The S^1-fixed point set X^{S^1} is Pin(2)-homotopy equivalent to $(\tilde{\mathbb{R}}^s)^+$, where $\tilde{\mathbb{R}}$ is the one-dimensional representation of Pin(2) on which S^1 acts trivially and j acts by -1;
- The action of Pin(2) on $X - X^{S^1}$ is free.

The definition is modeled on the properties of the Seiberg-Witten Floer spectra SWF(Y) for homology spheres Y. Any SWF(Y) is the formal (de)suspension of a space of type SWF. The condition on the fixed point set comes from the fact that there is a unique reducible solution to the Seiberg-Witten equations on Y.

The elements of $\mathfrak{LE}$ are equivalence classes $[X]$, where X is a formal (de)suspension of a space of type SWF, and the equivalence relation (called *local equivalence*) is given by: $X_1 \sim X_2 \iff$ there exist Pin(2)-equivariant stable maps

$$\phi : X_1 \to X_2, \quad \psi : X_2 \to X_1,$$

which are both Pin(2)-equivalences on the S^1-fixed point sets. This relation is motivated by the fact that if Y_1 and Y_1 are homology cobordant, then the induced cobordism maps on Seiberg-Witten Floer spectra give a local equivalence between SWF(Y_1) and SWF(Y_2).

We can turn $\mathfrak{LE}$ into an Abelian group, with addition given by smash product, the inverse given by taking the Spanier-Whitehead dual, and the zero element being $[S^0]$. We obtain a group homomorphism

$$\Theta^3_{\mathbb{Z}} \to \mathfrak{LE}, \ \ [Y] \to [\mathrm{SWF}(Y)].$$

The class $[\mathrm{SWF}(Y)] \in \mathfrak{LE}$ encapsulates all known information from Seiberg-Witten theory that is invariant under homology cobordism. The group $\mathfrak{LE}$ is still quite complicated, but there is a simpler version, called the *chain local equivalence group* $\mathfrak{CLE}$, which involves chain complexes rather than stable homotopy types. The elements of $\mathfrak{CLE}$ are modeled on the cellular chain complexes[1] $C^{CW}_*(\mathrm{SWF}(Y);\mathbb{F})$ with coefficients in the field $\mathbb{F} = \mathbb{Z}/2$, viewed as modules over

$$C^{CW}_*(\mathrm{Pin}(2);\mathbb{F}) \cong \mathbb{F}[s,j]/(sj = j^3 s, \ s^2 = 0, j^4 = 1).$$

and divided by an equivalence relation (called chain local equivalence), similar to the one used in the definition of $\mathfrak{LE}$. We have a natural homomorphism

$$\mathfrak{LE} \to \mathfrak{CLE}, \ \ [X] \to [C^{CW}_*(X;\mathbb{F})].$$

To construct interesting maps from $\Theta^3_{\mathbb{Z}}$ to $\mathbb{Z}$, one strategy is to factor them through the groups $\mathfrak{LE}$ or $\mathfrak{CLE}$. Indeed, the Frøyshov homomorphism δ can be obtained this way, by passing from chain complexes to the S^1-equvariant Borel cohomology, which is a module over

$$H^*_{S^1}(pt;\mathbb{F}) = H^*(\mathbb{CP}^\infty;\mathbb{F}) = \mathbb{F}[U], \ \deg(U) = 2.$$

Given the structure of the S^1-fixed point set of $\mathrm{SWF}(Y)$, one can show that $H^*_{S^1}(\mathrm{SWF}(Y);\mathbb{F})$ is the direct sum of an infinite tower $\mathbb{F}[U]$ and an $\mathbb{F}[U]$-torsion part. The invariant $\delta(Y)$ is set to be $1/2$ the minimal grading in the $\mathbb{F}[U]$ tower. The resulting homomorphism δ factors as

$$\Theta^3_{\mathbb{Z}} \longrightarrow \mathfrak{LE} \longrightarrow \mathfrak{CLE} \xrightarrow{\ \delta\ } \mathbb{Z},$$

Here, by a slight abuse of notation, we also used δ to denote the final map from $\mathfrak{CLE}$ to $\mathbb{Z}$.

The maps α, β, γ from (3) are constructed similarly to δ, but using the Pin(2)-equivariant Borel cohomology $H^*_{\mathrm{Pin}(2)}(\mathrm{SWF}(Y);\mathbb{F})$. This is a module over

$$H^*_{\mathrm{Pin}(2)}(pt;\mathbb{F}) = H^*(B\,\mathrm{Pin}(2);\mathbb{F}) = \mathbb{F}[q,v]/(q^3), \ \deg(q) = 1, \ \deg(v) = 4.$$

[1] When applied to SWF, all our chain complexes and homology theories are reduced, but we drop the usual tilde from notation for simplicity.

In this case, if we just consider the $\mathbb{F}[v]$-module structure, we find three infinite towers of the form $\mathbb{F}[v]$, and α, β, γ are the minimal degrees of elements in this towers, suitably renormalized. We can write

$$\Theta^3_{\mathbb{Z}} \longrightarrow \mathfrak{LE} \longrightarrow \mathfrak{CLE} \overset{\alpha,\beta,\gamma}{\dashrightarrow} \mathbb{Z}.$$

Two other numerical invariants $\underline{\delta}, \bar{\delta} : \mathfrak{CLE} \dashrightarrow \mathbb{Z}$ can be obtained by considering the $\mathbb{Z}/4$-equivariant Borel cohomology, where $\mathbb{Z}/4$ is the subgroup

$$\mathbb{Z}/4 = \{1, -1, j, -j\} \subset \mathrm{Pin}(2) = \mathbb{C} \oplus j\mathbb{C}.$$

As shown by Stoffregen [2016], if one considers the Borel homology for other subgroups $G \subset \mathrm{Pin}(2)$, one does not get any information beyond that in $\alpha, \beta, \gamma, \delta, \underline{\delta}$ and $\bar{\delta}$.

However, one can consider other equivariant generalized cohomology theories. For example, there are invariants κ_i, $i \in \{0, 1\}$ coming from $\mathrm{Pin}(2)$-equivariant K-theory (cf. Manolescu [2014] and Furuta and Li [2013]), and κo_i, $i = 0, \dots, 7$, from $\mathrm{Pin}(2)$-equivariant KO-theory (cf. J. Lin [2015]). These factor through $\mathfrak{LE}$, albeit not through $\mathfrak{CLE}$, and have applications to the study of intersection forms of spin four-manifolds with boundary.

In summary, we have a diagram

$$\begin{array}{ccccccc} \Theta^3_{\mathbb{Z}} & \longrightarrow & \mathfrak{LE} & \longrightarrow & \mathfrak{CLE} & \xrightarrow{\ \delta\ } & \mathbb{Z}, \\ & & \Big\downarrow{\scriptstyle \kappa_i, \kappa o_i} & & \Big\downarrow{\scriptstyle \underline{\delta}, \bar{\delta}} & \searrow{\scriptstyle \alpha,\beta,\gamma} & \\ & & \mathbb{Z} & & \mathbb{Z} & & \mathbb{Z} \end{array} \tag{4}$$

Recall that $\mathfrak{CLE}$ was defined using chain complexes with coefficients in $\mathbb{F} = \mathbb{Z}/2$. One could also take coefficients in other fields, say $\mathbb{Q}$ or $\mathbb{Z}/p$ for odd primes p. From the corresponding S^1-equivariant Borel cohomology (with coefficients in a field of characteristic p) one gets homomorphisms

$$\delta_p : \mathfrak{LE} \to \mathbb{Z}.$$

These are different on $\mathfrak{LE}$, but it is not known whether they are different when pre-composed with the map $\Theta^3_{\mathbb{Z}} \to \mathfrak{LE}$. For every homology sphere for which computations are available, the values of δ_p are the same for all p.

On the other hand, Stoffregen [2015b] showed that the information in chain local equivalence (for specific Seifert fibered homology spheres) goes beyond that in the numerical invariants from (4). In fact, using chain local equivalence, he defined an invariant of homology cobordism that takes the form of an Abelian group, called the *connected Seiberg-Witten Floer homology*.

Open problem: *Describe the structure of the groups $\mathcal{LE}$ and $\mathcal{CLE}$, and use it to understand more about $\Theta^3_{\mathbb{Z}}$.*

In particular, it would be interesting to construct more homomorphisms from $\mathcal{LE}$ and $\mathcal{CLE}$ to $\mathbb{Z}$, which could perhaps be used to produce new $\mathbb{Z}$ summands in $\Theta^3_{\mathbb{Z}}$. Of special interest is to construct a lift of the Rokhlin homomorphism to $\mathbb{Z}$, as a homomorphism (rather than just as a map of sets, as is the case with α, β, γ). The existence of such a lift would show that $\Theta^3_{\mathbb{Z}}$ has no torsion with $\mu = 1$, thus strengthening Theorem 3.1. In turn, one can show that this would give a simpler criterion for a high-dimensional manifold to be triangulable: the Galewski-Stern-Matumoto class $\delta(\Delta(M)) \in H^5(M; \ker(\mu))$ could be replaced with an equivalent obstruction in $H^5(M; \mathbb{Z})$.

4 Heegaard Floer homology and its involutive refinement

In a series of papers, Ozsváth and Szabó [2004b], Ozsváth and Szabó [2004a], Ozsváth and Szabó [2006], Ozsváth and Szabó [2003] developed *Heegaard Floer homology*: To every three-manifold Y and spin^c structure $\mathfrak{s}$, they associated invariants

$$\widehat{HF}(Y, \mathfrak{s}),\ HF^+(Y, \mathfrak{s}),\ HF^-(Y, \mathfrak{s}),\ HF^\infty(Y, \mathfrak{s}).$$

These are defined by choosing a pointed Heegaard diagram

$$\mathcal{H} = (\Sigma, \boldsymbol{\alpha}, \boldsymbol{\beta}, z)$$

consisting of the Heegaard surface Σ of genus g, two sets of attaching curves $\boldsymbol{\alpha} = \{\alpha_1, \dots, \alpha_g\}$, $\boldsymbol{\beta} = \{\beta_1, \dots, \beta_g\}$, and a basepoint $z \in \Sigma$, away from the attaching curves. The attaching curves describe two handlebodies, which put together should give the three-manifold Y. One then considers the Lagrangians

$$\mathbb{T}_\alpha = \alpha_1 \times \cdots \times \alpha_g,\ \ \mathbb{T}_\beta = \beta_1 \times \cdots \times \beta_g$$

inside the symmetric product $\mathrm{Sym}^g(\Sigma)$. The different flavors ($\widehat{\ }, +, -, \infty$) of Heegaard Floer homology are versions of the Lagrangian Floer homology $HF(\mathbb{T}_\alpha, \mathbb{T}_\beta)$.

The construction of Heegaard Floer homology was inspired by Seiberg-Witten theory: the symmetric product is related to moduli spaces of vortices on Σ. In fact, it has been recently established Kutluhan, Lee, and Taubes [2010], Colin, Ghiggini, and Honda [2012], and Taubes [2010] that Heegaard Floer homology is isomorphic to the monopole Floer homology from Kronheimer and Mrowka [2007]. In view of Lidman and Manolescu [2016], we obtain a relation to the different homologies applied to the Seiberg-Witten Floer spectrum SWF (for rational homology spheres). For example, we have

$$\widehat{HF} \cong H_*(\mathrm{SWF}),\ HF^+ \cong H_*^{S^1}(\mathrm{SWF}).$$

Heegaard Floer homology has had numerous applications to low dimensional topology, and is easier to compute than Seiberg-Witten Floer homology. In fact, it was shown to be algorithmically computable; cf. Sarkar and J. Wang [2010], Lipshitz, Ozsváth, and Thurston [2014], and Manolescu, Ozsváth, and Thurston [2009].

With regard to homology cobordism, in Ozsváth and Szabó [2003] Ozsváth and Szabó defined the *correction terms* $d(Y, \mathfrak{s})$, which are analogues of the Frøyshov invariant δ, and give rise to a homomorphism

$$d : \Theta^3_{\mathbb{Z}} \to \mathbb{Z}.$$

With the usual normalization in Heegaard Floer theory, we have $d = 2\delta$.

One could also ask about recovering $\mathrm{Pin}(2)$-equivariant Seiberg-Witten Floer homology and the invariants α, β, γ using Heegaard Floer homology. For technical reasons (related to higher order naturality), this seems currently out of reach. However, Hendricks and Manolescu [2017] developed *involutive Heegaard Floer homology*, as an analogue of $\mathbb{Z}/4$-equivariant Seiberg-Witten Floer homology, for the subgroup $\mathbb{Z}/4 = \langle j \rangle \subset \mathrm{Pin}(2)$. We start by considering the conjugation symmetry on Heegaard Floer complexes CF° ($\circ \in \{\widehat{\ }, +, -, \infty\}$), coming from interchanging the alpha and beta curves, and reversing the orientation of the Heegaard diagram. When $\mathfrak{s}$ is self-conjugate (i.e., comes from a spin structure), the conjugation symmetry gives rise to an automorphism

$$\iota : CF^\circ(Y, \mathfrak{s}) \to CF^\circ(Y, \mathfrak{s}),$$

which is a homotopy involution, that is, $\iota^2 \sim \mathrm{id}$. We then define the corresponding involutive Heegaard Floer homology as the homology of the mapping cone of $1 + \iota$:

$$HFI^\circ(Y, \mathfrak{s}) = H_*(Cone(CF^\circ(Y) \xrightarrow{(1+\iota)} CF^\circ(Y))).$$

While the usual Heegaard Floer homologies are modules over $H^*_{S^1}(pt) \cong \mathbb{F}[U]$, the involutive versions are modules over $H^*_{\mathbb{Z}/4}(pt) \cong \mathbb{F}[Q, U]/(Q^2)$, with $\deg(U) = -2$, $\deg(Q) = -1$.

Conjecture 4.1. *For every rational homology sphere Y with a self-conjugate* spin^c *structure $\mathfrak{s}$, we have an isomorphism of $\mathbb{F}[Q, U]/(Q^2)$-modules*

$$HFI^+(Y, \mathfrak{s}) \cong H^{\mathbb{Z}/4}_*(\mathrm{SWF}(Y, \mathfrak{s}); \mathbb{F}).$$

From involutive Heegaard Floer homology one can extract invariants $\underline{d}(Y, \mathfrak{s})$, $\bar{d}(Y, \mathfrak{s})$, which are the analogues of (twice) the invariants $\underline{\delta}, \bar{\delta}$ coming from $H^*_{\mathbb{Z}/4}(\mathrm{SWF})$. We get maps

$$\underline{d}, \bar{d} : \Theta^3_{\mathbb{Z}} \dashrightarrow \mathbb{Z}.$$

Involutive Heegaard Floer homology has been computed for various classes of three-manifolds, such as large surgeries on alternating knots (cf. Hendricks and Manolescu [2017]) and the Seifert fibered rational homology spheres $\Sigma(a_1, \dots, a_k)$ (or, more generally, almost-rational plumbings); see Dai and Manolescu [2017]. There is also a connected sum formula for involutive Heegaard Floer homology by Hendricks, Manolescu, and Zemke [2016], and a related connected sum formula for the involutive invariants of knots by Zemke [2017]. The latter had applications to the study of rational cuspidal curves; see Borodzik and Hom [2016].

The calculations of $\underline{d}$ and $\bar{d}$ for the above classes of manifolds (and their connected sums) give more constraints on which 3-manifolds are homology cobordant to each other; see Hendricks and Manolescu [2017], Hendricks, Manolescu, and Zemke [2016], Dai and Stoffregen [2017] for several examples. Furthermore, by imitating Stoffregen's arguments from Stoffregen [2015b], Dai and Manolescu [2017] used *HFI* to give a new proof that $\Theta^3_{\mathbb{Z}}$ has a $\mathbb{Z}^\infty$ subgroup.

The chain local equivalence group $\mathcal{CLE}$ admits an analogue in the involutive context, denoted $\mathfrak{I}$, whose definition is quite simple. Specifically, we define an *ι-complex* to be a pair (C, ι), consisting of

- a $\mathbb{Z}$-graded, finitely generated, free chain complex C over the ring $\mathbb{F}[U]$ ($\deg U = -2$), such that there is a graded isomorphism $U^{-1}H_*(C) \cong \mathbb{F}[U, U^{-1}]$;
- a grading-preserving chain homomorphism $\iota\colon\ C \to C$, such that $\iota^2 \sim \mathrm{id}$.

We say that two ι-complexes (C, ι) and (C', ι') are *locally equivalent* if there exist (grading-preserving) homomorphisms

$$F\colon\ C \to C', \quad G\colon\ C' \to C$$

such that

$$F \circ \iota \simeq \iota' \circ F, \quad G \circ \iota' \simeq \iota \circ G,$$

and F and G induce isomorphisms on $U^{-1}H_*$.

The elements of $\mathfrak{I}$ are the local equivalence classes of ι-complexes, and the multiplication in $\mathfrak{I}$ is given by

$$(C, \iota) * (C', \iota') := (C \otimes_{\mathbb{F}[U]} C',\ \iota \otimes \iota').$$

As shown in Hendricks, Manolescu, and Zemke [2016], there is a homomorphism

$$\Theta^3_{\mathbb{Z}} \to \mathfrak{I}, \quad [Y] \to [(CF^-(Y), \iota)],$$

and the maps $d, \underline{d}, \bar{d}$ factor through $\mathfrak{I}$.

Furthermore, Hendricks, Hom, and Lidman [2018] extract from $\mathfrak{I}$ a new invariant of homology cobordism, the connected Heegaard Floer homology, which is a summand of Heegaard Floer homology.

Open problem: *What is $\mathfrak{I}$ as an Abelian group? Can we use it to say more about $\Theta^3_{\mathbb{Z}}$?*

5 Variations

So far, we only studied homology cobordisms between integer homology spheres. However, one can define homology cobordisms between two arbitrary three-manifolds Y_0 and Y_1, by imposing the same conditions on the cobordism, $H_*(W, Y_i; \mathbb{Z}) = 0, i = 0, 1$. Note that, if Y_0 is homology cobordant to Y_1, then they necessarily have the same homology. The invariants $d, \underline{d}, \bar{d}, \alpha, \beta, \gamma$ admit extensions suitable for studying the existence of homology cobordisms between non-homology spheres; see for example Ozsváth and Szabó [2003, Section 4.2].

We could also weaken the definition of homology cobordism by using homology with coefficients in an Abelian group A different from $\mathbb{Z}$. One gets an *A-homology cobordism group* Θ^3_A, whose elements are A-homology spheres, modulo the relation of A-homology cobordism. Observe, for example, that there are natural maps

$$\Theta^3_{\mathbb{Z}} \to \Theta^3_{\mathbb{Z}/n} \to \Theta^3_{\mathbb{Q}}.$$

Fintushel and Stern [1984] showed that the homology sphere $\Sigma(2,3,7)$ bounds a rational ball, whereas it cannot bound an integer homology ball, because $\mu(\Sigma(2,3,7)) = 1$. This implies that the map $\Theta^3_{\mathbb{Z}} \to \Theta^3_{\mathbb{Q}}$ is not injective. It is also not surjective, and in fact its cokernel is infinitely generated; cf. Kim and Livingston [2014]. In a different direction, Lisca [2007] gave a complete description of the subgroup of $\Theta^3_{\mathbb{Q}}$ generated by lens spaces.

One can also construct other versions of homology cobordism by equipping the three-manifolds with spin^c structures, or self-conjugate spin^c structures. Ozsváth and Szabó did the former in Ozsváth and Szabó [2003], where they defined a spin^c homology cobordism group θ^c, and showed that their correction term gives rise to a homomorphism

$$d : \theta^c \to \mathbb{Q}.$$

The other invariants $\alpha, \beta, \gamma, \underline{d}, \bar{d}$ can be similarly extended to maps from a self-conjugate spin^c homology cobordism group (or, more simply, a spin homology cobordism group) to $\mathbb{Q}$. Moreover, on a $\mathbb{Z}/2$-homology sphere there is a unique self-conjugate spin^c-structure, which we can use to produce maps

$$d, \underline{d}, \bar{d}, \alpha, \beta, \gamma : \Theta^3_{\mathbb{Z}/2} \dashrightarrow \mathbb{Q}.$$

Finally, let us mention that homology cobordism is closely related to knot concordance. Indeed, a concordance between two knots $K_0, K_1 \subset S^3$ gives rise to a homology cobordism between the surgeries $S^3_m(K_0)$ and $S^3_m(K_1)$, for any integer m. It also gives a $\mathbb{Q}$-homology cobordism between the p^n-fold cyclic branched covers $\Sigma_{p^n}(K_0)$ and $\Sigma_{p^n}(K_1)$, for any prime p and $n \geq 1$. Thus, one can get knot concordance invariants from homology cobordism invariants, by applying them to surgeries or branched covers. See Ozsváth and Szabó [2003], Manolescu and Owens [2007], Jabuka [2012], and Hendricks and Manolescu [2017] for examples of this. For a survey of the knot concordance invariants coming from Heegaard Floer homology, we refer to Hom [2017].

Acknowledgments. I would like to thank Jennifer Hom, Charles Livingston, Robert Lipshitz, Andrew Ranicki, Sucharit Sarkar, Matt Stoffregen and Ian Zemke for comments on a previous version of this paper.

PROFINITE RIGIDITY

ALAN W. REID

Abstract

We survey recent work on profinite rigidity of residually finite groups.

1 Introduction

It is an old and natural idea to try to distinguish finitely presented groups via their finite quotients, and recently, there has been renewed interest, especially in the light of recent progress in 3-manifold topology, in the question of when the set of finite quotients of a finitely generated residually finite group determines the group up to isomorphism. In more sophisticated terminology, one wants to develop a complete understanding of the circumstances in which finitely generated residually finite groups have isomorphic *profinite completions*. Motivated by this, say that a residually finite group Γ is *profinitely rigid*, if whenever $\widehat{\Delta} \cong \widehat{\Gamma}$, then $\Delta \cong \Gamma$ (see Section 2.2 for definitions and background on profinite completions).

It is the purpose of this article to survey some recent work and progress on profinite rigidity, which is, in part, motivated by Remeslennikov's question (see Question 4.1) on the profinite rigidity of a free group. The perspective taken is that of a low-dimensional topologist, and takes advantage of the recent advances in our understanding of hyperbolic 3-manifolds and their fundamental groups through the pioneering work of Agol [2013] and Wise [2009].

Standing assumption: Throughout the paper all discrete groups considered will be finitely generated and residually finite.

Acknowledgments. Much of the work surveyed here is joint work of the author in several papers with multiple co-authors, and the author would like to sincerely thank his co-authors for their collaborations: M.D.E. Conder, D. B. McReynolds, R. Spitler and H. Wilton. He would like to single out M.R. Bridson for particular thanks in this regard. He would also like to thank M. Boileau, S. Friedl, D. D. Long, A. Lubotzky and P. Zalesskii for many helpful and stimulating conversations on topics related to this work.

The author was supported in part by an NSF grant.
MSC2010: primary 20E18; secondary 57M07.
Keywords: profinite completion, profinite rigidity, 3-manifold group.

2 Preliminaries

We begin by providing some background discussion on profinite groups and profinite completions of discrete groups. We refer the reader to Ribes and Zalesskii [2000] for a more detailed account of the topics covered here.

2.1 Profinite groups. A *directed set* is a partially ordered set I such that for every $i, j \in I$ there exists $k \in I$ such that $k \geq i$ and $k \geq j$. An *inverse system* is a family of sets $\{X_i\}_{\{i\in I\}}$, where I is a directed set, and a family of maps $\phi_{ij} : X_i \to X_j$ whenever $i \geq j$, such that:

- $\phi_{ii} = id_{X_i}$;
- $\phi_{ij}\phi_{jk} = \phi_{ik}$, whenever $i \geq j \geq k$.

Denoting this system by (X_i, ϕ_{ij}, I), the *inverse limit* of the inverse system (X_i, ϕ_{ij}, I) is the set

$$\varprojlim X_i = \{(x_i) \in \prod_{i\in I} X_i | \phi_{ij}(x_i) = x_j,\ \text{whenever } i \geq j\}.$$

If (X_i, ϕ_{ij}, I) is an inverse system of non-empty compact, Hausdorff, totally disconnected topological spaces (resp. topological groups) over the directed set I, then $\varprojlim X_i$ is a non-empty, compact, Hausdorff, totally disconnected topological space (resp. topological group).

In addition, if (X_i, ϕ_{ij}, I) is an inverse system, a subset $J \subset I$ is defined to be *cofinal*, if for each $i \in I$, there exists $j \in J$ with $j \geq i$. If J is cofinal we may form an inverse system (X_j, ϕ_j, J) obtained by omitting those $i \in I \setminus J$. The inverse limit $\varprojlim X_j$ can be identified with the image of $\varprojlim X_i$ under the projection map $\prod_{i\in I} X_i$ onto $\prod_{j\in J} X_j$.

2.2 Profinite completion. Let Γ be a finitely generated group (not necessarily residually finite for this discussion), and let $\mathfrak{N}$ denote the collection of all finite index normal subgroups of Γ. Note that $\mathfrak{N}$ is non-empty as $\Gamma \in \mathfrak{N}$, and we can make $\mathfrak{N}$ into directed set by declaring that

$$\text{for } M, N \in \mathfrak{N},\ M \leq N \text{ whenever } M\ contains\ N.$$

In this case, there are natural epimorphisms $\phi_{NM} : \Gamma/N \to \Gamma/M$, and the inverse limit of the inverse system $(\Gamma/N, \phi_{NM}, \mathfrak{N})$ is denoted $\widehat{\Gamma}$ and defined to be to the *profinite completion* of Γ.

Note that there is a natural map $\iota : \Gamma \to \widehat{\Gamma}$ defined by

$$g \mapsto (gN) \in \varprojlim \Gamma/N,$$

and it is easy to see that ι is injective if and only if Γ is residually finite.

An alternative, perhaps more concrete way of viewing the profinite completion is as follows. If, for each $N \in \mathfrak{N}$, we equip each Γ/N with the discrete topology, then

$\prod\{\Gamma/N : N \in \mathfrak{N}\}$ is a compact space and $\widehat{\Gamma}$ can be identified with $\overline{j(\Gamma)}$ where $j : \Gamma \to \prod\{\Gamma/N : N \in \mathfrak{N}\}$ is the map $g \mapsto (gN)$.

2.3 Profinite Topology. It will also be convenient to recall the profinite topology on a discrete group Γ, its subgroups and the correspondence between the subgroup structure of Γ and $\widehat{\Gamma}$.

The profinite topology on Γ is the topology on Γ in which a base for the open sets is the set of all cosets of normal subgroups of finite index in Γ.

Now given a tower $\mathfrak{T}$ of finite index normal subgroups of Γ:

$$\Gamma > N_1 > N_2 > \dots\dots > N_k > \dots$$

with $\cap N_k = 1$, this can be used to define an inverse system and thereby determines a completion of $\widehat{\Gamma}_{\mathfrak{T}}$ (in which Γ will inject). If the inverse system determined by $\mathfrak{T}$ is cofinal (recall Section 2.1) then the natural homomorphism $\widehat{\Gamma} \to \widehat{\Gamma}_{\mathfrak{T}}$ is an isomorphism. That is to say $\mathfrak{T}$ determines the full profinite topology of Γ.

The following is important in connecting the discrete and profinite worlds (see Ribes and Zalesskii [ibid., p. 3.2.2], where here we use Nikolov and Segal [2007] to replace "open" by "finite index").

Notation. Given a subset X of a profinite group G, we write $\overline{X}$ to denote the closure of X in G.

Proposition 2.1. *If Γ is a finitely generated residually finite group, then there is a one-to-one correspondence between the set $\mathfrak{X}$ of subgroups of Γ that are open in the profinite topology on Γ, and the set $\mathfrak{Y}$ of all finite index subgroups of $\widehat{\Gamma}$.*

Identifying Γ with its image in the completion, this correspondence is given by:

- *For $H \in \mathfrak{X}$, $H \mapsto \overline{H}$.*
- *For $Y \in \mathfrak{Y}$, $Y \mapsto Y \cap \Gamma$.*

If $H, K \in \mathfrak{X}$ and $K < H$ then $[H : K] = [\overline{H} : \overline{K}]$. Moreover, $K \triangleleft H$ if and only if $\overline{K} \triangleleft \overline{H}$, and $\overline{H}/\overline{K} \cong H/K$.

Thus Γ and $\widehat{\Gamma}$ have the same finite quotients. The key result to formalize the precise connection between the collection of finite quotients of Γ and those of $\widehat{\Gamma}$ is the following. This is basically proved in Dixon, Formanek, Poland, and Ribes [1982] (see also Ribes and Zalesskii [2000, pp. 88-89]), the mild difference here, is that we employ Nikolov and Segal [2007] to replace *topological isomorphism* with *isomorphism*. To state this we introduce the following notation:

$$\mathcal{C}(\Gamma) = \{Q : Q \text{ is a finite quotient of } \Gamma\}$$

Theorem 2.2. *Suppose that Γ_1 and Γ_2 are finitely generated abstract groups. Then $\widehat{\Gamma}_1$ and $\widehat{\Gamma}_2$ are isomorphic if and only if $\mathcal{C}(\Gamma_1) = \mathcal{C}(\Gamma_2)$.*

Given this, we make the following definition—this definition is taken, by analogy with the theory of quadratic forms over $\mathbb{Z}$, where two integral quadratic forms can be locally equivalent (i.e. at all places of $\mathbb{Q}$), but not globally equivalent over $\mathbb{Z}$.

Definition 2.3. The genus of a finitely generated residually finite group Γ is: $\mathcal{G}(\Gamma) = \{\Delta : \widehat{\Delta} \cong \widehat{\Gamma}\}$.

In addition, if $\mathcal{P}$ is a class of groups, then we define $\mathcal{G}_{\mathcal{P}}(\Gamma) = \{\Delta \in \mathcal{G}(\Gamma) : \Delta \in \mathcal{P}\}$. For convenience we restate the definition of profinite rigidity.

Definition 2.4. Let Γ be a finitely generated group. Say that Γ is profinitely rigid if $\mathcal{G}(\Gamma) = \{\Gamma\}$.

For convenience we often say that Γ is *profinitely flexible* if it is not profinitely rigid.

In addition when $\Gamma = \pi_1(M)$ where M is a compact 3-manifold we occasionally abuse notation and refer to M as being profinitely rigid or flexible.

The basic questions we are interested in are the following (and also within classes of groups $\mathcal{P}$).

Question 2.5. *Which finitely generated (resp. finitely presented) groups Γ are profinitely rigid (resp. profinitely flexible)?*

Question 2.6. *How large can $|\mathcal{G}(\Gamma)|$ be for finitely generated (resp. finitely presented) groups?*

Question 2.7. *What group theoretic properties are shared by (resp. are different for) groups in the same genus?*

These questions (and ones where the class of groups is restricted) provide the motivation and focus of this article, with particular attention paid to Question 2.5.

2.4 Inducing the full profinite topology. Let Γ be a finitely generated residually finite group and $H < \Gamma$. The profinite topology on Γ determines some pro-topology on H and therefore some completion of H. To understand what happens in certain cases that will be of interest to us, we recall the following. Since we are assuming that Γ is residually finite, H injects into $\widehat{\Gamma}$ and determines a subgroup $\overline{H} \subset \widehat{\Gamma}$. Hence there is a natural epimorphism $\widehat{H} \to \overline{H}$. This need not be injective. For this to be injective (i.e. the full profinite topology is induced on H) it is easy to see that the following needs to hold:

(*) For every subgroup H_1 of finite index in H, there exists a finite index subgroup $\Gamma_1 < \Gamma$ such that $\Gamma_1 \cap H < H_1$.

A important case where the full profinite topology is induced is when the ambient group Γ is *LERF*, the definition of which we recall here. Suppose that Γ is a group and H a subgroup of Γ, then Γ is called H-separable if for every $g \in G \setminus H$, there is a subgroup K of finite index in Γ such that $H \subset K$ but $g \notin K$; equivalently, the intersection of all finite index subgroups in Γ containing H is precisely H. The group Γ is called LERF (or *subgroup separable*) if it is H-separable for every finitely-generated subgroup H, or equivalently, if every finitely-generated subgroup is a closed subset in the profinite topology.

Lemma 2.8. *Let Γ be a finitely-generated group, and H a finitely-generated subgroup of Γ. Suppose that Γ is H_1-separable for every finite index subgroup H_1 in H. Then the profinite topology on Γ induces the full profinite topology on H; that is, the natural map $\widehat{H} \to \overline{H}$ is an isomorphism.*

Proof. Since Γ is H_1 separable, the intersection of all subgroups of finite index in Γ containing H_1 is H_1 itself. From this it easily follows that there exists $\Gamma_1 < \Gamma$ of finite index, so that $\Gamma_1 \cap H = H_1$. The lemma follows from (*) above. □

Immediately from this we deduce.

Corollary 2.9. *Let Γ be a finitely generated group that is LERF. Then if $H < \Gamma$ is finitely generated then the profinite topology on Γ induces the full profinite topology on H; that is, the natural map $\widehat{H} \to \overline{H}$ is an isomorphism.*

3 Two simple examples

We provide two elementary examples that already indicate a level of complexity in trying to understand profinite rigidity and lack thereof. In addition, some consequences of these results and techniques will be helpful in what follows.

Proposition 3.1. *Let Γ be a finitely generated Abelian group, then $\mathcal{G}(\Gamma) = \{\Gamma\}$.*

Proof. Suppose first that $\Delta \in \mathcal{G}(\Gamma)$ and Δ is non-abelian. We may therefore find a commutator $c = [a, b] \in \Delta$ that is non-trivial. Since Δ is residually finite there is a homomorphism $\phi : \Delta \to Q$, with Q finite and $\phi(c) \neq 1$. However, $\Delta \in \mathcal{G}(\Gamma)$, so Q is abelian and therefore $\phi(c) = 1$, a contradiction.

Thus Δ is Abelian, so we can assume that $\Gamma \cong \mathbb{Z}^r \oplus T_1$ and $\Delta \cong \mathbb{Z}^s \oplus T_2$, where T_i $(i = 1, 2)$ are finite Abelian groups. It is easy to see that $r = s$, for if $r > s$ say, we can choose a large prime p such that p does not divide $|T_1||T_2|$, and construct a finite quotient $(\mathbb{Z}/p\mathbb{Z})^r$ that cannot be a quotient of Δ.

In addition if T_1 is not isomorphic to T_2, then some invariant factor appears in T_1 say, but not in T_2. One can then construct a finite abelian group that is a quotient of T_1 (and hence Γ_1) but not of Γ_2. □

Remark 3.2. The proof of Proposition 3.1 also proves the following. Let Γ be a finitely generated group, and suppose that $\Delta \in \mathcal{G}(\Gamma)$. Then $\Gamma^{\mathrm{ab}} \cong \Delta^{\mathrm{ab}}$. In particular $b_1(\Gamma) = b_1(\Delta)$.

Somewhat surprisingly, moving only slightly beyond abelian groups (indeed $\mathbb{Z}$) to groups that are virtually $\mathbb{Z}$, the situation is dramatically different. The following result is due to Baumslag [1974].

Theorem 3.3. *There exists non-isomorphic meta-cyclic groups Γ_1 and Γ_2 for which $\widehat{\Gamma}_1 \cong \widehat{\Gamma}_2$. Both of these groups are virtually $\mathbb{Z}$ and defined as extensions of a fixed finite cyclic group F by $\mathbb{Z}$.*

A more precise form of what Baumslag actually proves in Baumslag [1974] is the following:

Let F be a finite cyclic group with an automorphism of order n, where n is different from 1, 2, 3, 4 and 6. Then there are at least two non-isomorphic cyclic extensions of F, say Γ_1 and Γ_2 with $\widehat{\Gamma}_1 \cong \widehat{\Gamma}_2$.

A beautiful, and useful observation, that is used in the proof that the constructed groups Γ_1 and Γ_2 lie in the same genus is the following that goes back to Hirshon Hirshon [1977]: Suppose that A and B are groups with $A \times \mathbb{Z} \cong B \times \mathbb{Z}$, then $\widehat{A} \cong \widehat{B}$.

Remark 3.4. Moving from meta-cyclic to meta-abelian provides even more striking examples of profinite flexibility. Pickel [1974] constructs finitely presented meta-abelian groups Γ for which $\mathcal{G}(\Gamma)$ is infinite.

4 Profinite rigidity and flexibility in low-dimensions

In connection with Question 2.5 perhaps the most basic case is the following that goes back to Noskov, Remeslennikov, and Romankov [1979, Question 15] and remains open:

Question 4.1. Let F_n be the free group of rank $n \geq 2$. Is F_n profinitely rigid?

The group F_n arises in many guises in low-dimensional topology and affords several natural ways to generalize. In the light of this, natural generalizations of Question 4.1 are the following (which remain open):

Question 4.2. Let Σ_g be a closed orientable surface of genus $g \geq 2$. Is $\pi_1(\Sigma_g)$ profinitely rigid?

As we will discuss in more detail below, profinite rigidity in the setting of 3-manifold groups is different, however, one generalization that we will focus on below is the following question:

Question 4.3. Let M be a complete orientable hyperbolic 3-manifold of finite volume. Is $\pi_1(M)$ profinitely rigid?

In this section we describe some recent progress on Questions 4.1, 4.2 and 4.3, as well as other directions that generalize Question 4.1. However, we begin by recalling some necessary background from the geometry and topology of 3-manifolds.

4.1 Some 3-manifold topology.

For the purposes of this subsection, M will always be a compact connected orientable 3-manifold whose boundary is either empty, or consists of a disjoint union of incompressible tori. The Geometrization Conjecture of

Thurston was established by Perelman (see Morgan and Tian [2014] for a detailed account) and we state what is needed here in a convenient form. We refer the reader to Bonahon [2002] or Thurston [1997] for background on geometric structures on 3-manifolds.

Recall that M is *irreducible* if every embedded 2-sphere in M bounds a 3-ball, and if M is *prime* (i.e. does not decompose as a non-trivial connect sum), then M is irreducible or is covered by $S^2 \times S^1$, in which case M admits a geometric structure modeled on $S^2 \times \mathbb{R}$.

Theorem 4.4. *Let M be an irreducible 3-manifold.*

1. *If $\pi_1(M)$ is finite, then M is covered by S^3.*
2. *If $\pi_1(M)$ is infinite, then M is either:*

   (i) hyperbolic and so arises as $\mathbb{H}^3/\Gamma$ where $\Gamma < \mathrm{PSL}(2,\mathbb{C})$ is a discrete torsion-free subgroup of finite co-volume, or;

   (ii) a Seifert fibered space and has a geometry modeled on $\mathbb{E}^3$, $\mathbb{H}^2 \times \mathbb{R}$, NIL or $\widetilde{SL}_2$, or;

   (iii) a $SOLV$ manifold, or;

   (iv) a manifold that admits a collection of essential tori that decomposes M into pieces that are Seifert fibered spaces with incompressible torus boundary, or have interior admitting a finite volume hyperbolic structure. In this case, we will say that M has a non-trivial JSJ decomposition.

An important well-known consequence of geometrization for us is the following corollary.

Corollary 4.5. *Let M be compact 3-manifold, then $\pi_1(M)$ is residually finite.*

A manifold M that admits a geometric structure modeled on $\mathbb{E}^3$, $S^2 \times \mathbb{R}$, $\mathbb{H}^2 \times \mathbb{R}$, NIL or $SOLV$ all *virtually fiber*. That is to say, given M admitting such a structure then there is a finite cover $M_f \to M$ with M_f constructed as the mapping torus of a surface homeomorphism $f : \Sigma_g \to \Sigma_g$, where $g = 0$ in the case of $S^2 \times \mathbb{R}$, $g = 1$ in the case of $\mathbb{E}^3$, NIL or $SOLV$ and $g > 1$ when the geometry is $\mathbb{H}^2 \times \mathbb{R}$. If M is a compact Seifert fibered space with incompressible torus boundary, then M also virtually fibers. On the other hand, it is known (see Gabai [1986]) that closed manifolds admitting a geometric structure modeled on $\widetilde{SL}_2$ do not virtually fiber.

Regarding virtual fibering of hyperbolic manifolds, a major breakthrough came with Agol's work in Agol [2008], which, taken together with work of Agol [2013] and Wise [2009] (see also Groves and Manning [2017]) leads to the following.

Theorem 4.6 (Virtual fibering)**.** *Let M be a finite volume hyperbolic 3-manifold. Then M has a finite cover that fibers over the circle.*

For manifolds with a non-trivial JSJ decomposition, it was known previously that there were *graph manifolds* (i.e. all pieces in the decomposition are Seifert fibered spaces) that do not virtually fiber Neumann [1997], whilst more recently it was shown in Przytycki and Wise [2018] that *mixed 3-manifolds* (i.e. those in Theorem 4.4 2(iv) that have a decomposition containing a hyperbolic piece) are all virtually fibered.

4.2 Profinite completions of 3-manifold groups after Agol and Wise. The remarkable work of Agol [2013] and Wise [2009] has had significant implications on our understanding of the profinite completion of the fundamental groups of finite volume hyperbolic 3-manifolds. We refer the reader to the excellent book Aschenbrenner, Friedl, and Wilton [2015] for a detailed discussion of the many consequences of Agol [2013] and Wise [2009] for 3-manifold groups. One such concerns LERF (recall Section 2.4). The following result summarizes work of Scott [1978] for Seifert fibered spaces, Agol [2013] and Wise [2009] in the hyperbolic setting, and Sun [2016] who showed that non-geometric irreducible 3-manifolds had non-LERF fundamental group

Theorem 4.7. *Let M be an irreducible 3-manifold (as in Section 4.1). Then $\pi_1(M)$ is LERF if and only if M is geometric (i.e covered by Theorem 4.4 1, 2(i), (ii), (iii)).*

Lemma 2.8 together with Theorem 4.7 yields the following consequence.

Corollary 4.8. *Let M be a finite volume hyperbolic 3-manifold and $H < \pi_1(M)$ a finitely generated subgroup. Then the full profinite topology on H is induced by the profinite topology of $\pi_1(M)$. In particular the closure of H in $\widehat{\pi_1(M)}$ is isomorphic to $\widehat{H}$.*

We now turn to *goodness* in the sense of Serre [1997]. Let G be a profinite group, M a discrete G-module (i.e. an abelian group M equipped with the discrete topology on which G acts continuously) and let $C^n(G, M)$ be the set of all continous maps $G^n \to M$. One defines the coboundary operator $d : C^n(G, M) \to C^{n+1}(G, M)$ in the usual way thereby defining a complex $C^*(G, M)$ whose cohomology groups $H^q(G; M)$ are called the continuous cohomology groups of G with coefficients in M.

Now let Γ be a finitely generated group. Following Serre [ibid.], we say that a group Γ is *good* if for all $q \geq 0$ and for every finite Γ-module M, the homomorphism of cohomology groups

$$H^q(\widehat{\Gamma}; M) \to H^q(\Gamma; M)$$

induced by the natural map $\Gamma \to \widehat{\Gamma}$ is an isomorphism between the cohomology of Γ and the continuous cohomology of $\widehat{\Gamma}$.

Example 4.9. Finitely generated free groups are good.

In general goodness is hard to establish, however, one can establish goodness for a group Γ that is LERF (indeed a weaker version of separability is all that is needed) and in addition has a ”well-controlled splitting of the group” as a graph of groups Grunewald, Jaikin-Zapirain, and Zalesskii [2008]; for example that coming from the virtual special technology Wise [2009]. In addition, a useful criterion for goodness is provided by the next lemma due to Serre [1997, Chapter 1, Section 2.6].

Lemma 4.10. *The group* Γ *is good if there is a short exact sequence*

$$1 \to N \to \Gamma \to H \to 1,$$

such that H *and* N *are good,* N *is finitely-generated, and the cohomology group* $H^q(N, M)$ *is finite for every* q *and every finite* Γ*-module* M.

Coupled with Theorem 4.6 (the virtual fibering theorem) and commensurability invariance of goodness Grunewald, Jaikin-Zapirain, and Zalesskii [2008], this proves that the fundamental groups of all finite volume hyperbolic 3-manifolds are good. Indeed, more is true using Agol [2013] and Wise [2009] (as noticed by Cavendish [2012], see also Reid [2015]):

Theorem 4.11. *Let* M *be a compact* 3*-manifold, then* $\pi_1(M)$ *is good.*

Several notable consequences of this are recorded below.

Corollary 4.12. *Let* M *be a closed irreducible orientable* 3*-manifold, and* N *a compact* 3*-manifold with* $\widehat{\pi_1(M)} \cong \widehat{\pi_1(N)}$*. Then:*

1. $\widehat{\pi_1(M)}$ *is torsion-free.*
2. N *is closed, orientable and can have no summand that has finite fundamental group.*

Proof. Let $\Gamma = \pi_1(M)$ and $\Delta = \pi_1(N)$. Since $\mathrm{cd}(\Gamma) = 3$, $H^3(\Gamma, \mathbb{F}_p) \neq 0$ for every prime p, and $H^q(\Gamma, M) = 0$ for every Γ-module M and every $q > 3$. By goodness, these transfer to the profinite setting in the context of finite modules. It follows from standard results about the cohomology of finite groups, that goodness forces $\widehat{\pi_1(M)}$ to be torsion-free. Hence Δ is also torsion-free, and so N cannot have a summand that has finite fundamental group.

In addition, N must be closed, since $H^3(\Gamma, \mathbb{F}_2) \neq 0$ implies $H^3(\widehat{\Gamma}, \mathbb{F}_2) \neq 0$, and if N is not closed we have, $H^3(\Delta, \mathbb{F}_2) = H^3(\widehat{\Delta}, F_2) = 0$. Orientability follows in a similar fashion using $H^3(\Gamma, \mathbb{F}_p) \neq 0$ for $p \neq 2$. □

Remark 4.13. In Lubotzky [1993], it is shown that there are torsion-free subgroups $\Gamma < \mathrm{SL(n}, \mathbb{Z})$ ($n \geq 3$) of finite index, for which $\widehat{\Gamma}$ contains torsion of all possible orders. It follows that $\mathrm{SL(n}, \mathbb{Z})$ is not good for $n \geq 3$).

4.3 Profinite flexibility of 3-manifold groups. We now describe some recent progress on identifying 3-manifold groups by their profinite completions restricted to the class of 3-manifold groups. To that end let

$$\mathfrak{M} = \{\pi_1(M) : M \text{ is a compact 3-manifold}\}.$$

We note that unlike in the previous subsection M need not be prime, can be non-orientable, may have boundary other than tori and this boundary may be compressible. By capping off 2-sphere boundary components with 3-balls, we can exclude S^2 boundary components (and $\mathbb{RP}^2$ boundary components). Also note that included in $\mathfrak{M}$ are the fundamental groups of non-compact finite volume hyperbolic 3-manifolds where such a manifold is viewed as the interior of a compact 3-manifold with boundary consisting of tori or Klein bottles.

Example 4.14 (Profinitely flexible Seifert fibered spaces)**.** We record a construction of Hempel [2014] that provides examples of closed Seifert fibered spaces M_1 and M_2 that are not homeomorphic but $\widehat{\pi_1(M_1)} \cong \widehat{\pi_1(M_2)}$. This builds on the idea of Baumslag mentioned in Section 3.

Let $f : S \to S$ be a periodic, orientation-preserving homeomorphism of a closed orientable surface S of genus at least 2, and let k be relatively prime to the order of f. Let M_f (resp. M_{f^k}) denote the mapping torus of f (resp. f^k), and let $\Gamma_f = \pi_1(M_f)$ (resp. $\Gamma_{f^k} = \pi_1(M_{f^k})$).

Hempel shows that $\widehat{\Gamma}_f \cong \widehat{\Gamma}_{f^k}$ by proving that $\Gamma_f \times \mathbb{Z} \cong \Gamma_{f^k} \times \mathbb{Z}$ (c.f. the example of Baumslag in Section 3). The proof is elementary group theory, but Hempel also notes that, interestingly, the isomorphism $\Gamma_f \times \mathbb{Z} \cong \Gamma_{f^k} \times \mathbb{Z}$ follows from Kwasik and Rosicki [2004] where it is shown that (in the notation above) $M_f \times S^1 \cong M_{f^k} \times S^1$.

Of course some additional work is needed to prove that the groups are not isomorphic, but in fact typically this is the case as Hempel describes in Hempel [2014]. Note that these examples admit a geometric structure modeled on $\mathbb{H}^2 \times \mathbb{R}$.

More recently it was shown by Wilkes [2017] that the construction of Hempel is the only occasion in which profinite rigidity fails in the closed case (there are also results in the bounded case). More precisely:

Theorem 4.15 (Wilkes)**.** *Let M be a closed Seifert fibered space with infinite fundamental group. Then $\mathcal{G}_{\mathfrak{M}}(\pi_1(M)) = \{\pi_1(M)\}$ unless M is as in Example 4.14 and the failure is precisely given by the construction in Example 4.14. In this case, $\mathcal{G}_{\mathfrak{M}}(\pi_1(M))$ is finite.*

The proof of this relies on some beautiful work of Wilton and Zalesskii [2017a] that remarkably detects geometric structure from finite quotients. We discuss this in more detail below in Section 4.4. but first give some other examples of profinite flexibility in the setting of closed 3-manifolds.

Example 4.16 (Profinitely flexible torus bundles)**.** Profinite flexibility for the fundamental groups of torus bundles admitting a $SOLV$ geometry was studied in detail in Funar [2013]. These torus bundles arise as the mapping torus of a self-homeomorphism $f : T^2 \to T^2$ which can be identified with an element of $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \mathrm{SL}(2,\mathbb{Z})$ with $|a+d| > 2$. In Funar [ibid.] it is shown that for any $m \geq 2$ there exist m torus bundles admitting $SOLV$ geometry whose fundamental groups have isomorphic profinite completions but are pairwise non-isomorphic.

A particular pair of examples of such torus bundles are give by the mapping tori of the following homeomorphisms:

$$f_1 = \begin{pmatrix} 188 & 275 \\ 121 & 177 \end{pmatrix} \text{ and } f_1 = \begin{pmatrix} 188 & 11 \\ 3025 & 177 \end{pmatrix}.$$

The methods of proof are very different from that used in Example 4.14. In particular it does not use the ideas in Baumslag's examples in Section 3, using instead, number theoretic techniques arising in understanding "local conjugacy" of matrices in $\mathrm{SL}(2,\mathbb{Z})$. Briefly, the fundamental groups of torus bundles M_f and M_g have isomorphic profinite completions if and only if the cyclic subgroups $< f >, < g > \subset \mathrm{SL}(2,\mathbb{Z})$ are locally conjugate, namely their images modulo m are conjugate in $\mathrm{GL}(2,\mathbb{Z}/\mathrm{m}\mathbb{Z})$, for any positive integer m (see Funar [ibid.]).

Interestingly, as described in Funar [ibid.] the issue of profinite flexibility in this case is related to problems arising from understanding quantum TQFT invariants of the torus bundles.

Example 4.17 (Profinitely flexible 3-manifolds with non-trivial JSJ decomposition)**.** The fundamental groups of the manifolds occurring in Theorem 4.4 2(iv) were investigated in Wilkes [2016]. We will not go into this in any detail here, other than to say that it is shown in Wilkes [ibid.] that there are non-homeomorphic closed graph manifolds whose fundamental groups have isomorphic profinite completions, and that graph manifolds can be distinguished from mixed 3-manifolds by the profinite completion of their fundamental groups. In addition it is shown that if M is a graph manifold that is profinitely flexible, then $|\mathcal{G}_{\mathfrak{M}}(\pi_1(M))| < \infty$.

4.4 Profinite completions of 3-manifold groups and geometric structures. We now turn to the work of Wilton and Zalesskii [2017a,b] that describes a beautiful connection between the existence of a particular geometric structure on a 3-manifold and the profinite completion of its fundamental group. We begin with a mild strengthening of Wilton and Zalesskii [2017a, Theorem 8.4]

Theorem 4.18 (Wilton-Zalesskii)**.** *Let M be a closed orientable 3-manifold with infinite fundamental group admitting one of Thurston's eight geometries and let $N \in \mathfrak{M}$ with $\pi_1(N) \in \mathcal{G}_{\mathfrak{M}}(\pi_1(M))$. Then N is closed and admits the same geometric structure.*

Proof. This is proved in Wilton and Zalesskii [ibid., Theorem 8.4] with N assumed to be closed, orientable and irreducible. However, the version stated in Theorem 4.18 quickly reduces to this. Briefly, by Theorem 4.11 $\pi_1(M)$ is good, so immediately we have N is closed and orientable by Corollary 4.12.

Furthermore, $\widehat{\pi_1(M)}$ is torsion-free by Corollary 4.12 and so if N is not prime, the summands must all have torsion-free fundamental group. However, in this case we can use the fact that the first L^2-betti number $b_1^{(2)}$ is a profinite invariant by Bridson, Conder, and Reid [2016], and this, together with the work of Lott and Lück [1995] shows that aspherical geometric 3-manifolds have $b_1^{(2)} = 0$, whilst manifolds that are not prime and have torsion-free fundamental group have $b_1^{(2)} \neq 0$. Note that their theorem is stated only for orientable manifolds but this is not a serious problem because, by Lück approximation Lück [1994], if X is a non-orientable compact 3-manifold with infinite fundamental group and $Y \to X$ is its orientable double cover, then $b_1^{(2)}(Y) = 2\, b_1^{(2)}(X)$. We can now use Wilton and Zalesskii [2017a] to complete the proof. □

Given Theorem 4.18, Theorem 4.15, is reduced to the consideration of Seifert fiber spaces. However, the proof still entails some significant work using Bridson, Conder, and Reid [2016] as well as the delicate issue of recovering the euler number of the Seifert fibration from the profinite completion.

In the context of hyperbolic manifolds, a corollary of Theorem 4.18 that is worth recording is.

Corollary 4.19. *Let M be a closed orientable hyperbolic 3-manifold and $N \in \mathfrak{M}$ with $\pi_1(N) \in \mathcal{G}_{\mathfrak{M}}(\pi_1(M))$, then N is closed orientable and hyperbolic.*

More recently Wilton and Zalesskii [2017b] have established a cusped version of this result, namely.

Theorem 4.20. *Let M be a finite volume non-compact orientable hyperbolic 3-manifold and $N \in \mathfrak{M}$ with $\pi_1(N) \in \mathcal{G}_{\mathfrak{M}}(\pi_1(M))$, then N is a finite volume non-compact orientable hyperbolic 3-manifold.*

The proofs of Theorems 4.18 and 4.20 also use the work of Agol and Wise, as well as crucially using "nice" actions of profinite groups on profinite trees which are transferred from the discrete setting using LERF and other parts of the virtual special technology of Wise [2009] (see Wilton and Zalesskii [2017a] and Wilton and Zalesskii [2017b] for details).

Actually what is really at the heart of Corollary 4.19 is a profinite analogue of the Hyperbolization Theorem, which asserts that M is hyperbolic if and only if $\pi_1(M)$ does not contain a copy of $\mathbb{Z} \oplus \mathbb{Z}$. The main part of the proof of Corollary 4.19 is to show that if M is a closed hyperbolic 3-manifold, then $\widehat{\pi_1(M)}$ does not contain a subgroup isomorphic to $\widehat{\mathbb{Z}} \oplus \widehat{\mathbb{Z}}$.

Remark 4.21. One might wonder about the extent to which the full profinite completion of the fundamental group of a hyperbolic 3-manifold is actually needed to distinguish the fundamental group. With that in mind, it is easy to give infinitely many examples of links $L \subset S^3$ (so-called homology boundary links) with hyperbolic complement for which $\pi_1(S^3 \setminus L)$ all have the same pro-p completion (namely the free pro-p group of rank 2) for all primes p, see Bridson and Reid [2015a, Section 8.4] for an explicit example.

4.5 Profinite rigidity amongst 3-manifold groups. We now turn to the issue of profinite rigidity. Given the discussion in Section 4.3 about the failure of profinite rigidity (even amongst 3-manifold groups) for Seifert fibered spaces, torus bundles admitting $SOLV$ geometry, and manifolds admitting a non-trivial JSJ decomposition, the case that needs to be understood is that of finite volume hyperbolic 3-manifolds. We focus on this case in the remainder of this section. We first deal with the case of $\mathcal{G}_{\mathfrak{M}}(\pi_1(M))$, where M is a finite volume hyperbolic 3-manifold. In the light of Theorem 4.6, a natural class of hyperbolic 3-manifolds to attempt to establish rigidity for are hyperbolic 3-manifolds that fiber over the circle, since, as we now explain, this can be used to help organize an approach to profinite rigidity of the fundamental groups of hyperbolic 3-manifolds.

Proposition 4.22. *Suppose that for any orientable finite volume hyperbolic 3-manifold M that fibers over the circle we have $\mathcal{G}_{\mathfrak{M}}(\pi_1(M)) = \{\pi_1(M)\}$. Then if N is a finite* *volume hyperbolic 3-manifold and Y a compact 3-manifold with $\pi_1(Y) \in \mathcal{G}_{\mathfrak{M}}(\pi_1(N))$, then Y is commensurable to N.*

Proof. Note that from Corollary 4.19 and Theorem 4.20, Y is a finite volume hyperbolic 3-manifold. By Theorem 4.6, we can pass to finite covers N_f and Y_f of N and Y respectively, that are both fibered, and with $\widehat{\pi_1(N_f)} \cong \widehat{\pi_1(Y_f)}$. By the "rigidity hypothesis" of Proposition 4.22, it follows that $\pi_1(N_f) \cong \pi_1(Y_f)$, and so N and Y share a common finite sheeted cover $N_f \cong Y_f$. □

Thus, it is natural to focus on the case of surface bundles. The following rigidity result is proved in Bridson, Reid, and Wilton [2017] (see also Bridson and Reid [2015b] and Boileau and Friedl [2015] for the the case of the figure-eight knot complement). This is the first family of hyperbolic 3-manifolds that fiber over the circle for which the rigidity required in Proposition 4.22 has been carried to completion. An approach to handle other fibered hyperbolic 3-manifolds is described in Bridson, Reid, and Wilton [2017].

Theorem 4.23. *Let M be a once-punctured torus bundle over the circle (hyperbolic or otherwise). Then $\mathcal{G}_{\mathfrak{M}}(\pi_1(M)) = \{\pi_1(M)\}$.*

Some ideas in the proof: We only discuss the hyperbolic case, and refer the reader to Bridson, Reid, and Wilton [ibid.] for the remaining (simpler) cases. In this case $b_1(M) = 1$. From Theorem 4.20 we can assume that if N is a compact 3-manifold with $\pi_1(N) \in \mathcal{G}_{\mathfrak{M}}(\pi_1(M))$, then N is a cusped hyperbolic 3-manifold with $b_1(N) = 1$ (recall Remark 3.2). The proof can be broken down into two main steps as follows:

Step 1: Prove that N is fibered with fiber a once-punctured torus.

Step 2: Since M is a once-punctured torus bundle, given Step 1, a simple analysis gives finitely many possibilities for N. Distinguish these finitely many.

We will make no further comment on Step 2 and refer the reader to Bridson, Reid, and Wilton [ibid.]. The proof of Step 1 follows Bridson and Reid [2015b] and we briefly comment on this (a different proof of this is given in Boileau and Friedl [2015]). The main difficulty is in establishing that N is fibered. Once this is done, the fact that the fiber is a once-punctured torus follows routinely.

Note that in Bridson and Reid [2015b] the cases that N is hyperbolic or not hyperbolic were treated separately (since Theorem 4.20 was unavailable at the time of writing). As noted above, using Theorem 4.20 we can now reduce to the case that N is hyperbolic. Regardless of this development, we still need to follow the argument of Bridson and Reid [ibid.] to complete the proof. The key point is that if N is not fibered, then using B. Freedman and M. H. Freedman [1998] we can build a surface subgroup $H < K = \ker\{\pi_1(N) \to \mathbb{Z}\}$ (this homomorphism is unique since $b_1(N) = 1$). By Corollaries 4.8 and 2.9 we deduce that $\widehat{H} \cong \overline{H} < \overline{K} < \widehat{\pi_1(N)}$. Now by uniqueness of the homomorphism $\pi_1(M) \to \mathbb{Z}$, which has kernel a free group F of rank 2, we get $\widehat{H} < \overline{K} \cong \widehat{F}$. However, using cohomological dimension in the context of profinite groups (see Serre [1997]) we get a contradiction: the cohomological dimension of $\widehat{H}$ is 2 and it is 1 for $\widehat{F}$. □

Since Bridson, Reid, and Wilton [2017] was written, the fact that fibering is a profinite invariant has been established by Jaikin-Zapirain [n.d.] without the restriction on $b_1(M)$. The proof of this uses very different methods to those outlined above.

Theorem 4.24 (Jaikin-Zapirain)**.** *Let M be a compact irreducible 3-manifold and let $\Gamma = \pi_1(M)$.*

1. *If $\widehat{\Gamma}$ is isomorphic to the profinite completion of free-by-cyclic group, then M has non-empty boundary consisting of a disjoint union of incompressible tori and Klein bottles, and fibers over the circle with fiber a compact surface with non-empty boundary.*
2. *If $\widehat{\Gamma}$ is isomorphic to the profinite completion of the fundamental group of a closed 3-manifold that fibers over the circle, then M is a surface bundle over the circle with fiber a closed surface.*

One can distill from the cohomological dimension argument used at the end of the proof of Theorem 4.23 the following useful proposition.

Proposition 4.25. *Let Γ be a finitely generated residually finite group that contains a subgroup $H \cong \pi_1(\Sigma_g)$ for some $g \geq 1$ and for which $\overline{H} \cong \widehat{H}$ in $\widehat{\Gamma}$. Then $\Gamma \notin \mathcal{G}(F_n)$ for any $n \geq 2$.*

Remark 4.26. It is worth remarking that $\widehat{F}_n$ contains a subgroup isomorphic to some $\pi_1(\Sigma_g)$ which is dense in $\widehat{F}_n$ (see Breuillard, Gelander, Souto, and Storm [2006]).

4.6 A profinitely rigid Kleinian group. At present it still remains open as to whether there is *any* finite volume hyperbolic 3-manifold $M = \mathbb{H}^3/\Gamma$ with $\mathcal{G}(\Gamma) = \{\Gamma\}$. However in recent work Bridson, McReynolds, Reid, and Spitler [n.d.] if we allow Γ to be a Kleinian group (i.e. a discrete subgroup of $\mathrm{PSL}(2, \mathbb{C})$) containing torsion then this can be done. As far as we can tell, this seems to be first example (indeed we give two) of a group "similar to a free group" that can be proved to be profinitely rigid, and can be viewed as providing the first real evidence towards answering Question 4.3 (and 4.1) in the affirmative. Namely we prove the following theorem in Bridson, McReynolds, Reid, and Spitler [ibid.] (where $\omega^2 + \omega + 1 = 0$).

Theorem 4.27. *The Kleinian groups* $\mathrm{PGL}(2, \mathbb{Z}[!])$ *and* $\mathrm{PSL}(2, \mathbb{Z}[!])$ *are profinitely rigid.*

The case of $\mathrm{PGL}(2, \mathbb{Z}[!])$ follows from that of $\mathrm{PSL}(2, \mathbb{Z}[!])$, and we so we limit ourselves to briefly indicating the strategy of the proof of Theorem 4.27 for $\mathrm{PSL}(2, \mathbb{Z}[!])$.

There are three key steps in the proof which we summarize below.

Theorem 4.28 (Representation Rigidity)**.** *Let $\iota : \Gamma \to \mathrm{PSL}(2, \mathbb{C})$ denote the identity homomorphism, and $c = \bar{\iota}$ the complex conjugate representation. Then if $\rho : \Gamma \to \mathrm{PSL}(2, \mathbb{C})$ is a representation with infinite image, $\rho = \iota$ or c.*

Using Theorem 4.28 we are able to get some control on $\mathrm{PSL}(2,\mathbb{C})$ representations of a finitely generated residually finite group with profinite completion isomorphic to $\widehat{\Gamma}$, and to that end we prove:

Theorem 4.29. *Let Δ be a finitely generated residually finite group with $\widehat{\Delta} \cong \widehat{\Gamma}$. Then Δ admits an epimorphism to a group $L < \Gamma$ which is Zariski dense in* $\mathrm{PSL}(2,\mathbb{C})$.

Finally, we make use of Theorem 4.29, in tandem with an understanding of the topology and deformations of orbifolds $\mathbb{H}^3/G$ for subgroups $G < \Gamma$. Briefly, in the notation of Theorem 4.29, the case of L having infinite index can be ruled out using Teichmüller theory to construct explicit finite quotients of L and hence Δ that cannot be finite quotients of Γ. To rule out the finite index case we make use of information about low-index subgroups of Γ, together with the construction of L, and 3-manifold topology to show that L contains the fundamental group of a once-punctured torus bundle over the circle of index 12. We can then invoke Bridson, Reid, and Wilton [2017] to yield the desired conclusion that $\Delta \cong \Gamma$. □

5 Virtually free groups, Fuchsian groups and Limit groups

We now turn from the world of 3-manifold groups to other classes of groups closely related to free groups; virtually free groups (i.e. contains a free subgroup of finite index), Fuchsian groups which are discrete subgroups of $\mathrm{PSL}(2,\mathbb{R})$ and limit groups which we define below. All three classes of these groups contain the class of free groups amongst them. As already noted even groups that are virtually $\mathbb{Z}$ can fail to be profinitely rigid. In Grunewald and Zalesskii [2011] this is extended to give examples of virtually non-abelian free groups in the same genus, as well as providing cases where they show that certain virtually free groups are the only groups in the genus when restricted to virtually free groups.

5.1 Some restricted genus results. Regarding Fuchsian groups, the following is proved in Bridson, Conder, and Reid [2016].

Theorem 5.1. *Let $\mathcal{L}$ denote the collection of lattices in connected Lie groups and let Γ be a finitely generated Fuchsian group. Then $\mathcal{G}_{\mathcal{L}}(\Gamma) = \{\Gamma\}$.*

Using the profinite invariance of $b_1^{(2)}$ Bridson, Conder, and Reid [ibid.], it turns out that the hard case of Theorem 5.1 is ruling out non-isomorphic Fuchsian having isomorphic profinite completions. The main part of the proof of this step is to rule out "fake torsion" in the profinite completion, and uses the technology of profinite group actions on profinite trees (see Bridson, Conder, and Reid [ibid.] for details).

By a limit group we mean a finitely-generated group Γ that is fully residually free; i.e. a finitely generated group in which every finite subset can be mapped injectively into a free group by a group homomorphism. In connection with Question 4.1, Wilton [2017] recently proved the following:

Theorem 5.2. *Let Γ be a limit group that is not a free group, and let F be a free group. Then $\widehat{\Gamma}$ is not isomorphic to $\widehat{F}$.*

The key point in the proof of Theorem 5.2 (and indeed the main point of Wilton [2017]) is to construct a surface subgroup in a non-free limit group. One can then follow an argument in Bridson, Conder, and Reid [2016] that uses Wilton [2008] (which proves LERF for limit groups) and Proposition 4.25 to complete the proof.

5.2 Profinite genus of free groups and one-ended hyperbolic groups. We close this section with a discussion of possible groups in the genus for free groups. As noted above, Theorem 5.2 uses the existence of surface subgroups to show that non-free limit groups do not lie in the same genus as a free group. The next result from Bridson, Conder, and Reid [2016] takes up this theme, and connects to two well-known open problems about word hyperbolic groups, namely:

(A) Does every 1-ended word-hyperbolic group contain a surface subgroup?

(B) Is every word-hyperbolic group residually finite?

The first question, due to Gromov, was motivated by the case of hyperbolic 3-manifolds, and in this special case the question was settled by Kahn and Markovic [2012]. Indeed, given Kahn and Markovic [ibid.], a natural strengthening of (A) above is to ask:

(A′) Does every 1-ended word-hyperbolic group contain a quasi-convex surface subgroup?

Theorem 5.3. *Suppose that every 1-ended word-hyperbolic group is residually finite and contains a quasi-convex surface subgroup. Then there exists no 1-ended word-hyperbolic group Γ and free group F such that $\widehat{\Gamma} \cong \widehat{F}$.*

Proof. Assume the contrary, and let Γ be a counter-example, with $\widehat{\Gamma} \cong \widehat{F}$ for some free group F. Let H be a quasi-convex surface subgroup of Γ. Note that the finite-index subgroups of H are also quasi-convex in Γ. Under the assumption that all 1-ended hyperbolic groups are residually finite, it is proved in Agol, Groves, and Manning [2009] that H and all its subgroups of finite index must be separable in Γ. Hence by Lemma 2.8, the natural map $\widehat{H} \to \overline{H} < \widehat{\Gamma} \cong \widehat{F}$ is an isomorphism, and can use Proposition 4.25 to complete the proof. □

Corollary 5.4. *Suppose that there exists a 1-ended word hyperbolic group Γ with $\widehat{\Gamma} \cong \widehat{F}$ for some free group F. Then either there exists a word-hyperbolic group that is not residually finite, or there exists a word-hyperbolic group that does not contain a quasi-convex surface subgroup.*

6 Profinite rigidity and flexibility in other settings

Although our attention has been on groups arising from low-dimensional geometry and topology we think it worthwhile to include a (far from complete) survey of profinite rigidity and flexibility for other classes of finitely generated or finitely presented groups.

6.1 Nilpotent and polycyclic groups. As is already evident from Baumslag's examples of meta-cyclic groups in Section 3, the case of nilpotent groups already shows some degree of subtlety. The case of nilpotent groups more generally is well understood due to work of Pickel [1971]. We will not discuss this in any detail, other than to say that, in Pickel [ibid.] it is shown that for a finitely generated nilpotent group Γ, $\mathcal{G}(\Gamma)$ consists of a finite number of isomorphism classes of nilpotent groups, and moreover, examples where the genus can be made arbitrarily large are known (see for example Segal [1983] Chapter 11). Examples of profinitely rigid nilpotent groups of class 2 are constructed in Grunewald and Scharlau [1979].

Similar results are also known for polycyclic groups and we refer the reader to Grunewald and Segal [1978] and Segal [1983]. Note that in the case of nilpotent groups it is straightforward to prove that any finitely generated residually finite group in the same genus as a nilpotent group is nilpotent. The same holds for polycyclic groups (see Sabbagh and Wilson [1991]), but this is a good deal harder.

These results should be compared with the examples of the meta-abelian groups (which are solvable) of Pickel given in Remark 3.4 where the genus is infinite.

6.2 Lattices in semi-simple Lie groups. Let Γ be a lattice in a semi-simple Lie group, for example, in what follows we shall take $\Gamma = \mathrm{SL(n, R_k)}$ where R_k denotes the ring of integers in a number field k. A natural, obvious class of finite quotients of Γ, are those of the form $\mathrm{SL(n, R_k/I)}$ where $I \subset R_k$ is an ideal. Let $\Gamma(I)$ denote the kernel of the reduction homomorphism $\Gamma \to \mathrm{SL(n, R_k/I)}$. By Strong Approximation for $\mathrm{SL_n}$ (see Platonov and Rapinchuk [1994] Chapter 7.4 for example) these reduction homomorphisms are surjective for all I. A *congruence subgroup* of Γ is any subgroup $\Delta < \Gamma$ such that $\Gamma(I) < \Delta$ for some I. A group Γ is said to have the *Congruence Subgroup Property* (abbreviated to CSP) if every subgroup of finite index is a congruence subgroup.

Thus, if Γ has CSP, then $\mathcal{C}(\Gamma)$ is known precisely, and in effect, to determine $\mathcal{C}(\Gamma)$ is reduced to number theory. Expanding on this, since R_k is a Dedekind domain, any ideal I factorizes into powers of prime ideals. If $I = \prod \mathcal{P}_i^{a_i}$, then it is known that $\mathrm{SL(n, R_k/I)} = \prod \mathrm{SL(n, R_k/\mathcal{P}_i^{a_i})}$. Thus the finite groups that arise as quotients of $\mathrm{SL(n, R_k)}$ are determined by those of the form $\mathrm{SL(n, R_k/\mathcal{P}_i^{a_i})}$. Hence we are reduced to understanding how a rational prime p behaves in the extension $k/\mathbb{Q}$. This idea, coupled with the work of Serre [1970] which has shed considerable light on when Γ has CSP allows construction of non-isomorphic lattices in the same genus. We refer the reader to Aka [2012b], Aka [2012a] and Reid [2015] for further details.

6.3 Grothendieck's Problem. A particular case of when discrete groups groups have isomorphic profinite completions is the following (which goes back to Grothendieck [1970]).

Let Γ be a residually finite group and let $u : P \hookrightarrow \Gamma$ be the inclusion of a subgroup P. Then (Γ, P) is called a *Grothendieck Pair* if the induced homomorphism $\widehat{u} : \widehat{P} \to \widehat{\Gamma}$ is an isomorphism but u is not.

We say that Γ is *Grothendieck Rigid* if no proper finitely generated subgroup $u : P \to \Gamma$ gives a Grothendieck Pair.

Grothendieck [1970] asked about the existence of Grothendieck Pairs of finitely presented groups and the first such pairs were constructed by Bridson and Grunewald [2004]. The analogous problem for finitely generated groups had been settled earlier by Platonov and Tavgen [1990] (see also Bass and Lubotzky [2000]). Using different methods, Pyber [2004] gave a construction of continuously many finitely generated groups Γ_α with subgroups H_α for which $(\Gamma_\alpha, H_\alpha)$ are Grothendieck Pairs.

The constructions of Platonov and Tavgen [1990] and Bridson and Grunewald [2004] rely on versions of the following result (see also Bridson [2010]). We remind the reader that the *fibre product* $P < \Gamma \times \Gamma$ associated to an epimorphism of groups $p : \Gamma \to Q$ is the subgroup $P = \{(x, y) \mid p(x) = p(y)\}$.

Proposition 6.1. *Let $1 \to N \to \Gamma \to Q \to 1$ be a short exact sequence of groups with Γ finitely generated and let P be the associated fibre product. Suppose that $Q \neq 1$ is finitely presented, has no proper subgroups of finite index, and $H_2(Q, \mathbb{Z}) = 0$. Then*

1. *$(\Gamma \times \Gamma, P)$ is a Grothendieck Pair;*
2. *if N is finitely generated then (Γ, N) is a Grothendieck Pair.*

More recently in Bridson [2016], examples of Grothendieck Pairs were constructed so as to provide the first examples of finitely-presented residually finite groups Γ that contain an infinite sequence of non-isomorphic finitely presented subgroups P_n so that (Γ, P_n) are Grothendieck Pairs. In particular, this provides examples of finitely presented groups Γ for which $\mathcal{G}(\Gamma)$ is infinite. These examples are non-solvable in contrast to those of Pickel in Remark 3.4

Note that if a H is a subgroup of a group Γ and Γ is H-separable then it is easy to see that (Γ, H) cannot be a Grothendieck Pair (since H is not dense in the profinite topology). This was noticed in Platonov and Tavgen [1990] to observe that free groups and Fuchsian groups were Grothendieck Rigid. For 3-manifolds Grothendieck Rigidity was shown in Long and Reid [2011] for the fundamental groups of closed geometric 3-manifolds and finite volume hyperbolic 3-manifolds without appealing to LERF in the hyperbolic case. In Cavendish [2012] and Reid [2015] this was extended to the fundamental groups of all closed irreducible 3-manifolds (as a consequence of Theorem 4.11). This program has been completed by Boileau and Friedl [2017] who proved:

Theorem 6.2. *The fundamental group of any compact, connected, irreducible, orientable 3-manifold with empty or toroidal boundary is Grothendieck Rigid.*

7 Final remarks and further questions

As should be clear from this article, the questions posed in Section 4 remain stubbornly open, and even questions about the nature of $\mathcal{G}_{\mathfrak{M}}(\pi_1(M))$ for M a finite volume hyperbolic 3-manifold seem hard to resolve. Never the less, these open problems can be used as platforms for other, perhaps more approachable problems. We discuss a few, other problems for other classes of groups can be found in Reid [2015].

Question 7.1. Let Γ denote the fundamental group of the figure-eight knot complement. It is well-known that Γ has index 12 in the group $\mathrm{PSL}(2, \mathbb{Z}[!])$ of Theorem 4.27. Is Γ is profinitely rigid?

As noted in Section 4.5, it was shown in Bridson and Reid [2015b] and Boileau and Friedl [2015] that $\mathcal{G}_{\mathfrak{M}}(\Gamma) = \{\Gamma\}$.

Question 7.2. Let M_W denote the Weeks manifold. This is the smallest volume hyperbolic 3-manifold Gabai, Meyerhoff, and Milley [2009]. Is $\mathcal{G}_{\mathfrak{M}}(\pi_1(M_W) = \{\pi_1(M_W)\}$?

Indeed, one might wonder whether the techniques of Bridson, McReynolds, Reid, and Spitler [n.d.] (as described in Theorem 4.27) can be brought to bear in this example since $\pi_1(M_W)$ exhibits a certain amount of representation rigidity.

Question 7.3. In Section 4.5 it was pointed out that recently Jaikin-Zapirain [n.d.] showed that being fibered is a profinite invariant. Given this, a natural question is:

Is the Thurston norm ball a profinite invariant? That is to say, if M is a closed hyperbolic 3-manifold and N a closed hyperbolic 3-manifold with $\pi_1(N) \in \mathcal{G}_{\mathfrak{M}}(\pi_1(M))$ are the Thurston norm balls isomorphic?

Some progress on this is given in Boileau and Friedl [2015] under an additional condition on the isomorphsim between profinite completions. However, it seems unlikely that this condition will hold in general.

Question 7.4. Is the volume a profinite invariant? That is to say, if M is a finite volume hyperbolic 3-manifold and N a finite volume hyperbolic 3-manifold with $\pi_1(N) \in \mathcal{G}_{\mathfrak{M}}(\pi_1(M))$ does $\mathrm{vol}(M) = \mathrm{vol}(N)$?

It follows from well-known properties of the set of volumes of hyperbolic 3-manifolds Thurston [1979] that if Question 7.4 has a positive answer then $|\mathcal{G}_{\mathfrak{M}}(\pi_1(M))|$ is finite.

There does appear to be some conjectural evidence to support a positive answer. Briefly, it is conjectured (roughly) that if $\{\Gamma_n\}$ is a cofinal sequence of subgroups of finite index in $\pi_1(M)$ (as above), then:

$$\frac{\log|\mathrm{Tor}(H_1(\Gamma_n, \mathbb{Z}))|}{[\pi_1(M) : \Gamma_n]} \to \frac{1}{6\pi}\mathrm{vol}(M) \text{ as } n \to \infty.$$

Note that $\mathrm{Tor}(H_1(\Gamma_n, \mathbb{Z}))$ is visible in the profinite completions $\widehat{\Gamma}_n$ and so if the above conjecture is true, this would allow one to deduce $\pi_1(N) \in \mathcal{G}_{\mathfrak{M}}(\pi_1(M))$ implies $\mathrm{vol}(M) = \mathrm{vol}(N)$.

THE EVENNESS CONJECTURE IN EQUIVARIANT UNITARY BORDISM

Bernardo Uribe

Abstract

The evenness conjecture for the equivariant unitary bordism groups states that these bordism groups are free modules over the unitary bordism ring in even dimensional generators. In this paper we review the cases on which the conjecture is known to hold and we highlight the properties that permit to prove the conjecture in these cases.

Introduction

The G-equivariant unitary bordism groups for G a compact Lie group are the bordism groups of G-equivariant tangentially stable almost complex manifolds, also known as G-equivariant unitary manifolds. These are closed G-manifolds M for which a stable tangent bundle $TM \oplus \underline{\mathbb{R}}^k$, where $\underline{\mathbb{R}}^k$ denotes the trivial bundle $\mathbb{R}^k \times M$ with trivial G-action, can be endowed with the structure of a G-equivariant complex bundle. Two tangentially stable almost complex G-structures are identified if after stabilization with further G-trivial $\underline{\mathbb{C}}$ summands the structures become G-homotopic through complex G-structures. Being unitary is inherited to the fixed points sets. Whenever H is a closed subgroup of G the fixed points M^H are also tangentially stable almost complex, and moreover a N_H-tubular neighborhood around M^H in M possesses a complex N_H structure May [1996, §XVIII, Prop. 3.2].

For a cofibration of G-spaces $Y \to X$, the geometric G-equivariant unitary bordism groups $\Omega_n^G(X, Y)$ are the G-bordism classes of G-equivariant n-dimensional manifolds with map $(M^n, \partial M^n) \to (X, Y)$.

Keywords: Equivariant unitary bordism, equivariant vector bundle.

The G-equivariant unitary bordism groups of a point Ω_*^G become a ring under the cartesian product of manifolds with the diagonal G-action, and therefore a module of the unitary bordism ring Ω_* whenever we consider a unitary manifold as a trivial G-manifold. Milnor [1960] and Novikov [1960], using Thom's remarkable calculation of the unoriented bordism groups Thom [1954], showed that the unitary bordism ring is a polinomial ring $\Omega_* = \mathbb{Z}[x_{2i} : i \geq 1]$ with one generator in each even degree. In this work we will be interested in the Ω_*-module structure of the equivariant unitary bordism groups Ω_*^G.

Explicit calculations carried out by Landweber [1972] in the cyclic case and by Stong [1970] in the abelian p-group case permitted them to conclude that in these cases the equivariant unitary bordism group Ω_*^G is a free Ω_*-module in even dimensional generators. Ossa [1972] generalized this result to any finite abelian group and Löffler [1974] and Comezaña in May [1996, §XXVIII, Thm. 5.1] showed that this also holds whenever G is a compact abelian Lie group. Explicit calculations done for the Diehadral groups D_{2p} with p prime by Ángel, Gómez, and B. Uribe [n.d.] for groups of order pq with p and q different primes by Lazarov [1972] and for metacyclic groups by Rowlett [1980] show that for these groups this phenomenon also occurs. We believe that this property should hold in the G-equivariant unitary bordism groups for any compact Lie group G, in the same way that the coefficients for G-equivariant K-theory are trivial in odd degrees and a free module over the integers in even degrees.

The theme of this work is the

Evenness conjecture for the equivariant unitary bordism groups

which states that the G-equivariant unitary bordism group is a free Ω_*-modules in even dimensional generators whenever G is a compact Lie group. Rowlett explicitly mentions this conjecture in his work of 1980 Rowlett [ibid.] and later Comezaña in his work of 1996 May [1996, §XXVIII.5]. We also believe that this conjecture holds in general and we do hope that this paper will help spreading it to the mathematical community for its eventual proof.

In this work we survey the original proofs of the known cases of the evenness conjecture for finite groups. We start in Section 1 with the definition of the equivariant unitary bordism groups for pairs of families and the long exact sequence associated to them. In Section 2 we review the decomposition of equivariant complex vector bundles restricted to fixed point sets done by Ángel, Gómez, and B. Uribe [n.d.] and how this decomposition allows to write the equivariant unitary bordism groups of adjacent pair of families as the bordism groups of equivariant classifying spaces. In Section 3 we review the proofs of the evenness conjecture for done by Landweber [1972] for cyclic groups, by Stong [1970] for abelian p-groups and by Ossa [1972] for general finite abelian groups. In Section 4 we review the proof of the evenness conjecture for metacyclic groups done by Rowlett [1980] and we finish with in Section 5 with some conclusions.

1 Equivariant unitary bordism for families of subgroups

To study the equivariant bordism groups Conner and Floyd introduced the study of bordism groups of manifolds with prescribed isotropy groups Conner and Floyd [1966, §5]. A family of subgroups $\mathfrak{F}$ of G is a set of subgroups of G which is closed under taking subgroups and under conjugation. The classifying space for the family $E\mathfrak{F}$ is a G-space which is terminal in the category of $\mathfrak{F}$-numerable G-spaces tom Dieck [1987, §1, Thm 6.6] and characterized by the following properties on fixed point sets: $E\mathfrak{F}^H \simeq *$ if $H \in \mathfrak{F}$ and $E\mathfrak{F}^H = \varnothing$ if $H \notin \mathfrak{F}$. This classifying space may be constructed in such a way that whenever $\mathfrak{F}' \subset \mathfrak{F}$, the induced map $E\mathfrak{F}' \to E\mathfrak{F}$ is a G-cofibration.

The equivariant unitary bordism groups for pairs of families may be defined as follows

$$\Omega_*^G[\mathfrak{F}, \mathfrak{F}'](X, A) := \Omega_*^G(X \times E\mathfrak{F}, X \times E\mathfrak{F}' \cup A \times E\mathfrak{F}'),$$

see tom Dieck [1972, p. 310], or alternatively they may be defined in a geometric way is in Stong [1970, §2].

A $(\mathfrak{F}, \mathfrak{F}')$ *free geometric unitary bordism element* of (X, A) is an equivalence class of 4-tuples (M, M_0, M_1, f), where:

- M is an n-dimensional G-manifold endowed with tangentially stable almost G structure which is moreover $\mathfrak{F}$-free, i.e. such that all isotropy groups $G_m = \{g \in G | gm = m\}$ for $m \in M$ belong to $\mathfrak{F}$, and such that $f : M \to X$ is G-equivariant; and

- M_0, M_1 are compact submanifolds of the boundary of M, with $\partial M = M_0 \cup M_1$, $M_0 \cap M_1 = \partial M_0 = \partial M_1$ having tangentially stable almost complex structure induced from M, both G-invariant, such that $f(M_1) \subset A$ and M_0 if $\mathfrak{F}'$-free, i.e. all isotropy groups of M_0 belong to $\mathfrak{F}'$.

Two four tuples (M, M_0, M_1, f) and (M', M_0', M_1', f) are equivalent if there is a 5-tuple (V, V^+, V_0, V_1, F) where

- V is a $\mathfrak{F}$-free manifold and $F : V \to X$ is a G-equivariant map;

- The boundary of V is the union of M, M' and V^+ with $M \cap V^+ = \partial M$, $M' \cap V^+ = \partial M'$, $M \cap M' = \varnothing$, $V^+ \cap (M \cup M') = \partial V^+$, with V inducing the tangentially stable almost complex G-structure on M and the opposite one on M'; V^+ is G-invariant and F restricts to f in M and to f' on M'; and

- V^+ is the union of the G-invariant submanifolds V_0, V_1 with intersection a submanifold V^- in their boundaries, such that $\partial V_i = M_i \cup V^- \cup M_i'$, $M_i \cap V^- = \partial M_i$, $M_i' \cap V^- = \partial M_i'$ with V_0 is $\mathfrak{F}'$-free and $F(V_1) \subset A$.

Definition 1.1. The set of equivalence classes of $(\mathfrak{F}, \mathfrak{F}')$-free geometric unitary bordism elements of (X, A), consisting of clases (M, M_0, M_1, f) where the dimension of M is n, and under the operation of disjoint union, forms an abelian group denoted by

$$\Omega_n^G\{\mathfrak{F}, \mathfrak{F}'\}(X, A).$$

Call these groups the geometric G-equivariant unitary bordism groups of the pair (X, A) restricted to the pair of families $\mathfrak{F}' \subset \mathfrak{F}$.

Note that if N is a tangentially stable almost complex closed manifold, we can define $N \cdot (M, M_0, M_1, f) = (N \times M, N \times M_0, N \times M_1, f \circ \pi_M)$ thus making $\Omega_n^G\{\mathfrak{F}, \mathfrak{F}'\}(X, A)$ a module over the unitary bordism ring Ω_*.

The covariant functor $\Omega_*^G\{\mathfrak{F}, \mathfrak{F}'\}$ defines a G-equivariant homology theory Stong [1970, Prop. 2.1], the boundary map on A

$$\begin{aligned} \delta : \Omega_n^G\{\mathfrak{F}, \mathfrak{F}'\}(X, A) &\to \Omega_{n-1}^G\{\mathfrak{F}, \mathfrak{F}'\}(A, \varnothing) \\ (M, M_0, M_1, f) &\mapsto (M_1, \partial M_1, \varnothing, f|_{M_1}) \end{aligned}$$

defines the long exact sequence in homology for pairs

$$\cdots \Omega_n^G\{\mathfrak{F}, \mathfrak{F}'\}(X, A) \xrightarrow{\delta} \Omega_{n-1}^G\{\mathfrak{F}, \mathfrak{F}'\}(A, \varnothing) \to \Omega_{n-1}^G\{\mathfrak{F}, \mathfrak{F}'\}(X, \varnothing) \to \cdots,$$

and for families $\mathfrak{F}'' \subset \mathfrak{F}' \subset \mathfrak{F}$, choosing the boundary which is $\mathfrak{F}'$-free

$$\begin{aligned} \partial : \Omega_n^G\{\mathfrak{F}, \mathfrak{F}'\}(X, A) &\to \Omega_{n-1}^G\{\mathfrak{F}', \mathfrak{F}''\}(X, A) \\ (M, M_0, M_1, f) &\mapsto (M_0, \varnothing, \partial M_0, f|_{M_0}) \end{aligned}$$

one obtains by Stong [ibid., Prop. 2.2] the long exact sequence in homology for families

$$\cdots \Omega_n^G\{\mathfrak{F}, \mathfrak{F}'\}(X, A) \xrightarrow{\partial} \Omega_{n-1}^G\{\mathfrak{F}', \mathfrak{F}''\}(X, A) \to \Omega_{n-1}^G\{\mathfrak{F}, \mathfrak{F}''\}(X, A) \to \cdots.$$

The bordism condition restricted to the non-relative case $\Omega_*^G\{\mathfrak{F}, \mathfrak{F}'\}(X)$ can be read as the set bordism classes of maps $f : M \to X$ such that M is $\mathfrak{F}$-free and ∂M is $\mathfrak{F}'$-free with M endowed with a tangentially stable almost complex G-structure. Two become equivalent if there exists a G-manifold $F : V \to X$ which is $\mathfrak{F}$-free such that $\partial V = M \cup M' \cup V^+$ and $M \cap V^+ = \partial M$, $M' \cap V^+ = \partial M'$, $M \cap M' = \varnothing$, $V^+ \cap (M \cup M') = \partial V^+$, with the property that F restricts to f on M and to f' on M' and with V^+ $\mathfrak{F}'$-free.

In tom Dieck [1972, Satz 3] it is shown that the canonical map that one can define

$$\mu : \Omega_n^G\{\mathfrak{F}, \mathfrak{F}'\}(X, A) \to \Omega_n^G[\mathfrak{F}, \mathfrak{F}'](X, A) \tag{1.2}$$

becomes a natural isomorphism of homology theories.

A key fact about the $(\mathfrak{F}, \mathfrak{F}')$-free geometric unitary bordism elements of X is the following result proven in Conner and Floyd [1966, Lemma 5.2]. Whenever $(M^n, \partial M^n, f)$ is a $(\mathfrak{F}, \mathfrak{F}')$-free geometric unitary bordism element of X and W^n a compact manifold with boundary regularly embedded in the interior of M^n and invariant under the G-action, such that $G_m \in \mathfrak{F}'$ for all $m \in M^n \backslash W^n$, then $[M^n, \partial M^n, f] = [W^n, \partial W_n, f|_{W^n}]$ in $\Omega_n^G\{\mathfrak{F}, \mathfrak{F}'\}(X)$.

Whenever the pair of families $\mathfrak{F}' \subset \mathfrak{F}$ differ by a fixed group A, i.e. $\mathfrak{F} \backslash \mathfrak{F}' = (A)$ with (A) the set of subgroups of G conjugate to A, then the pair $(\mathfrak{F}, \mathfrak{F}')$ is called *adjacent pair of families of groups*. In the case that A is normal in G a $(\mathfrak{F}, \mathfrak{F}')$-free geometric unitary bordism class $[M, \partial M, f]$ of X is equivalent to $\sum_{j=1}^{l} [U_j, \partial U_j, f|_{U_j}]$ where the U_j's are disjoint G-equivariant tubular neighborhoods of the M_j^A's and these sets are the connected components of the A-fixed point set M^A. Since the normal bundle of the fixed point set M_j^A may be classified with a map to an appropriate classifying space, the groups $\Omega_*^G\{\mathfrak{F}, \mathfrak{F}'\}(X)$ become isormophic to the direct sum of G/A-free equivariant unitary bordism groups of the prroduct of X^A with an appropriate classifying space (see Ángel, Gómez, and B. Uribe [n.d., Thm. 4.5]). To introduce this result we need to understand how the fixed points of universal equivariant bundles behave. This is the subject of the next section.

2 Equivariant vector bundles and fixed points

2.1 Complex representations. Let G be a compact Lie group and A a closed and normal subgroup of G fitting in the exact sequence

$$1 \to A \to G \to Q \to 1.$$

Let $\rho : A \to U(V_\rho)$ be an irreducible unitary representation of A, denote by $\mathrm{Irr}(A)$ the set of isomorphism classes of irreducible representations of A and let W be a finite dimensional complex G-representation. Then we have an isomorphism of A-representations

$$\bigoplus_{\rho \in \mathrm{Irr}(A)} V_\rho \otimes \mathrm{Hom}_A(V_\rho, W) \xrightarrow{\cong} W.$$

The group G acts on the set of A-representations

$$(g \cdot \rho)(a) := \rho(g^{-1} a g)$$

and therefore it acts on $\mathrm{Irr}(A)$. Denote by $G_\rho := \{g \in G | g \cdot \rho \cong \rho\}$ the isotropy group of the isomorphism class of ρ and denote $Q_\rho := G_\rho / A$.

If $g \cdot \rho \cong \rho$ then there exists $M \in U(V_\rho)$ such that $g \cdot \rho(a) = M^{-1}\rho(a)M$. Since this matrix M is unique up to a central element, we obtain a homomorphism $f : G_\rho \to PU(V_\rho)$ which fits in the following diagram

$$\begin{array}{ccc} A & \overset{\iota}{\hookrightarrow} & G_\rho \\ {\scriptstyle\rho}\downarrow & & \downarrow{\scriptstyle f} \\ U(V_\rho) & \overset{p}{\longrightarrow} & PU(V_\rho). \end{array}$$

thus making V_ρ into a projective G_ρ-representation.

Define the $\mathbb{S}^1$-central extension $\widetilde{G}_\rho := f^*U(V_\rho)$ of G_ρ which fits into following diagram

$$\begin{array}{ccccc} & & \mathbb{S}^1 & & \mathbb{S}^1 \\ & & \downarrow & & \downarrow \\ A & \overset{\widetilde{\iota}}{\longrightarrow} & \widetilde{G}_\rho & \overset{\widetilde{f}}{\longrightarrow} & U(V_\rho) \\ \downarrow{\scriptstyle =} & & \downarrow & & \downarrow \\ A & \overset{\iota}{\longrightarrow} & G_\rho & \overset{f}{\longrightarrow} & PU(V_\rho). \end{array}$$

endowing V_ρ with the structure of a $\widetilde{G}_\rho$-representation where $\mathbb{S}^1$ acts by multiplication with scalars.

The vector space $\mathrm{Hom}_A(V_\rho, W)$ is also a $\widetilde{G}_\rho$-representation where for $\phi \in \mathrm{Hom}_A(V_\rho, W)$ and $\widetilde{g} \in \widetilde{G}_\rho$ we set

$$(\widetilde{g} \bullet \phi)(v) := g\phi(\widetilde{f}(\widetilde{g})^{-1}v).$$

It follows that A acts trivially on $\mathrm{Hom}_A(V_\rho, W)$ and moreover the lements of $\mathbb{S}^1$ act by multiplication of their inverse.

Hence $V_\rho \otimes \mathrm{Hom}_A(V_\rho, W)$ is a G_ρ representation, where $\mathrm{Hom}_A(V_\rho, W)$ is a $\widetilde{Q}_\rho := \widetilde{G}_\rho / A$ representation where $\mathbb{S}^1$ acts by multiplication of the inverse. Here $\widetilde{Q}_\rho$ is an $\mathbb{S}^1$-central extension of Q_ρ.

Since the isotropy group G_ρ contains the connected component of the identity in G, the index $[G\colon G_\rho]$ is finite and we may induce the G_ρ-representation $V_\rho \otimes \mathrm{Hom}_A(V_\rho, W)$ to G thus obtaining the following result.

Theorem 2.1. *There is a canonical isomorphism of G-representations*

$$\bigoplus_{\rho \in G \backslash \mathrm{Irr}(A)} Ind_{G_\rho}^{G} \left(V_\rho \otimes \mathrm{Hom}_A(V_\rho, W)\right) \cong W$$

where ρ runs over representatives of the orbits of the action of G on $Irr(A)$.

2.2 Equivariant complex bundles. The previous result generalizes to equivariant complex vector bundles, but prior to showing this generalization we need to recall the multiplicative induction map introduced in Bix and tom Dieck [1978, §4]. Let H be a closed subgroup of the compact Lie group G. The right adjoint to the restriction functor r_H^G from G-spaces to H-spaces is called the multiplicative induction functor and takes an H-space Y and returns the G-space

$$m_H^G(Y) := \mathrm{map}(G, Y)^H$$

of H-equivariant maps from G to Y, with G considered as an H-space by left multiplication. The G-action on $m_H^G(Y)$ is given by $(g \cdot f)(k) := f(kg)$, it is homeomorphic to the space of sections of the projection map $G \times_H Y \to G/H$ and, in the case that G/H is finite, it is homeomorphic to $[G : H]$ copies of Y.

There is a homeomorphism

$$\mathrm{map}(X, m_H^G(Y))^G \xrightarrow{\cong} \mathrm{map}(r_H^G(X), Y)^H, \quad F \mapsto (x \mapsto F(x)(1_G))$$

whose inverse maps f to $m_H^G(f) \circ p_H^G$ where $p_H^G : X \to m_H^G(r_H^G(X))$, $p_H^G(x)(g) = gx$, is the unit of the adjunction.

Now consider a G-space X on which the closed and normal subgroup A acts trivially. Take a G-equivariant complex vector bundle $p : E \to X$ and assume that E has an hermitian metric in such a way that G acts through unitary matrices on the complex fibers. For a complex A-respresentation $\rho : A \to U(V_\rho)$ denote by $\mathbb{V}_\tau$ the trivial A-vector bundle $\pi_2 : V_\rho \times X \to X$.

The complex vector bundle $\mathrm{Hom}_A(\mathbb{V}_\rho, E)$ is a $\widetilde{Q}_\rho$-equivariant complex vector bundle where $\mathbb{S}^1$-acts on the fibers bymultiplication of the inverse, $\mathbb{V}_\rho \otimes \mathrm{Hom}_A(\mathbb{V}_\rho, E)$ is a G_ρ-equivariant complex vector bundle and

$$(p_{G_\rho}^G)^* \left(m_{G_\rho}^G (\mathbb{V}_\rho \otimes \mathrm{Hom}_A(\mathbb{V}_\rho, E)) \right) \to X$$

is a G-equivariant complex vector bundle over X.

Theorem 2.2. *Ángel, Gómez, and B. Uribe [n.d., Thm. 2.7] Let G be a compact Lie group, A a closed and normal subgroup, X a G-space on which A acts trivially and $E \to X$ a G-equivariant complex vector bundle. Then there is an isomorphism of G-equivariant complex vector bundles*

$$\bigoplus_{\rho \in G \backslash \mathrm{Irr}(A)} (p_{G_\rho}^G)^* \left(m_{G_\rho}^G (\mathbb{V}_\rho \otimes \mathrm{Hom}_A(\mathbb{V}_\rho, E)) \right) \xrightarrow{\cong} E$$

where ρ runs over representatives of the orbits of the G-action on the set of isomorphism classes of A-irreducible representations.

With the same hypothesis as in the previous theorem, there is an induced decomposition in equivariant K-theory

$$K^*_G(X) \cong \bigoplus_{\rho\in G\backslash \mathrm{Irr}(A)} {}^{\widetilde{Q}_\rho}K^*_{Q_\rho}(X), \quad E \mapsto \bigoplus_{\rho\in G\backslash \mathrm{Irr}(A)} \mathrm{Hom}_A(\mathbb{V}_\rho, E)$$

where ${}^{\widetilde{Q}_\rho}K^*_{Q_\rho}(X)$ is the $\widetilde{Q}_\rho$-twisted Q_ρ- equivariant K-theory of X which is built out of the Grothendieck group of $\widetilde{Q}_\rho$-equivariant complex vector bundles over X on which the central $\mathbb{S}^1$ acts by multilpication of the fibers.

2.3 Classifying spaces. The decomposition described above can also be written at the level of classifying spaces; let us set up the notation first. Let G be a compact Lie group and $\widetilde{G}$ a $\mathbb{S}^1$-central group extension of G. Let $\widetilde{\mathbf{C}}^\infty$ be a countable direct sum of all complex irreducible $\widetilde{G}$ representations on which $\mathbb{S}^1$ acts by multiplication of their inverse. Denote by ${}^{\widetilde{G}}B_GU(n)$ the Grasmannian of n-planes of $\widetilde{\mathbf{C}}^\infty$ and denote by ${}^{\widetilde{G}}\gamma_GU(n)$ the canonical n-plane bundle over ${}^{\widetilde{G}}B_GU(n)$. The complex vector bundle

$$\mathbb{C}^n \to {}^{\widetilde{G}}\gamma_GU(n) \to {}^{\widetilde{G}}B_GU(n)$$

is a universal $\widetilde{G}$-twisted G-equivariant complex vector bundle of rank n. Denote by $\gamma_GU(n) \to B_GU(n)$ the universal G-equivariant complex vector bundle of rank n.

Take a closed subgroup A of G, let N_A denote the normalizer of A in G and $W_A := N_A/A$. Consider the fixed point set $B_GU(n)^A$ and the restriction $\gamma_GU(n)|_{B_GU(n)^A}$ of the universal bundle to this fixed point set. Take $\rho \in \mathrm{Irr}(A)$ and by the arguments above we have that

$$\mathrm{Hom}_A(\mathbb{V}_\rho, \gamma_GU(n)|_{B_GU(n)^A})$$

is a $(\widetilde{W_A})_\rho$-twisted $(W_A)_\rho$-equivariant complex bundle, but since the space $B_GU(n)^A$ is not necessarily connected, it may not have constant rank. Therefore Theorem 2.2 implies the following equivariant homotopy equivalence.

Theorem 2.3. *Ángel, Gómez, and B. Uribe [n.d., Thms. 3.3 & 3, 5] There are W_A-equivariant homotopy equivalences*

$$\bigsqcup_{n=0}^{\infty} \gamma_GU(n)^A \simeq \left(\bigsqcup_{n=0}^{\infty} \gamma_{W_A}U(n_1)\right) \times \prod_{\substack{\rho\in W_A\backslash \mathrm{Irr}(A)\\ \rho\neq 1}} m^{W_A}_{(W_A)_\rho}\left(\bigsqcup_{n_\rho=0}^{\infty} {}^{(\widetilde{W_A})_\rho}B_{(W_A)_\rho}U(n_\rho)\right),$$

$$\bigsqcup_{n=0}^{\infty} B_GU(n)^A \simeq \prod_{\rho\in W_A\backslash \mathrm{Irr}(A)} m^{W_A}_{(W_A)_\rho}\left(\bigsqcup_{n_\rho=0}^{\infty} {}^{(\widetilde{W_A})_\rho}B_{(W_A)_\rho}U(n_\rho)\right).$$

If G is abelian then A is normal, G acts trivially on $\mathrm{Irr}(A)$ and all the irreducible representations are 1-dimensional. Therefore we get a G/A-homotopy equivalence

$$\gamma_G U(n)^A \simeq \coprod_{\substack{(n_\rho)_{\rho\in\mathrm{Irr}(A)}\\ \sum_\rho n_\rho = n}} \left(\gamma_{G/A} U(n_1) \times \prod_{\substack{\rho\in\mathrm{Irr}(A)\\ \rho\neq 1}} B_{G/A} U(n_\rho) \right).$$

In order to get a similar formula for the case on which G is not abelian we need to add up some notation and make some choices. Let $\mathcal{P}(n,A)$ be the set of arrangements of non-negative integers $(n_\rho)_{\rho\in\mathrm{Irr}(A)}$ such that

$$\sum_{\rho\in\mathrm{Irr}(A)} n_\rho|\rho| = n,$$

then non-equivariantly there is a homotopy equivalence

$$B_G U(n)^A \simeq \coprod_{(n_\rho)\in\mathcal{P}(n,A)} \prod_{\rho\in\mathrm{Irr}(A)} \left({}^{(\widetilde{W_A})_\rho} B_{(W_A)_\rho} U(n_\rho) \right).$$

The group W_A acts on $\mathcal{P}(n,A)$ on the right permuting the arrangements, i.e. the action of $g \in W_A$ on the arrangement (n_ρ) is the arrangement $(n_\rho)\cdot g := (n_{g\cdot\rho})$ meaning that it has the number $n_{g\cdot\rho}$ in the coordinate ρ. Denote by $(W_A)_{(n_\rho)}$ the isotropy group of the arrangement (n_ρ). Rearranging the terms we obtain the following W_A-equivariant homotopy equivalence

(2.4) $$B_G U(n)^A \simeq$$

$$\coprod_{(n_\rho)\in\mathcal{P}(n,A)/W_A} W_A \underset{(W_A)_{(n_\rho)}}{\times} \left(\prod_{\rho\in(W_A)_{(n_\rho)}\backslash \mathrm{Irr}(A)} m^{(W_A)_{(n_\rho)}}_{(W_A)_\rho\cap(W_A)_{(n_\rho)}} \left({}^{(\widetilde{W_A})_\rho} B_{(W_A)_\rho} U(n_\rho) \right) \right)$$

where (r_ρ) runs over representatives of the orbits of the action of W_A on $\mathcal{P}(n,A)$, and ρ runs over representatives of the orbits of the action of $(W_A)_{(n_\rho)}$ on $\mathrm{Irr}(A)$.

For the calculation of the equivariant unitary bordism of adjacent families of groups we need to consider only the arrangements of non-negative integers (n_ρ) such that the number associated to the trivial representation is zero, i.e. $n_1 = 0$. Denote by $\overline{\mathcal{P}}(n,A)$ the set of arrangements (n_ρ) such that $n_1 = 0$ and define the W_A space:

(2.5) $$C_{N_A,A}(k) :=$$

$$\coprod_{(n_\rho)\in\overline{\mathcal{P}}(k,A)/W_A} W_A \underset{(W_A)_{(n_\rho)}}{\times} \left(\prod_{\substack{\rho\in(W_A)_{(n_\rho)}\backslash \mathrm{Irr}(A)\\ \rho\neq 1}} m^{(W_A)_{(n_\rho)}}_{(W_A)_\rho\cap(W_A)_{(n_\rho)}} \left({}^{(\widetilde{W_A})_\rho} B_{(W_A)_\rho} U(n_\rho) \right) \right)$$

Therefore we have the following W_A-homotopy equivalence

$$\gamma_G U(n)^A \simeq \bigsqcup_{k=0}^{n} \gamma_{W_A} U(n-k) \times C_{N_A,A}(k) \tag{2.6}$$

such that in the case that G is abelian we have the simple formula

$$C_{G,A}(k) = \bigsqcup_{(n_\rho)\in\overline{\mathcal{P}}(k,A)} \prod_{\substack{\rho\in\mathrm{Irr}(A)\\ \rho\neq 1}} B_{G/A} U(n_\rho). \tag{2.7}$$

Now we are ready to state the relation between the G-equivariant unitary bordism groups of adjacent pair of families of groups and the classifying spaces defined above.

Theorem 2.8. *Ángel, Gómez, and B. Uribe [n.d., Cor. 4.6] Let G be a finite group, X a G-space and $(\mathfrak{F}, \mathfrak{F}')$ an adjacent pair of families differing by the conjugacy class of the subgroup A, then there is an isomorphism*

$$\Omega_n^G\{\mathfrak{F}, \mathfrak{F}'\}(X) \cong \bigoplus_{0\leq 2k\leq n} \Omega_{n-2k}^{W_A}\{\{1\}\}(X^A \times C_{N_A,A}(k))$$

where $\{1\}$ is the family of subgroups of W_A which only contains the trivial group.

Take a bordism class $[M, \partial M, f : M \to X]$ in $\Omega_n^G\{\mathfrak{F}, \mathfrak{F}'\}(X)$ and note that $M^A \cap M^{gAg^{-1}} = \varnothing$ whenever g does not belong to N_A. Then choose a N_A-equivariant tubular neighborhood U of M^A such that its G-orbit $G\cdot U$ is a G-equivariant tubular neighborhood of $G \cdot M^A$ and such that

$$G \underset{N_A}{\times} U \overset{\cong}{\to} G \cdot U, \quad [(g, u)] \to gu$$

is a G-equivariant diffeomorphism. The assignment

$$[M, \partial M, f : M \to X] \mapsto [U, \partial U, f|_U : U \to X]$$

induces an isomorphism

$$\Omega_n^G\{\mathfrak{F}, \mathfrak{F}'\}(X) \overset{\cong}{\to} \Omega_n^{N_A}\{\mathfrak{F}|_{N_A}, \mathfrak{F}'|_{N_A}\}(X).$$

Let M^A_{n-2k} denote the component of M^A which is a $(n-2k)$-dimensional W_A-free manifold and such that $M^A = \bigcup_{0\leq 2k\leq n} M^A_{n-2k}$. The tubular neighborhood U is N_A-equivariantly diffeomorphic to $\bigcup_{0\leq 2k\leq n} D(\nu_{n-2k})$ where $\nu_{n-2k} \to M^A_{n-2k}$ is the normal bundle of the inclusion $M^A_{n-2k} \to M$. Since the trivial A-representation does not appear on the fibers of the normal bundles, by Theorem 2.3 and formula (2.6) we know that the bundle ν_{n-2k} is classified by a W_A-equivariant map $h_{n-2k} : M^A_{n-2k} \to C_{N_A,A}(k)$. The bordism class $[M^A_{n-2k}, f|_{M^A_{n-2k}} \times h_{n-2k} : M^A_{n-2k} \to X^A \times C_{N_A,A}(k)]$ belongs to $\Omega^{W_A}_{n-2k}\{\{1\}\}(X^A \times C_{N_A,A}(k))$ and the assignment

$$[M, \partial M, f : M \to X] \mapsto \bigoplus_{0 \le 2k \le n} [M^A_{n-2k}, f|_{M^A_{n-2k}} \times h_{n-2k} : M^A_{n-2k} \to X^A \times C_{N_A,A}(k)]$$

induces the desired isomorphism.

3 The evenness conjecture for finite abelian groups

In this section we will outline the main ingredients that used Landweber [1972] in the cyclic group case, Stong [1970] in the p-group case and Ossa [1972] in the general case to show that evenness conjecture holds for finite abelian groups. The conjecture also holds for compact abelian groups, Löffler [1974] showed it for the homotopic G-equivariant unitary bordism groups in the case that G is a unitary torus, and Comezaña in May [1996, §XXVIII] generalized it to any compact abelian group. Comezaña furthermore showed that the map from the G-equivariant unitary bordism groups to the homotopic ones is injective whenever G is compact abelian thus proving the evenness conjecture for any compact abelian group. In this work we will address the finite group case.

Prior to addressing the study of the G-equivariant unitary bordism groups for finite abelian groups we need to recall some results on the unitary bordism groups.

Thom's remarkable Theorem 1954 shows that the unitary bordism groups Ω_* can be calculated as the stable homotopy groups $\lim_k \pi_{n+k}(MU(k))$ of the Thom spaces $MU(k)$ of the canonical complex vector bundles over $BU(k)$. Milnor [1960, Thm. 3] showed that the these stable homotopy groups are zero if n is odd and free abelian if n is even with a number of generators equal to the number of partitions of $n/2$. Indepently Novikov [1960, Thm. 4] showed that as a ring the unitary bordism groups are isomorphic to the ring of polynomials over the integers with generators x_{2i} of degree $2i$ for $i \ge 1$. The spectrum MU that the Thom spaces $MU(k)$ defines permitted Atiyah [1961] to define the homotopy unitary bordism groups $MU_*(X)$ and the homotopy unitary cobordism groups $MU^*(X)$ of a space X as a generalized homology and cohomology theory respectively. Thom's theorem implies that for X a CW-complex the unitary bordism groups over X are equivalent to the homotopic ones $\Omega_*(X) \cong MU_*(X)$ via the Thom-Pontrjagin map.

The spectral sequence of Atiyah and Hirzebruch [1961] (cf. Kochman [1996, §4.2]) applied to the unitary bordism groups of a CW-complex X produces a spectral sequence which converges to $\Omega_*(X)$ and whose second page is $E^2_{p,q} \cong H_p(X; \Omega_q)$; let us call this spectral sequence the *bordism spectral sequence*. The Thom homomorphism

$$\mu : \Omega_*(X) \to H_*(X;\mathbb{Z}), \ \ [M, f : M \to X] \mapsto f_*[M],$$

which takes a unitary bordism element in X and maps it to he image under f of the fundamental class $[M] \in H_*(M;\mathbb{Z})$, is a natural transformation of homology theories and is also the edge homomorphism $\Omega_*(X) \to E^2_{*,0} \cong H_*(X;\mathbb{Z})$ of the spectral sequence.

Whenever X is a CW-complex whose homology $H_*(X;\mathbb{Z})$ is free abelian then by Conner and Smith [1969, Lemma 3.1] the bordism spectral sequence collapses, the unitary bordism group $\Omega_*(X)$ is a free Ω_*-module and the homomorphism induced by Thom map

$$\widetilde{\mu} : \mathbb{Z} \underset{\Omega_*}{\otimes} \Omega_*(X) \to H_*(X;\mathbb{Z})$$

is an isomorphism.

Applying the bordism spectral sequence to the unitary bordism groups of $BU(n)$ it is shown in Kochman [1996, Prop. 4.3.3] that $\Omega_*(BU(n))$ is a free Ω_*-module with basis

$$\Omega_*(BU(n)) \cong \Omega_*\{\alpha_{k_1}\alpha_{k_2}\dots\alpha_{k_n} : k_1 \leq \dots \leq k_n\}$$

where $\alpha_{k_1}\alpha_{k_2}\dots\alpha_{k_n}$ is the unitary bordism class of the bordism element

$$(\mathbb{C}P^{k_1} \times \dots \times \mathbb{C}P^{k_n}, F : \mathbb{C}P^{k_1} \times \dots \times \mathbb{C}P^{k_n} \to BU(n))$$

where the map F classifies the canonical rank n complex vector bundle over the product of projective spaces.

In Conner and Smith [1969, Prop. 3.6] it is shown that if X is a finite CW-complex such that the Thom homomorphism is surjective then the bordism spectral sequence collapses. Whenever BG is the classifying space of a finite group G Landweber [1971, Thm. 3] showed that the following conditions are equivalent:

- The Thom homomorphism $\mu : \Omega_*(BG) \to H_*(BG;\mathbb{Z})$ is surjective.
- The bordism spectral sequence collapses.
- G has periodic cohomology, i.e. every abelian subgroup of G is cyclic.
- $H^n(BG;\mathbb{Z}) = 0$ for all odd n.
- The projective dimension of $\Omega_*(BG)$ as a Ω_*-module is 1 or 0.

The previous result implies that whenever we consider the cyclic group $G = \mathbb{Z}/k$ of order k, the bordism classes $[L^{2n+1}(k), \iota : L^{2n+1}(k) \to B\mathbb{Z}_k]$ of the Lens spaces $L^{2n+1}(k) := S_k^{2n+1}/(\mathbb{Z}/k)$, where S_k^{2n+1} denotes the sphere of unit vectors in $\mathbb{C}^{n+1}$

with the $\mathbb{Z}/k$-action given by multiplication of the root of unity $e^{\frac{2\pi i}{k}}$, generate $\Omega_*(B\mathbb{Z}_k)$ as a Ω_*-module.

One property of finite abelian groups that will be used is the following. If A is a subgroup of a finite abelian group G and Γ is a product of classifying spaces of the form $B_G U(k)$, then by Theorem 2.3 the fixed point set Γ^A is a product of classifying spaces of the form $B_{G/A}U(l)$. This fact permits to use an induction hypothesis when calculating the equivariant unitary bordism groups of products of spaces of the form $B_G U(k)$.

Now when can start with the proof of the evenness conjecture for finite abelian groups. First we will handle the case of cyclic p-groups following Landweber [1972], then we will review the case of general abelian p-groups following Stong [1970] and we will show the general case using a simple argument on localization shown in Ossa [1972].

3.1 Cyclic p-groups. Let G be a cyclic group of order p^s a power of the prime p. Let $\Gamma := \prod_{i=1}^{l} B_G U(k_i)$ be a product of spaces of the form $B_G U(k)$ and $\mathfrak{F}_t = \{H \subset G : |H| \leq p^t\}$ the family of of subgroups or order bounded by p^t; the family $\mathfrak{F}_s$ is the family of all subgroups of G and therefore $\Omega_*^G(\ ) = \Omega_*^G\{\mathfrak{F}_s\}(\ )$. Let us split $\Omega_*^G(\ ) = \Omega_+^G(\ ) \oplus \Omega_-^G(\ )$ where $\Omega_+^G(\ )$ denotes the even degree bordism groups and $\Omega_-^G(\ )$ the odd degree ones. We will prove by induction on the size of the group that for any $0 \leq t < s$ the following properties hold:

- $\Omega_*^G\{\mathfrak{F}_s, \mathfrak{F}_t\}(\Gamma)$ is a free Ω_*-module in even dimensional generators.
- $\Omega_+^G\{\mathfrak{F}_t, \mathfrak{F}_{t-1}\}(\Gamma)$ is a free Ω_*-module.
- The boundary homomorphism is surjective

$$\Omega_+^G\{\mathfrak{F}_s, \mathfrak{F}_t\}(\Gamma) \xrightarrow{\partial} \Omega_-^G\{\mathfrak{F}_t, \mathfrak{F}_{t-1}\}(\Gamma).$$

Let us see that these properties imply that $\Omega_*^G(\Gamma)$ is a free Ω_*-module in even dimensional generators. Since $\Omega_*^G\{\mathfrak{F}_s, \mathfrak{F}_0\}(\Gamma)$ is a free Ω_*-module in even dimensional generators, the long exact sequence associated to the families of groups $\mathfrak{F}_0 \subset \mathfrak{F}_s$ induce the exact sequence

$$0 \to \Omega_+^G\{\mathfrak{F}_0\}(\Gamma) \to \Omega_+^G(\Gamma) \to \Omega_+^G\{\mathfrak{F}_s, \mathfrak{F}_0\}(\Gamma) \xrightarrow{\partial} \Omega_-^G\{\mathfrak{F}_0\}(\Gamma) \to \Omega_-^G(\Gamma) \to 0.$$

The unitary bordism group of free actions $\Omega_*^G\{\mathfrak{F}_0\}(\Gamma)$ is isomorphic to $\Omega_*(BG \times \prod_{i=1}^{l} BU(k_i))$ since both $EG \times B_G U(k_i)$ and $EG \times BU(k_i)$ classify G-equivariant complex vector bundles of rank k_i over free G-spaces. The unitary bordism groups of

$BU(k_i)$ are free Ω_*-modules in even dimensional generators, and therefore by the Kunneth theorem we have that

$$\Omega_*^G\{\mathfrak{F}_0\}(\Gamma) \cong \Omega_*(BG) \underset{\Omega_*}{\otimes} \Omega_* \left(\prod_{i=1}^{l} BU(k_i) \right).$$

Hence we have that $\Omega_+^G\{\mathfrak{F}_0\}(\Gamma)$ is a free Ω_*-module in even degrees and that $\Omega_-^G\{\mathfrak{F}_0\}(\Gamma)$ is all p-torsion. Consider a unitary bordism class defined by the map $h : M \to \prod_{i=1}^{l} BU(k_i)$ and denote by $E := E_1 \oplus \cdots \oplus E_l$ with E_j the complex vector bundle that the map $\pi_j \circ h : M \to BU(k_j)$ defines. Take the ball $B_{p^s}^{2n+2}$ of vectors in $\mathbb{C}^{n+1}$ with norm less than 1 endowed with the action of G given by multiplication by $e^{\frac{2\pi i}{p^s}}$ and consider the G-equivariant $\prod_{i=1}^{l} U(k_i)$ complex bundle that the product $B_{p^s}^{2n+2} \times E \to B_{p^s}^{2n+2} \times M$ defines.

This G-equivariant $\prod_{i=1}^{l} U(k_i)$ complex bundle is classified by a G-equivariant map

$$f : B_{p^s}^{2n+2} \times M \to \Gamma$$

and its G-equivarian unitary bordism class $[B_{p^s}^{2n+2} \times M, f]$ belongs to $\Omega_+^G\{\mathfrak{F}_s, \mathfrak{F}_0\}(\Gamma)$. Its boundary is $[S_{p^s}^{2n+1} \times M, f|_{S_{p^s}^{2n+1} \times M}]$ and it belongs to $\Omega_-^G\{\mathfrak{F}_0\}(\Gamma)$. By the Kunneth isomorphism described above we know that the unitary bordism classes $[S_{p^s}^{2n+1} \times M, f|_{S_{p^s}^{2n+1} \times M}]$ generate $\Omega_-^G\{\mathfrak{F}_0\}(\Gamma)$ and therefore the boundary homomorphism $\Omega_+^G\{\mathfrak{F}_s, \mathfrak{F}_0\}(\Gamma) \xrightarrow{\partial} \Omega_-^G\{\mathfrak{F}_0\}(\Gamma)$ is surjective. This implies that $\Omega_-^G(\Gamma)$ is trivial.

Since $\Omega_+^G\{\mathfrak{F}_0\}(\Gamma) \cong \Omega_+(\prod_{i=1}^{l} BU(k_i))$ is a free Ω_*-module, and by hypothesis $\Omega_+^G\{\mathfrak{F}_s, \mathfrak{F}_0\}$ also, then it implies that $\Omega_+^G(\Gamma)$ is a free Ω_*-module.

In particular we have that the G-equivariant unitary bordism group Ω_*^G is a free Ω_*-module in even dimensional generators.

Now let us sketch the proof of the properties cited above. Let us assume that the properties hold for cyclic groups of order less than p^s and let us proceed by induction on the families of subgroups of G. For the adjacent pair of families $(\mathfrak{F}_s, \mathfrak{F}_{s-1})$ differing by the group G, we know by Theorem 2.8 that $\Omega_*^G\{\mathfrak{F}_s, \mathfrak{F}_{s-1}\}(\Gamma)$ is a direct sum of groups $\Omega_*(\Gamma^G \times \Gamma')$ where both Γ^G and Γ' are products of classifying spaces of unitary groups. Therefore $\Omega_*^G\{\mathfrak{F}_s, \mathfrak{F}_{s-1}\}(\Gamma)$ is a free Ω_*-module in even dimensional generators and we have started our induction.

Now let us assume that the properties hod for the pair of families $(\mathfrak{F}_s, \mathfrak{F}_j)$ for $s > j \geq t$. Therefore we get the following exact sequence of groups

$$\begin{aligned} 0 \to \Omega_+^G\{\mathfrak{F}_t, \mathfrak{F}_{t-1}\}(\Gamma) \to \Omega_+^G\{\mathfrak{F}_s, \mathfrak{F}_{t-1}\}(\Gamma) \to \Omega_+^G\{\mathfrak{F}_s, \mathfrak{F}_t\}(\Gamma) \xrightarrow{\partial} \\ \Omega_-^G\{\mathfrak{F}_t, \mathfrak{F}_{t-1}\}(\Gamma) \to \Omega_-^G\{\mathfrak{F}_s, \mathfrak{F}_{t-1}\}(\Gamma) \to 0. \end{aligned} \tag{3.1}$$

Since the pair of families $(\mathfrak{F}_t, \mathfrak{F}_{t-1})$ differ by the cyclic group H or order p^t, G/H is a cyclic group of order p^{s-t}, and Γ^H is a product of classifying spaces of the form $B_{G/H}U(k)$, then by Theorem 2.8 there is an isomorphism

$$\Omega_*^G\{\mathfrak{F}_t, \mathfrak{F}_{t-1}\}(\Gamma) \cong \bigoplus_{k\geq 0} \Omega_{*-2k}^{G/H}\{\mathfrak{F}_0\}(\Gamma^H \times C_{G,H}(k))$$

where both Γ^H and $C_{G,H}(k)$ are disjoint unions of products of classifying spaces of the form $B_{G/H}U(k)$.

Therefore we know that $\Omega_+^G\{\mathfrak{F}_t, \mathfrak{F}_{t-1}\}(\Gamma)$ is a free Ω_*-module and by the induction hypothesis we know that the boundary map

$$\Omega_+^{G/H}\{\mathfrak{F}_{s-t}, \mathfrak{F}_0\}(\Gamma^H \times C_{G,H}(k)) \xrightarrow{\partial} \Omega_-^{G/H}\{\mathfrak{F}_0\}(\Gamma^H \times C_{G,H}(k)) \tag{3.2}$$

is surjective. A bordism class in $\Omega_-^G\{\mathfrak{F}_t, \mathfrak{F}_{t-1}\}(\Gamma)$ can be represented by a class $[D(E), f : D(E) \to \Gamma]$ where $D(E)$ is the disk bundle of a G-equivariant vector bundle $E \to M$ over a manifold M on which H acts trivially and G/H acts freely, and such that the trivial representation of H does not appear on the fibers of E. This bundle is classified by a G/H-equivariant map $h : M \to C_{G,H}(k)$ for some k, and the bordism class $[M, f|_M \times h : M \to \Gamma^H \times C_{G,H}(k)]$ lives in $\Omega_-^{G/H}\{\mathfrak{F}_0\}(\Gamma^H \times C_{G,H}(k))$. By the surjectivicty of (3.2) there is a bordism class $[Z, F \times \tilde{h} : Z \to \Gamma^H \times C_{G,H}(k)]$ in $\Omega_+^{G/H}\{\mathfrak{F}_{s-t}, \mathfrak{F}_0\}(\Gamma^H \times C_{G,H}(k))$ such that $\partial Z = M$, $F|_M = f|_M$ and $\tilde{h}|_M = h$. Let $p : V \to Z$ denote the G-equivariant vector bundle over Z that the map $\tilde{h}$ defines and note that the bordism class $[D(V), F \circ p : D(V) \to \Gamma]$ defines an element in $\Omega_*^G\{\mathfrak{F}_s, \mathfrak{F}_t\}(\Gamma)$ since the trivial H-representation does not appear on the fibers of V and the action of G/H over M is free. The boundary of $D(V)$ is the union of the sphere bundle $S(V)$ and $D(V)|_M = D(E)$, but since $S(V)$ is $\mathfrak{F}_{t-1}$-free we have that

$$\begin{aligned}\partial[D(V), F \circ p : D(V) \to \Gamma] &= [D(E), p|_E \circ f|_M : D(E) \to \Gamma] \\ &= [D(E), f : D(E) \to \Gamma]\end{aligned}$$

and therefore the boundary map

$$\Omega_+^G\{\mathfrak{F}_s, \mathfrak{F}_t\}(\Gamma) \xrightarrow{\partial} \Omega_-^G\{\mathfrak{F}_t, \mathfrak{F}_{t-1}\}(\Gamma)$$

is surjective.

By the long exact sequence of (3.1) we deduce that $\Omega_*^G\{\mathfrak{F}_s, \mathfrak{F}_{t-1}\}(\Gamma)$ is a free Ω_*-module on even-dimensional generators and we conclude that the properties also hold for the pair of families $(\mathfrak{F}_s, \mathfrak{F}_{t-1})$.

Therefore the evenness conjecture holds for cyclic p-groups Landweber [1972, Thm. 1’].

3.2 General p-groups. The argument to show the evenness conjecture for general p-groups is more elaborate than the one done above for cyclic p-groups. We will follow the original proof of Stong [1970] on which the author uses very cleverly the Thom isomorphism and the long exact sequence for pairs of spaces in order to understand the long exact sequence for a pair of families once restricted to a special kind of actions on manifolds. Here we shorten the original proof and we highlight its main ingredients.

Let $G = H \times \mathbb{Z}/q$ with $q = p^s$ such that all elements in H have order less or equal than p^s and let

$$\Gamma := \prod_{i=1}^{l} B_G U(k_i)$$

be a product of spaces of the form $B_G U(k)$. We will show by induction on the order of the group G that the bordism group $\Omega_*^G(\Gamma)$ is a free Ω_*-module on even dimensional generators. Therefore let us assume that $\Omega_*^K(\Gamma')$ is a free Ω_*-module in even dimensional generators for all p-groups of order less than the order of G and Γ' any product of classifying spaces of the form $B_K U(l)$.

Following the notation of Stong [ibid.] let us consider the following families of subgroups of G:

- $\mathfrak{F}_a$ is the family of all subgroups of G,
- $\mathfrak{F}_s$ is the family of subgroups whose intersection with $\mathbb{Z}/q$ is proper, i.e. $\mathfrak{F}_s := \{W \subset H \times Z/q \colon \{1\} \times Z/q \not\subset W\}$,
- $\mathfrak{F}_f$ is the family of subgroups whose intersection with $\mathbb{Z}/q$ is the unit subgroup, i.e. $\mathfrak{F}_f := \{W \subset H \times Z/q \colon \{1\} \times Z/q \cap W = \{(1,1)\}$

A manifold M is $\mathfrak{F}_s$-free if for every $x \in M$ the isotropy group $(\mathbb{Z}/q)_x \neq \mathbb{Z}/q$, and it is $\mathfrak{F}_f$-free if the restriction of the action to $\mathbb{Z}/q$ is free.

The classifying space $E\mathfrak{F}_f$ has a free $\mathbb{Z}/q$-action and can be understood as the universal H-equivariant $\mathbb{Z}/q$-principal bundle $E_H\mathbb{Z}/q$ Lück and Uribe [2014, Thm 11.4] . Hence $E\mathfrak{F}_f = E_H\mathbb{Z}/q$ and its quotient $E\mathfrak{F}_f/(\mathbb{Z}/q) = B_H\mathbb{Z}/q$ is the classifynig space of H-equivariant $\mathbb{Z}/q$-principal bundles. By the isomorphism of (1.2), and since the action of $\mathbb{Z}/q$ is free, we get the following isomorphisms (see Stong [1970, Prop. 3.1]):

$$\Omega_*^G\{\mathfrak{F}_f\}(X) \cong \Omega_*^G(X \times E_H\mathbb{Z}/q) \cong \Omega_*^H(X \times_{\mathbb{Z}/q} E_H\mathbb{Z}/q). \tag{3.3}$$

Since both spaces $E_H\mathbb{Z}/q \times B_G U(k_i)$ and $E_H\mathbb{Z}/q \times B_H U(k_i)$ classify $H \times \mathbb{Z}/q$-equivariant $U(k_i)$-principal bundles over spaces with free $\mathbb{Z}/q$-action, we may take the maps

$$B_H U(k_i) \to B_G U(k_i) \to B_H U(k_i),$$

where the left hand side map classifies the G-equivariant complex bundles such that the action of $\mathbb{Z}/q$ is trivial over the total space of the bundle, and the right hand side is the one that forgets the $\mathbb{Z}/q$-action, thus producing G-equivariant homotopy equivalences.

$$E_H\mathbb{Z}/q \times E_H U(k_i) \xrightarrow{\simeq} E_H\mathbb{Z}/q \times E_G U(k_i) \xrightarrow{\simeq} E_H\mathbb{Z}/q \times E_H U(k_i).$$

If we denote by

$$\Gamma' := \prod_{i=1}^{l} B_H U(k_i)$$

and the map $\iota : \Gamma' \to \Gamma$ is the one that classifies trivial $\mathbb{Z}/q$-bundles over H-spaces, then the argument above implies that the following isomorphism holds (see Stong [ibid., Prop. 3.2]) :

(3.4) $$\Omega_*^H(B_H\mathbb{Z}/q \times \Gamma') \cong \Omega_*^G(E_H\mathbb{Z}/q \times \Gamma') \underset{\cong}{\xrightarrow{\iota_*}} \Omega_*^G\{\mathfrak{F}_f\}(\Gamma).$$

Let T be the generator of the group $\mathbb{Z}/q$ and denote by $\mathbb{Z}/p^t$ the subgroup generated by $T^{p^{s-t}}$. A manifold is $\mathfrak{F}_f$-free if and only if $T^{p^{s-1}}$ acts freely and therefore a $(\mathfrak{F}_a, \mathfrak{F}_f)$-manifold M can be localized to the normal bundle of the fixed point set $M^{\mathbb{Z}/p}$ of the subgroup $\mathbb{Z}/p$. The normal bundle is a G-equivariant complex bundle over the trivial $\mathbb{Z}/p$ space and once it is classified to the appropriate spaces $C_{G,\mathbb{Z}/p}(k)$ of (2.5) we obtain the isomorphism (see Stong [ibid., Prop. 3.4]):

(3.5) $$\Omega_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(X) \cong \bigoplus_{0\le 2k\le *} \Omega_{*-2k}^{G/(\mathbb{Z}/p)}\left(X^{\mathbb{Z}/p} \times C_{G,\mathbb{Z}/p}(k)\right).$$

Applying the previous isomorphism to $\Gamma = \prod_{i=1}^{l} B_G U(k_i)$ we obtain that

$$\Omega_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma)$$

is a free Ω_*-module in even dimensional generators since both $\Gamma^{\mathbb{Z}/p}$ and $C_{G,\mathbb{Z}/p}(k)$ are products of spaces of the form $B_{G/(\mathbb{Z}/p)}U(l)$ and by induction we assumed that the evenness conjecture was true for groups of order less than the one of G and spaces of this type. Therefore the long exact sequence for the pair of families $(\mathfrak{F}_a, \mathfrak{F}_f)$ becomes:

(3.6) $$0 \to \Omega_+^G\{\mathfrak{F}_f\}(\Gamma) \to \Omega_+^G(\Gamma) \to \Omega_+^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma) \xrightarrow{\partial} \Omega_-^G\{\mathfrak{F}_f\}(\Gamma) \to \Omega_-^G(\Gamma) \to 0.$$

A $(\mathfrak{F}_a, \mathfrak{F}_s)$-free manifold M once restricted to the action of $\mathbb{Z}/q$ becomes a $\mathbb{Z}/q$-manifold on which the boundary has no fixed points of the whole group. Therefore the manifold can be localized on the normal bundle of the fixed point set $M^{\mathbb{Z}/q}$ and the information of th normal bundle can be recorded with appropriate maps to the classifying spaces $C_{G,\mathbb{Z}/q}(k)$ of (2.5). Following the same proof as in Theorem 2.8 one obtains the following isomorphism (see Stong [1970, Prop. 3.3]):

$$\Omega_*^G\{\mathfrak{F}_a, \mathfrak{F}_s\}(X) \cong \bigoplus_{0\leq 2k\leq *} \Omega^H_{*-2k}\left(X^{\mathbb{Z}/q} \times C_{G,\mathbb{Z}/q}(k)\right). \tag{3.7}$$

Since both $\Gamma^{\mathbb{Z}/q}$ and $C_{G,\mathbb{Z}/q}(k)$ are products of spaces of the form $B_H U(l)$, by the induction hypothesis we obtain that $\Omega_*^G\{\mathfrak{F}_a, \mathfrak{F}_s\}(\Gamma)$ is a free Ω_*-module in even dimensional generators.

In order to understand the image of the boundary map of (3.6) Stong restricted the equivariant bordism groups to manifolds with a special type of G action. Stong noticed that the image of the boundary map could be determined by restricting to manifolds on which the $\mathbb{Z}/q$-fixed points are of codimension 2 and therefore he studied the class of *special G actions*.

Definition 3.8. Let $G = H \times \mathbb{Z}/q$ be a finite abelian group. The class of *special G actions* is the collection of G-equivariant unitary manifolds M satisfying:

- The restriction to a $\mathbb{Z}/q$-action is semi-free, i.e. for each $x \in M$ the isiotropy group $(\mathbb{Z}/q)_x$ is either $\mathbb{Z}/q$ or $\{1\}$.
- The set $M^{\mathbb{Z}/q}$ of fixed point sets has codimension 2 in M and $\mathbb{Z}/q$ acts in the normal bundle of $M^{\mathbb{Z}/q}$ so that the generator T of $\mathbb{Z}/q$ acts by multiplication by $e^{\frac{2\pi i}{q}}$, or the fixed point set $M^{\mathbb{Z}/q}$ is empty.

The class of special G actions is sufficiently large to permit all constructions done in Section 1, and for a pair of families $(\mathfrak{F}, \mathfrak{F}')$ in G we denote by $\overline{\Omega}_*^G\{\mathfrak{F}, \mathfrak{F}'\}$ the equivariant homology theory defined by using only special G actions. The inclusion of special G actions in the class of all G actions defines natural transformations of homology theories

$$I_* \colon \overline{\Omega}_*^G\{\mathfrak{F}, \mathfrak{F}'\} \to \Omega_*^G\{\mathfrak{F}, \mathfrak{F}'\}$$

preserving the relations between these functors. The G-equivariant unitary bordism groups of special G actions satisfy the following properties:

(i) The natural transformation

$$I_* \colon \overline{\Omega}_*^G\{\mathfrak{F}_f\} \xrightarrow{\cong} \Omega_*^G\{\mathfrak{F}_f\}$$

is an equivalence since every $\mathfrak{F}_f$ action is a special G action.

(ii) The inclusion $(\mathfrak{F}_a, \mathfrak{F}_f) \subset (\mathfrak{F}_a, \mathfrak{F}_s)$ induces an isomorphism

$$\overline{\Omega}_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(X) \xrightarrow{\cong} \overline{\Omega}_*^G\{\mathfrak{F}_a, \mathfrak{F}_s\}(X)$$

since $\mathfrak{F}_s$-free special G actions are $\mathfrak{F}_f$-free.

(iii) From the equation (3.7) we get the isomorphism

$$\overline{\Omega}_*^G\{\mathfrak{F}_a, \mathfrak{F}_s\}(X) \cong \Omega_{*-2}^H(X^{\mathbb{Z}/q} \times B_H U(1)),$$

thus implying that $\overline{\Omega}_*^G\{\mathfrak{F}_a, \mathfrak{F}_s\}(X)$ maps isomorphically to a direct summand in $\Omega_*^G\{\mathfrak{F}_a, \mathfrak{F}_s\}(X)$.

(iv) For $\Gamma := \prod_{i=1}^l B_G U(k_i)$ the induction hypothesis implies that $\overline{\Omega}_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma)$ is a free Ω_*-module in even dimensional generators. Therefore the canonical maps

$$\overline{\Omega}_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma) \to \Omega_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma) \to \Omega_*^G\{\mathfrak{F}_a, \mathfrak{F}_s\}(\Gamma)$$

imply that $\overline{\Omega}_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma)$ also maps isomorphically to a direct summand in $\Omega_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma)$.

Let us now concentrate in understanding the five term exact sequence restricted to special G actions

(3.9) $$0 \to \overline{\Omega}_+^G\{\mathfrak{F}_f\}(\Gamma) \to \overline{\Omega}_+^G(\Gamma) \to \overline{\Omega}_+^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma) \xrightarrow{\partial} \overline{\Omega}_-^G\{\mathfrak{F}_f\}(\Gamma) \to \overline{\Omega}_-^G(\Gamma) \to 0.$$

Note that the map $\iota_* : \Gamma' \to \Gamma$ induces the commutative diagram

$$\begin{array}{ccccc} \Omega_{*-2}^H(\Gamma^{\mathbb{Z}/q} \times B_H U(1)) & \xrightarrow{\cong} & \overline{\Omega}_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma) & \xrightarrow{\partial} & \overline{\Omega}_{*-1}^G\{\mathfrak{F}_f\}(\Gamma) \\ \uparrow & & \uparrow \iota_* & & \uparrow \iota_* \cong \\ \Omega_{*-2}^H(\Gamma' \times B_H U(1)) & \xrightarrow{\cong} & \overline{\Omega}_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma') & \xrightarrow{\partial} & \overline{\Omega}_{*-1}^G\{\mathfrak{F}_f\}(\Gamma') \end{array}$$

where the middle homomorphism ι_* maps isomorphically $\overline{\Omega}_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma')$ into a direct summand in $\overline{\Omega}_*^G\{\mathfrak{F}_a, \mathfrak{F}_f\}(\Gamma)$ since Γ' is mapped to one connected component of the fixed point set $\Gamma^{\mathbb{Z}/q}$. Therefore the image of the boundary homomorphism ∂ is the same same in both cases.

In what follows we will study the induced boundary homomorphism

(3.10) $$\Omega_{*-2}^H(\Gamma' \times B_H U(1)) \to \overline{\Omega}_{*-1}^G\{\mathfrak{F}_f\}(\Gamma') \cong \Omega_{*-1}^H(\Gamma' \times B_H \mathbb{Z}/q)$$

using the Thom isomorphism, the long exact sequence for pairs and a particular model for $E_H\mathbb{Z}/q$.

Let $\mathbf{C}_H^\infty$ be a countable direct sum of all complex irreducible H-representations and consider the $\mathbb{Z}/q$ action on $\mathbf{C}_H^\infty$ such that the generator T of $\mathbb{Z}/q$ acts by mutliplication of $e^{\frac{2\pi i}{q}}$. The sphere $S(\mathbf{C}_H^\infty)$ of vectors of norm 1 is an $G = \mathbb{Z}/q \times H$ space on which $\mathbb{Z}/q$ acts freely and moreover is a $\mathfrak{F}_f$-free space. Since the non empty fixed point sets are infinitely dimensional spheres we know that this sphere $S(\mathbf{C}_H^\infty)$ is a model for $E_H\mathbb{Z}/q$. The Grassmannian $Gr_1\mathbf{C}_H^\infty$ is a model for $B_HU(1)$ since $\mathbb{Z}/q$ acts trivially on the one dimensional vector spaces, and $\mathbb{Z}/q$ acts on the fibers of the canonical line bundle $\gamma_H U(1) \to B_H U(1)$ by multiplication of $e^{\frac{2\pi i}{q}}$. To simplify the notation denote by

$$\gamma_1 := \gamma_H U(1)$$

and note that $S(\mathbf{C}_H^\infty) \cong S(\gamma_1)$ where $S(\gamma_1)$ denotes the sphere bundle of γ_1.

Consider now the line bundle $\gamma_1^{\otimes q}$ over $B_HU(1)$ which is q-fold tensor product of γ_1. The diagonal map

$$\Delta : \gamma_1 \to \gamma_1^{\otimes q}, \quad v \mapsto v \otimes \cdots \otimes v$$

is a q to 1 map on the fibers of the line bundles and therefore it induces an H-equivariant homeomorphism

$$S(\gamma_1)/(\mathbb{Z}/q) \cong S(\gamma_1^{\otimes q}).$$

Therefore we have that we may take either $S(\gamma_1)/(\mathbb{Z}/q)$ or $S(\gamma_1^{\otimes q})$ as a model for $B_H\mathbb{Z}/q$. The Thom isomorphism

$$\Omega_*^H((D(\gamma_1^{\otimes q}), S(\gamma_1^{\otimes q})) \times \Gamma') \cong \Omega_{*-2}^H(B_HU(1) \times \Gamma')$$

together with the long exact sequence for the pair $(D(\gamma_1^{\otimes q}), S(\gamma_1^{\otimes q}))$ and the induction hypothesis provides a four term exact sequence

$$0 \to \Omega_+^H(\Gamma' \times S(\gamma_1^{\otimes q})) \to \Omega_+^H(\Gamma' \times B_HU(1)) \to \\ \Omega_+^H(\Gamma' \times B_HU(1)) \to \Omega_-^H(\Gamma' \times S(\gamma_1^{\otimes q})) \to 0,$$

where the right hand side homomorphism is precisely the one of (3.10). Therefore we obtain that the boundary homomorphism of (3.10) is surjective, and since by the induction hypothesis $\Omega_+^H(\Gamma' \times B_HU(1))$ is a free Ω_*-module, we conclude that $\Omega_+^H(\Gamma' \times S(\gamma_1^{\otimes q}))$ is also a free Ω_*-module.

Therefore we obtain the following commutative diagram with exact rows

$$\begin{array}{ccccccccccc}
0 \longrightarrow & \Omega_+^G\{\mathfrak{F}_f\}(\Gamma) & \longrightarrow & \Omega_+^G(\Gamma) & \longrightarrow & \Omega_+^G\{\mathfrak{F}_a,\mathfrak{F}_f\}(\Gamma) & \xrightarrow{\partial} & \Omega_-^G\{\mathfrak{F}_f\}(\Gamma) & \longrightarrow 0 \\
& \uparrow\cong & & \uparrow & & \uparrow & & \uparrow\cong & \\
0 \longrightarrow & \overline{\Omega}_+^G\{\mathfrak{F}_f\}(\Gamma) & \longrightarrow & \overline{\Omega}_+^G(\Gamma) & \longrightarrow & \overline{\Omega}_+^G\{\mathfrak{F}_a,\mathfrak{F}_f\}(\Gamma) & \xrightarrow{\partial} & \overline{\Omega}_-^G\{\mathfrak{F}_f\}(\Gamma) & \longrightarrow 0 \\
& \iota_*\uparrow\cong & & \uparrow & & \uparrow & & \iota_*\uparrow\cong & \\
0 \longrightarrow & \overline{\Omega}_+^G\{\mathfrak{F}_f\}(\Gamma') & \longrightarrow & \overline{\Omega}_+^G(\Gamma') & \longrightarrow & \overline{\Omega}_+^G\{\mathfrak{F}_a,\mathfrak{F}_f\}(\Gamma') & \xrightarrow{\partial} & \overline{\Omega}_-^G\{\mathfrak{F}_f\}(\Gamma') & \longrightarrow 0,
\end{array}$$

thus implying that $\Omega_-^G(\Gamma) = 0$ and that $\Omega_+^G(\Gamma)$ is a free Ω_*-module since both $\Omega_+^G\{\mathfrak{F}_f\}(\Gamma)$ and $\Omega_+^G\{\mathfrak{F}_a,\mathfrak{F}_f\}(\Gamma)$ are free Ω_*-modules.

Therefore the evenness conjecture holds for finite abelian p-groups.

3.3 The general case. The proof of the evenness conjecture for general finite abelian groups was done by Ossa [1972] and is based on the proof of Stong for p-groups and appropriate localizations at different primes. For a finite abelian group K denote by $Z_K := \mathbb{Z}[1/|K|]$ the localization of the integers at the ideal generated by the order of K.

Let $G = K \times L$ with K and L finite abelian with $|K|$ and $|L|$ relatively prime and consider the homomorphism $\Omega_*^{K\times L}\{\mathfrak{F}\} \to \Omega_*^L\{\mathfrak{F}\}$ which forgets the K action and $\mathfrak{F}$ is any family of subgroups of L . Let us show that the localized homomorphism

$$\Omega_*^{K\times L}\{\mathfrak{F}\}(\Gamma) \otimes Z_K \to \Omega_*^L\{\mathfrak{F}\}(\Gamma) \otimes Z_K$$

is an isomorphism whenever $\Gamma := \prod_{i=1}^l B_G U(k_i)$. Let us proceed by induction over L and over the family $\{\mathfrak{F}\}$.

For the trivial family $\mathfrak{F} = \{\{1\}\}$ we obtain the isomorphism

$$\Omega_*(BK \times BL \times \prod_i BU(k_i)) \otimes Z_K \xrightarrow{\cong} \Omega_*(BL \times \prod_i BU(k_i)) \otimes Z_K$$

since $\Omega_*(BK) \otimes Z_K \cong \Omega_* \otimes Z_K$.

Whenever the adjacent pair of families $(\mathfrak{F},\mathfrak{F}')$ differ by $H \subset L$ we obtain the homomorphism of long exact sequences

$$\begin{array}{ccccccc}
\longrightarrow & \Omega_*^{K\times L}\{\mathfrak{F}'\}(\Gamma) & \longrightarrow & \Omega_*^{K\times L}\{\mathfrak{F}\}(\Gamma) & \longrightarrow & \Omega_*^{K\times L/H}\{\{1\}\}(\Gamma^H \times \Gamma') & \longrightarrow \\
& \downarrow & & \downarrow & & \downarrow & \\
\longrightarrow & \Omega_*^{L}\{\mathfrak{F}'\}(\Gamma) & \longrightarrow & \Omega_*^{L}\{\mathfrak{F}\}(\Gamma) & \longrightarrow & \Omega_*^{L/H}\{\{1\}\}(\Gamma^H \times \Gamma') & \longrightarrow
\end{array}$$

with Γ' a disjoint union of products of spaces of the form $B_{K\times L/H}U(l)$. Tensoring with Z_K induces an isomorphism on the left vertical arrow by the induction hypothesis on the families and an isomorphism on the right vertical arrow by the induction hypothesis on the group L/H. The 5-lemma implies the desired isomorphism.

Now let $\mathfrak{F}$ be any family of subgroups of K and denote by $\mathfrak{F}\times\Phi$ the family of subgroups of G whose elements are groups $J \times H$ with $J \in \mathfrak{F}$ and H any subgroup of L. Let us show by induction on $\mathfrak{F}$ and on the group K that the localized module

$$\Omega_*^{K\times L}\{\mathfrak{F}\times\Phi\}(\Gamma)\otimes Z_K$$

is a free $\Omega_*\otimes Z_K$-module. Whenever $\mathfrak{F}$ is the trivial family we have shown above that

$$\Omega_*^{K\times L}\{\{1\}\times\Phi\}(\Gamma)\otimes Z_K \xrightarrow{\cong} \Omega^L(\Gamma)\otimes Z_K$$

is an isomorphism.

If the adjacent pair of families $(\mathfrak{F},\mathfrak{F}')$ differ by the subgroup J, then we obtain the long exact sequence

$$\cdots\to\Omega_*^{K\times L}\{\mathfrak{F}'\times\Phi\}(\Gamma)\to\Omega_*^{K\times L}\{\mathfrak{F}\times\Phi\}(\Gamma)\to\Omega_*^{K/J}\{\{1\}\}(\Gamma^{J\times L}\times\Gamma'')\to\cdots$$

where Γ'' is a disjoint union of spaces of the form $B_{K/J}U(l)$. Tensoring with Z_K gives us free $\Omega_*\otimes Z_K$-modules on the left hand side by the induction on families and on the right hand side by the induction on the group K. Therefore the middle term is also a free $\Omega_*\otimes Z_K$-module.

Therefore we have proved that if $\Omega^L(\Gamma)$ is free Ω_*-module then $\Omega^{K\times L}(\Gamma)\otimes Z_K$ is a free $\Omega_*\otimes Z_K$-module. Let us now write $G = P_1\times\cdots\times P_k$ with P_i its sylow p_i-subgroup. Since the evenness conjecture holds for p-groups, we have that $\Omega_*^{P_i}(\Gamma)$ is a free Ω_*-module and therefore $\Omega_*^G(\Gamma)\otimes\mathbb{Z}[1/[G:P_i]]$ is a free $\Omega_*\otimes\mathbb{Z}[1/[G:P_i]]$-module. Since the numbers $[G:P_i]$ are relatively prime it follows that $\Omega_*^G(\Gamma)$ is a free Ω_*-module.

Therefore the evenness conjecture holds for finite abelian groups.

4 The equivariant unitary bordism groups for non abelian groups

The evenness conjecture has been shown to be true for the dihedral groups D_{2p} with p-prime by Ángel, Gómez, and B. Uribe [n.d.], for groups of order pq where p and q are different primes by Lazarov [1972] and for the more general case of metacyclic groups by Rowlett [1980]. In these cases the group G is a semidirect product $\mathbb{Z}/r\rtimes\mathbb{Z}/s$ of cyclic groups with r and s relatively prime, and the study of the equivariant unitary bordism groups is also carried out calculating the equivariant unitary bordism groups of adjacent pair of families of subgroups as is done in the cyclic group case of Section 3.1.

The main tool used by Rowlett to study the metacyclic case is the equivariant unitary spectral sequence constructed by himself in Rowlett [1978, Prop. 2.1]. Suppose that A is a normal subgroup of G and that $Q = G/A$. A family $\mathfrak{F}$ of subgroups of A is called G-invariant if it is closed under conjugation by elements of G. Consider a pair $(\mathfrak{F}, \mathfrak{F}')$ of G-invariant families of A and note that $\Omega_*^A\{\mathfrak{F}, \mathfrak{F}'\}$ becomes a Q-module in the following way. Consider an A-manifold M with action $\theta : A \times M \to M$ and take an element $g \in G$. Define a new action on M by the map $g_*\theta : A \times M \to M$, $g_*(a, m) := \theta(g^{-1}ag, m)$ and denote the action of g on the bordism class $[M, \theta]$ by $\overline{g}[M, \theta] := [M, g_*\theta]$. This action is trivial on elements of A and therefore it boils down to an action of Q. Then there is a first quadrant spectral sequence E^r converging to $\Omega_*^G\{\mathfrak{F}, \mathfrak{F}'\}$ whose second page is

$$E^2_{p,q} \cong H_p(Q, \Omega_q^A\{\mathfrak{F}, \mathfrak{F}'\}).$$

In the case that both groups A and Q are cyclic of relative prime order, the action of Q on $\Omega_+^A\{\mathfrak{F}, \mathfrak{F}'\}$ factors through a permutation action on the free generators and therefore the second page is not difficult to calculate. If we take the family $\mathfrak{F}_A$ of all subgroups of A, the second page of the spectral sequence becomes $H_q(Q, \Omega_q^A)$, and since Ω_*^A is a free Ω-module in even dimensional generators, then we obtain that $\Omega_+^G\{\mathfrak{F}\}$ is a free Ω_*-module. Moreover, the same explicit construction carried out in Section 3.1 can be adopted in this case to show that the long exact sequence associated to the pair of families $\{\mathfrak{F}_a, \mathfrak{F}_A\}$, with $\mathfrak{F}_a$ the family of all subgroups, becomes

$$0 \to \Omega_+^G\{\mathfrak{F}_A\} \to \Omega_+^G \to \Omega_+^G\{\mathfrak{F}_a, \mathfrak{F}_A\} \xrightarrow{\partial} \Omega_-^G\{\mathfrak{F}_A\} \to 0.$$

The same argument as in (3.5) shows that $\Omega_*^G\{\mathfrak{F}_a, \mathfrak{F}_A\}$ is a free Ω_*-module in even dimensional generators and therefore we conclude that Ω_-^G is zero and Ω_+^G a free Ω_*-module.

The spectral sequence defined above can also be used in order to understand the torsion free part of the G-equivariant unitary groups for any abelian group. Take any subgroup A of G and let $(\mathfrak{F}_A, \mathfrak{F}'_A)$ be the adjacent pair of families of G which differ by the conjugacy class of A. Tensoring with the rationals we obtain an isomorphism

$$\Omega_*^G\{\mathfrak{F}_A, \mathfrak{F}'_A\} \otimes \mathbb{Q} \cong \Omega_*^A\{\mathfrak{F}_A, \mathfrak{F}'_A\}^{W_A} \otimes \mathbb{Q}$$

where the right hand side consists of the W_A-invariant part. Since $\Omega_*^A\{\mathfrak{F}_A, \mathfrak{F}'_A\}$ is a free Ω_*-module in even dimensional generators we obtain the isomorphism

$$\Omega_*^G \otimes \mathbb{Q} \cong \bigoplus_{(A)} \Omega_*^A\{\mathfrak{F}_A, \mathfrak{F}'_A\}^{W_A} \otimes \mathbb{Q}$$

where (A) runs over the conjugacy classes of subgroups of G (see Rowlett [ibid., Thm. 1.1], c.f. tom Dieck [1973, Thm. 1]). In particular the torsion-free component of Ω_*^G is all of even degree.

Apart from the non-abelian groups which are metacyclic, there is no other finite non-abelian group on which the evenness conjecture has been shown to hold.

The main difficulty lies in the understanding of the equivariant bordism groups $\Omega_*^G\{\mathcal{F}\}(^{\widetilde{G}}B_G U($ of the classifying spaces $^{\widetilde{G}}B_G U(n)$ associated to $\mathbb{S}^1$-central extensions $\widetilde{G}$ of G for different families $\mathcal{F}$ of subgroups. These bordism groups are the ones appearing once we try to calculate the equivariant unitary bordism groups for adjacent pair of families. Any development on the understanding of these equivariant unitary bordism groups will shed a light on the proof of the evenness conjecture for a bigger class of groups.

5 Conclusion

The evenness conjecture for equivariant unitary bordism has been an important question in algebraic topology for more than forty years. The conjecture has been proved to hold only for compact abelian Lie groups and finite metacyclic groups, for all other groups the conjecture remains open. We do hope that the present summary of known results will help settle the conjecture in the near future.

LITTLE DISKS OPERADS AND FEYNMAN DIAGRAMS

Thomas Willwacher

Abstract

The little disks operads are classical objects in algebraic topology which have seen a wide range of applications in the past. For example they appear prominently in the Goodwillie-Weiss embedding calculus, which is a program to understand embedding spaces through algebraic properties of the little disks operads, and their action on the spaces of configurations of points (or disks) on manifolds. In this talk we review the recent understanding of the rational homotopy theory of the little disks operads, and how the resulting knowledge can be used to fulfil the promise of the Goodwillie-Weiss calculus, at least in the "simple" setting of long knot spaces and over the rationals. The derivations prominently use and are connected to graph complexes, introduced by Kontsevich and other authors.

1 Introduction

The little disks operads are collections of spaces $\mathrm{D}_n(r)$ of rectilinear embeddings of r little disks in the n-dimensional unit disk

$$\mathrm{D}_n(r) = \mathrm{Emb}^{rl}(\mathbb{D}_n^{\sqcup r}, \mathbb{D}_n).$$

Here rectilinear means that the embedding may rescale and translate the little disks, but not rotate or otherwise deform them. The operadic compositions are defined through the gluing of configurations of disks, with one configuration being

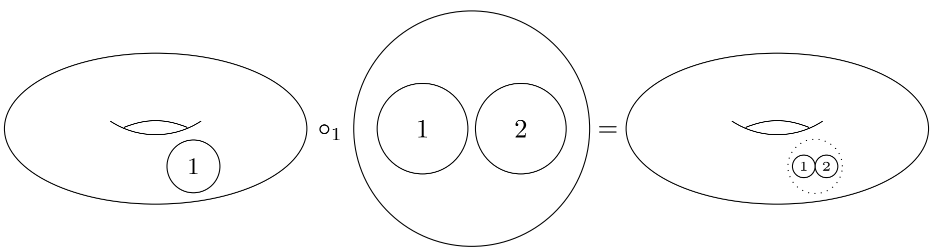
MSC2010: primary 18D50; secondary 55P62, 57Q45, 81T18, 57R56.

inserted in place of small disk as the following example illustrates.

(1) 
The framed little n-disks operad D_n^{fr} is a variant in which one allows the embeddings to also rotate the little disks.

The little disks operads have seen various applications in algebra, topology, and even some branches of mathematical physics. We will focus on one particular relatively recent application here, the manifold calculus of Weiss and Goodwillie [1999] and Weiss [1999]. To this end let M be a manifold of dimension m. We may consider the spaces of embeddings of m-dimensional disks in M, $\mathrm{conf}_M(r) = \mathrm{Emb}(\mathbb{D}_m^r, M)$. Again by composition of embeddings (i.e., gluing of disks) the operad D_m (and likewise D_m^{fr}) naturally acts on the the collection of spaces conf_M.



The idea of the Goodwillie-Weiss manifold calculus is then that properties of the space M, and spaces derived from it, may be accessed using the spaces $\mathrm{conf}_M(r)$ and the action of $\mathrm{D}_n^{(fr)}$ upon them. In particular, for N another manifold of dimension n, and under the technical condition that $n \geq m+3$, one can express the space of embeddings from M into N as a derived mapping space between the right D_m^{fr}-modules conf_M and conf_N, see the work of Weiss and Boavida de Brito [2013],

$$\mathrm{Emb}(M, N) \simeq \mathrm{Map}^h_{mod-\mathrm{D}_m^{fr}}(\mathrm{conf}_M, \mathrm{conf}_N). \tag{2}$$

In other words, the manifold calculus replaces the complicated topological space of knottings of M in N on the left by a (potentially) accessible algebraic object on the right. One problem of this approach had been that the algebraic object on the right is still relatively complicated and hard to understand. However, due to recent progress in understanding the rational (or real) homotopy theory of the little disks operads and configuration spaces Campos and Willwacher [2016] and Idrissi [2016], information about the right-hand side may be obtained.

For this exposition we will in fact restrict to the simplest setting, when $M = \mathbb{R}^m$ and $N = \mathbb{R}^n$. In this case one studies the spaces of long knots $\mathrm{Emb}_\partial(\mathbb{R}^m, \mathbb{R}^n)$, i.e., of embeddings of $\mathbb{R}^m$ into $\mathbb{R}^n$ which agree with the standard embedding outside of a compact. For technical reasons one furthermore reduces to the homotopy fiber over immersions

$$\overline{\mathrm{Emb}}_\partial(\mathbb{R}^m, \mathbb{R}^n) = \mathrm{hofiber}\left(\mathrm{Emb}_\partial(\mathbb{R}^m, \mathbb{R}^n) \to \mathrm{Imm}_\partial(\mathbb{R}^m, \mathbb{R}^n)\right).$$

The appropriate version of the embedding calculus for this situation then states that for $n - m \geq 3$ there is a weak equivalence (cf. Weiss and Boavida de Brito [2015], Ducoulombier and Turchin [2017], and Dwyer and Hess [2012])

$$\overline{\mathrm{Emb}}_\partial(\mathbb{R}^m, \mathbb{R}^n) \simeq \Omega^{m+1}\mathrm{Map}^h_{op}(\mathrm{D}_m, \mathrm{D}_n), \tag{3}$$

where on the right-hand side we have the $m+1$-fold loop space of the derived mapping space of operads between D_m and D_n. In particular, note that the Goodwillie-Weiss calculus states that the homotopy type of the space of (codimension $\geq$ 3-)knots is already fully encoded in the homological algebra of the relatively "simple" insertion operations (1).

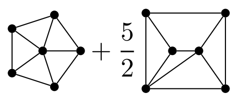
The final result we want to study is that the rational homotopy type of the right-hand side of (3) may be computed and expressed fully in terms of combinatorial data, through graph complexes and algebraic structures on graph complexes. The results we review here are mostly taken from joint works of the author Fresse and Willwacher [2015] and Fresse, Turchin, and Willwacher [2017b]. We also refer to these works for more technical details, which often have to be omitted from our exposition for reasons of brevity.

Notation and conventions. We generally work over the ground field $\mathbb{Q}$ unless otherwise stated, i.e., all vector spaces, commutative algebras etc. are considered over $\mathbb{Q}$. As usual we abbreviate the phrase "differential graded" by dg, and "differential graded commutative algebra" by dgca. We omit the prefix dg if clear from the context. For example "vector space" will typically mean dg vector space. We generally work in cohomological conventions, so that all of our differentials have degree +1. For a (dg) vector space V we denote by $V[k]$ the degree shifted vecor space. If $v \in V$ has degree d then the corresponding object in $V[k]$ has degree

$d - k$. For an introduction to the language of operads we refer the reader to the textbooks Loday and Vallette [2012] or Fresse [n.d.], whose notation we shall essentially follow. A standard reference for the little disks operads is May [1972, section 4].

2 Graph complexes

Graph complexes are differential graded vector spaces of linear combinations or series of combinatorial graphs. There are various versions depending on the type of graphs considered, for example complexes of undirected graphs, directed acyclic graphs, ribbon graphs etc. Here we will consider only the simplest version, as introduced by M. Kontsevich. We define GC_n to be the $\mathbb{Q}$-vector space of series of isomorphism classes of admissible graphs. Here an admissible graph is a connected undirected graph with an orientation, all of whose vertices have valence ≥ 2, and which does not have odd symmetries, a condition we shall elucidate shortly.

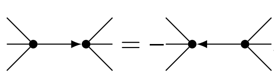


The definition depends on an integer n, which determines the cohomological degree of graphs, with a graph in GC_n being assigned degree

$$(\#\text{vertices} - 1)n - (\#\text{edges})(n - 1).$$

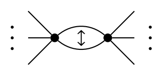
In other words, we consider the vertices as carrying degree n, and the edges as carrying degree $1-n$. An orientation on a graph Γ is the following data, depending on the parity of n:

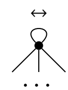
- For n even, an orientation of Γ is an ordering or of the set of edges of Γ. If two such orderings or, or′ differ by a permutation σ, we identify the oriented graphs up to sign
$$(\Gamma, \mathrm{or}) = \mathrm{sgn}(\sigma)(\Gamma, \mathrm{or}').$$
- For n odd an orientation consists of an ordering of the set of vertices and half-edges. Again we identify two such orderings up to sign. Note that providing an ordering of the set of half-edges up to sign is equivalent to providing a direction on edges, identifying directions up to sign



The presence of the orientation implies that graphs with orientation reversing (odd) symmetries yield zero vectors in the graph complex. More concretely, for n even and odd symmetry of a graph is an automorphism inducing an odd permutation on the set of edges. Similarly, for n odd an odd symmetry is an automorphism inducing an odd permutation on the set of half-edges and vertices.

Note that this in particular implies that for n even any graph with a double edge is considered zero, for it has an odd symmetry by swapping the edges in the double edge. Likewise, for n odd any graph with a tadpole (or short cycle) is zero due to the symmetry reversing the cycle.

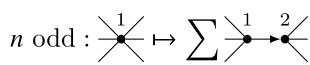




We define on GC_n a differential d, splitting vertices of graphs. More concretely

$$d\Gamma = \sum_v split(\Gamma, v)$$

with the operation $split(\Gamma, v)$ replacing the vertex v by two vertices connected by an edge and summing over all ways of reconnecting the edges incident at v to the two new vertices. Here the orientation on graphs in $split(\Gamma, v)$ is chosen so that for n even the newly created edge becomes the first in the ordering of edges. For n odd assume without loss of generality that v is the first vertex in the ordering. The orientation is chosen such that the newly created vertices are the first two in the ordering, with the newly created edge pointing from the first to the second.



It is an easy exercise to check that with these conventions on the orientation $d^2 = 0$, so that we can consider the graph cohomology $H(\mathrm{GC}_n) = \ker d/\mathrm{im} d$. This cohomology is a somewhat mysterious object that can at present only partially be computed. Let us recall a few known facts.

First note that the differential cannot alter the loop order of a graph, and hence the graph complex decomposes into a direct product of subcomplexes of fixed loop order $\mathrm{GC}_n^{k\text{-loop}}$. Furthermore, GC_n depends on n essentially only up to parity, and hence one can see that

$$H^j(\mathrm{GC}_{n+2}^{k\text{-loop}}) \cong H^{j+2k}(\mathrm{GC}_n^{k\text{-loop}}).$$

In particular, knowing $H(\mathrm{GC}_n)$ for one even and one odd n suffices to determine $H(\mathrm{GC}_n)$ for all n. On the other hand, despite considerable effort, the author has not found any relation between $H(\mathrm{GC}_n)$ and $H(\mathrm{GC}_{n+1})$ that would allow for the computation of one through the other.

In low loop orders the graph cohomology can be computed explicitly by hand or with the help of computers. For example, in loop order 1 the most general graph has the form

(4) $L_k =$  (k vertices and k edges, deg$=n-k$).

These graphs have odd symmetries, and hence vanish as elements of the graph complex, unless $k \equiv 2n+1 \mod 4$, so that

$$H(\mathrm{GC}_n^{1\text{-loop}}) \cong \prod_{\substack{k\geq 1 \\ k\equiv 2n+1 \mod 4}} \mathbb{Q}W_k, \tag{5}$$

with the class W_k living in cohomological degree $k-n$.

For loop order $k \geq 2$ one can show that the inclusion of the subcomplex

$$\mathrm{GC}_n^{k\text{-loop},\geq 3} \subset \mathrm{GC}_n^{k\text{-loop}}$$

spanned by graphs all of whose vertices are at least trivalent is a quasi-isomorphism, cf. Kontsevich [1993] and Willwacher [2015b]. In this subcomplex, a graph with v vertices must then have at least $\frac{3}{2}v$ edges, and hence one can derive the simple upper degree bound for $k \geq 2$

$$H^{>-k(n-3)-3}(\mathrm{GC}_n^{k\text{-loop}}) = 0. \tag{6}$$

By somewhat different methods one can also derive a lower degree bound (cf. Willwacher [2015b])

$$H^{<-k(n-2)-1}(\mathrm{GC}_n^{k\text{-loop}}) = 0.$$

Next, we shall note that GC_n carries the structure of a dg Lie algebra. The Lie bracket is defined combinatorially by inserting a graph in vertices of another.

$$[\gamma, \nu] = \gamma \bullet \nu - (-1)^{|\gamma||\nu|}\nu \bullet \gamma$$

with

$$\gamma \bullet \nu := \sum_{x \in V\gamma} \gamma(\text{insert } \nu \text{ in place of } x)$$

In the case of $n = 2$ the author showed the following.

Theorem 1 (Willwacher [ibid.]). The zeroth cohomology $H^0(\mathrm{GC}_2)$ can be identified with the (completed) Grothendieck-Teichmüller Lie algebra $\mathfrak{grt}_1$. Furthermore $H^1(\mathrm{GC}_2) \cong \mathbb{K}$ and $H^{\leq 1}(\mathrm{GC}_2) = 0$.

We will not recall the somewhat technical definition of the Grothendieck-Teichmüller Lie algebra $\mathfrak{grt}_1$ defined by Drinfeld [1990], but rather recall the following important result of Francis Brown.

Theorem 2 (Brown [2012]). There is an injective Lie algebra morphism

$$F_{Lie}(\sigma_3, \sigma_5, \sigma_7, \dots) \to \mathfrak{grt}_1$$

from the complete free Lie algebra in generators $\sigma_3, \sigma_5, \dots$.

Both results together yield an infinite family of nontrivial graph cohomology classes. One can provide explicit integral formulas for the graph cocycles representing σ_{2j+1} as in "P. Etingof's conjecture about Drinfeld associators" [2014]. Concretely, σ_{2k+1} is represented by a linear combination of diagrams of loop order $2k+1$

$\sigma_{2k+1} \simeq$  $+ (\cdots),$

where the first "wheel" graph has $2k+2$ vertices, and the terms (...) on the right which are not explicitly written are linear combinations of graphs all of whose vertices have valence $\leq 2k$.

We shall not recall here in detail the known results for the graph cohomology $H(\mathrm{GC}_3)$, or equivalently $H(\mathrm{GC}_n)$ for n odd. Let us just mention that a large family of non-trivial cohomology classes in top degree is known through Chern-Simons theory. Furthermore there are conjectures regarding the precise shape of the top degree cohomology, see Vogel [2011] and Kneissler [2000, 2001a,b] for details.

Computer generated tables of the numbers $\dim H^j(\mathrm{GC}_n^{k-\mathrm{loop}})$ can be found in Figure 1. The red lines depict the degree bounds beyond which the cohomology is zero. The cohomology classes giving rise to the numbers appearing in the (computer accessible portion of) the tables can be "explained", see Khoroshkin, Willwacher, and Živković [2017] for more details. However, at large we still do not know what $H(\mathrm{GC}_n)$ is, and in particular which entries of the table are zero. To this end, let us just note a famous vanishing conjecture which goes back to Kontsevich, and in a similar form to Drinfeld.

Conjecture 3. $H^1(\mathrm{GC}_2) = 0$.

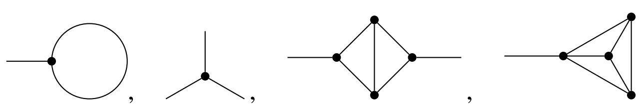
Figure 2: Table of the Euler characteristics of the graph complexes GC_n for even and odd n from Willwacher and Živković [2015]. Note that for high loop orders the Euler characteristics for the even and odd complexes are astonishingly similar, with the sign difference being due to conventions.

As a final remark we shall mention that while the above tables suggest that the cohomology of the graph complexes $H(\mathrm{GC}_n)$ for even and odd n is very different. However, the Euler characteristic computations of GC_n from Willwacher and Živković [2015], which we reproduce in Figure 2, show that at least the Euler characteristics of both complexes in high loop orders are strikingly similar. The author can currently not explain this fact.

2.1 A variant with external legs. We will also need a slight variant of the above graph complexes. We may consider a complex of graphs $\mathrm{HGC}_{m,n}$ built using graphs with "external legs" or hairs, as shown in the following pictures



We require that all non-hair vertices are at least trivalent. The cohomological degree of a graph is determined by the formula

$$n(\#\text{internal vertices}) - (n-1)(\#\text{edges}) + m(\#\text{internal vertices} - 1).$$

Here we count the edges being part of a hair as edges as well. One also equips these hairy graphs with an orientation. Graphs that possess odd symmetries are hence considered zero in the graph complex. The differential is again given by splitting (non-hair) vertices. This operation cannot change the number of hairs, nor the first Betti number (i.e„ the number of loops) of a graph, Hence the complex $\mathrm{HGC}_{m,n}$ splits into a direct product of subcomplexes of fixed number of hairs and loops

$$\mathrm{HGC}_{m,n}^{k\text{-loop},h\text{-hair}} \subset \mathrm{HGC}_{m,n}.$$

In general, the cohomology of these complexes is not known, but at least one has partial information. In low loop orders, or for low numbers of hairs one can explicitly compute the cohomology. For example, in loop order zero the cohomology is precisely one dimensional, and represented by the following graph cocycles:

(7)

 for $n-m$ even, in cohomological degree $m-n+1$

 for $n-m$ odd, in cohomological degree $2(m-n)+3$

The computation of the loop order one cohomology we leave to the reader. The computation in loop order two can be found in Conant, Costello, Turchin, and Weed [2014].

Next, using that non-hair vertices can be required to be at least trivalent one can easily derive the upper degree bounds

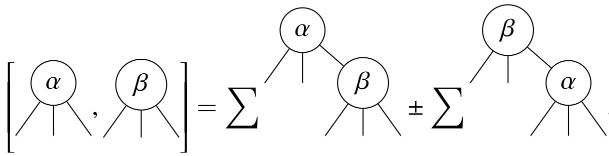
$$H^{>-k(n-3)-(h-1)(n-m-2)-1}(\mathrm{HGC}_{m,n}^{k\text{-loop},h\text{-hair}}) = 0. \tag{8}$$

For example, we will use below that for $n-3 \geq m$ the only non-trivial classes in degree $-m$ live in loop order $k=0$ and are hence found in the list (7).

By other methods (see Arone and Turchin [2014] and Willwacher [2015b]) one can also obtain the lower degree bound

$$H^{<-k(n-2)-(h-1)(n-m-1)}(\mathrm{HGC}_{m,n}^{k\text{-loop},h\text{-hair}}) = 0.$$

Furthermore, the complexes $\mathrm{HGC}_{m,n}$ are also dg Lie algebras. The Lie bracket of two hairy graphs is computed by connecting a hair of one graph to vertices of the other as indicated in the following picture:



For further information about the hairy graph cohomology $H(\mathrm{HGC}_{m,n})$, we refer the reader to Arone and Turchin [2015] containing a computation of the Euler characteristic, to Khoroshkin, Willwacher, and Živković [2015] containing a construction of infinite series of nontrivial classes and numerical results, or to Fresse, Turchin, and Willwacher [2017b] for general information.

3 The little disks operads

3.1 Cohomology of the little disks operad. The cohomology of the little disks operads D_n has been computed by Arnold (for $n = 2$) and F. Cohen (for all n).

Theorem 4 (Arnold [1969] and Cohen [1976]). For $n \geq 2$ and $r \geq 1$ the cohomology algebra of the space $\mathrm{D}_n(r)$ has the presentation

$$H(\mathrm{D}_n(r)) = \mathbb{Q}[\omega_{ij} \mid 1 \leq i \neq j \leq n]/\langle R\rangle,$$

where ω_{ij} are generators of degree $n-1$ and the relations R read

$$\omega_{ij} = (-1)^n \omega_{ji} \qquad \omega_{ij}^2 = 0 \qquad \omega_{ij}\omega_{jk} + \omega_{jk}\omega_{ki} + \omega_{ki}\omega_{ij} = 0$$

From the operad structure on D_n the collection of graded commutative algebras $H(\mathrm{D}_n)$ receives a cooperad structure. Generally, we will call a cooperad in the category of dg commutative algebras a Hopf cooperad, so that in particular $H(\mathrm{D}_n)$ is a Hopf cooperad.

To understand the operad structure it is slightly easier to consider the dual operad $H_\bullet(\mathrm{D}_n)$. For $n = 1$ this is just the associative operad. For $n \geq 2$ it can be identified with the n-Poisson operad Pois_n, which generated by a commutative product operation $\wedge$ of degree 0 and a Lie bracket $[,]$ of degree $1-n$ satisfying the compatibility relation

$$[x_1, x_2 \wedge x_3] = [x_1, x_2] \wedge x_3 + x_2 \wedge [x_1, x_3].$$

3.2 Rational homotopy theory of operads. Rational homotopy theory is the study of rational homotopy types of spaces. In Sullivan's approach, the main ingredient is a Quillen adjunction between the categories of simplicial sets (which we shall think of as topological spaces) and of dg commutative algebras

$$\Omega : \mathrm{sSet} \leftrightarrows \mathrm{dgca}^{op} : G.$$

Sullivan's functor Ω sends a simplicial set X to the dg commutative algebra of piecewise polynomial differential forms

$$\Omega(X) := \mathrm{Hom}_{\mathrm{sSet}}(X, \Omega_{poly}(\Delta^\bullet)).$$

We readily extend the definition to topological spaces instead of simplicial sets via the singular simplicial complexes functor $\mathrm{Sing}_\bullet$. We shall quietly abuse the notation and write, for a topological space X,

$$\Omega(X) := \Omega(\mathrm{Sing}_\bullet X).$$

When X is a manifold $\Omega(X) \otimes_{\mathbb{Q}} \mathbb{R}$ is weakly equivalent to the dg commutative algebra of de Rham differential forms on X. For our purposes, rational homotopy theory can be seen as the study of the quasi-isomorphism type of the dg commutative algebra $\Omega(X)$.

Let us next consider a topological operad $\mathcal{T}$. To study its rational homotopy type we would like to apply the functor Ω and study the resulting cooperad object in dg commutative algebras. Unfortunately, due to incompatible monoidality properties of the functor Ω the collection $\Omega(\mathcal{T})$ is not naturally a cooperad. More concretely, the problem here is that one has a natural quasi-isomorphism $\Omega(X) \otimes \Omega(Y) \to \Omega(X \times Y)$, but no natural morphism in the other direction. There are essentially three known approaches to work around this technical problem, by (i) using operads up to homotopy or (ii) changing the functor Ω or (iii) to use completed tensor products in the smooth setting.

While all three approaches have been used in the literature, we use here approach (ii). We shall follow Fresse's rational homotopy theory for operads, see Fresse [n.d.] and Fresse and Willwacher [2015, section 0], which we briefly outline. For brevity we call a cooperad in dg commutative algebras a Hopf cooperad. Fresse constructs a Quillen adjunction

$$\Omega_\sharp : \mathrm{sSet\text{-}Op} \leftrightarrows \mathrm{Hopf\text{-}Op}^c : G$$

between the model categories of reduced operads in simplicial sets, and that of dg Hopf cooperads. The functor $\Omega_\sharp$ here is defined as left adjoint of the realization functor G and shall be seen as an operadic upgrade of Sullivan's functor Ω. In each arity, $\Omega_\sharp$ is weakly equivalent to Ω.

For our purposes, studying the rational homotopy type of a topological operad $\mathcal{T}$ amounts to studying the quasi-isomorphism class of the dg Hopf cooperad $\Omega_\sharp(\mathcal{T})$, where we again quietly extend $\Omega_\sharp$ to topological spaces instead of simplicial sets, taking singular simplices. Furthermore, if $\mathcal{S}$ and $\mathcal{T}$ are simplicial (or topological) operads, then one can use the Quillen adjunction above to compute

$$\mathrm{Map}_{\text{sSet-Op}}(\mathcal{S}, \mathcal{T}^{\mathbb{Q}}) = \mathrm{Map}_{\text{sSet-Op}}(\mathcal{S}, G(\Omega_\sharp(\mathcal{T}))) \simeq \mathrm{Map}_{HopfOp^c}(\Omega_\sharp(\mathcal{T}), \Omega_\sharp(\mathcal{S})).$$

We finally note that Fresse's framework has the downside that it requires our operads to be reduced, i.e., that $\mathcal{T}(0) = \mathcal{T}(1) = *$ is a point. Unfortunately the little disks operads introduced above are not reduced, since $\mathrm{D}_n(1)$ is not a point, only contractible. However, there are homotopy equivalent variants of D_n, for example the Fulton-MacPherson operad FM_n Getzler and Jones [1994], which are reduced. Generally, an E_n operad is a topological operad weakly equivalent to D_n. In the following we will abuse the notation a bit and denote by E_n some chosen reduced operad weakly equivalent to D_n. Furthermore, for technical reasons the arity zero operations in $\mathcal{T}(0) = *$ are encoded in a Λ-structure instead of considering them as operations in the operad. A Λ-structure is the collection of all possible composition maps with nullary operations $\mathcal{T}(r+s) \to \mathcal{T}(r)$, which are required to satisfy natural compatibility relations. For simplicity of notation we will hide this further technical complication and do not mark the presence of the Λ-structure in our notation. We refer to Fresse's book Fresse [n.d.] for details. It is shown in Fresse, Turchin, and Willwacher [2017a] that the mapping spaces computed in the category of reduced operads are weakly equivalent to those computed in the full category of operads, thus justifying our restriction to the reduced setting.

3.3 Formality and intrinsic formality of E_n operads. Today the rational homotopy types of the little disks operads are fully understood through the following Theorem.

Theorem 5 (Formality Theorem for the E_n operads). The dg Hopf cooperads $\Omega_\sharp(E_n)$ are formal, i.e., connected by a chain of weak equivalences to the cohomology cooperad $\mathrm{e}_n^c = H(E_n)$.

The Theorem has the following history. The formality of E_2 was first shown by Tamarkin [2003]. The statement for higher n was first established by Kontsevich [1999], albeit over the ground ring $\mathbb{R}$. It has then been noted in Guillén Santos, Navarro, Pascual, and Roig [2005] that Kontsevich's statement can be improved to yield formality over $\mathbb{Q}$, provided one disregards the arity zero operations in the cooperads. Finally, the remaining statement of formality over $\mathbb{Q}$ with zero-ary operations was shown by Fresse and the author in Fresse and Willwacher [2015]. Also, surprisingly, we were able to show a significantly stronger result. A dg Hopf cooperad $\mathfrak{C}$ is called intrinsically formal if any dg Hopf cooperad $\mathfrak{D}$ with $H(\mathfrak{D}) \simeq H(\mathfrak{C})$ is weakly equivalent to $\mathfrak{C}$. One then has:

Theorem 6 (Intrinsic formality for the little diks operadsFresse and Willwacher [ibid.]). The dg Hopf cooperad $\Omega_\sharp(E_n)$ is intrinsically formal for $n \geq 3$ and n not divisible by 4. If $n \geq 3$ is divisible by 4, one does not have intrinsic formality, but the following statement is retained: Suppose that $\mathfrak{D}$ is another dg Hopf cooperad such that $H(D) \cong H(E_n)$. Suppose further that $I : \mathfrak{D} \to \mathfrak{D}$ is an involution which agrees on cohomology with the canonical involution of E_n by mirror reflection along a coordinate axis. Then $\mathfrak{D} \simeq H(E_n)$.

For $n = 2$ the analogous statement is an open conjecture.

Conjecture 7. The little 2-disks operad is rationally intrinsically formal.

In fact, this conjecture would follow from the vanishing Conjecture 3 on the graph cohomology above.

To conclude this subsection let us also remark on several closely connected formality questions for the little disks operads. First we note that the little disks operads come with natural maps $\mathrm{D}_m \to \mathrm{D}_n$. One may ask what the rational (or real) homotopy type of these maps are. The question has been answered in works of Turchin and the author Turchin and Willwacher [2014] and Fresse and the author Fresse and Willwacher [2015], improving upon earlier results by Lambrechts and Volić Loday and Vallette [2012].

Theorem 8 (Fresse and Willwacher [2015], Turchin and Willwacher [2014], and Loday and Vallette [2012]). Let $n \geq m \geq 1$. Then the map $E_m \to E_n$ is rationally formal for $n - m \neq 1$, and not formal (even over $\mathbb{R}$) for $n - m = 1$.

Furthermore the real homotopy type of the map $E_{n-1} \to E_n$ can be fully described.

In a different direction, note that the group $O(n)$ naturally acts on the little n-disks operad $\mathrm{D}(n)$. One can hence ask whether the operad $\mathrm{D}(n)$ is $O(n)$-equivariantly formal or not. This is equivalent to asking whether the framed little disks operads are formal or not. This latter question has also been answered by now: The framed little 2-disks operad D_2^{fr} was shown to be formal by Giansiracusa and Salvatore [2010] (over $\mathbb{R}$) and independently by Ševera [2010] (over $\mathbb{Q}$).

Furthermore, the formality (over $\mathbb{R}$) of D_n^{fr} for n is even is shown in Khoroshkin and Willwacher [2017]. For $n \geq 3$ odd the operad D_n^{fr} is not formal, but explicit "small" models capturing the real homotopy type can be found Khoroshkin and Willwacher [2017] and Moriya [2017]

At present, the (arguably) most important remaining open problem regarding the formality of the little disks operads is the following.

Open Problem 9. Determine the $O(m) \times O(n-m)$-equivariant rational homotopy type of the Map $D_m \to D_n$.

This homotopy type appears for example in connection to the Goodwillie-Weiss manifold calculus, see Section 5 below.

3.4 Kontsevich's graphical model for E_n. The intrinsic formality statement (Theorem 6 above) can be shown by an analysis of the graph complex GC_n discussed in Section 2. The object that builds the bridge are the graphical models Graphs_n for the E_n opeads introduced by Kontsevich [1999]. More concretely, one defines a collection of dg commutative algebras $\mathrm{Graphs}_n(r)$ as follows. The space $\mathrm{Graphs}_n(r)$ is the space of linear combinations of isomorphism classes of graphs of the following type:

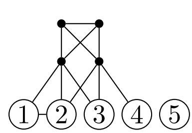
- The graph is an undirected graph with r numbered "external" vertices, and an arbitrary (but finite) number of "internal" vertices.

- All internal vertices have valence at least 2.

- Every connected component contains at least one external vertex.

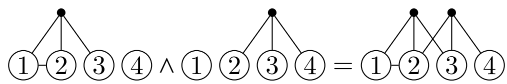
- Graphs are equipped with an orientation, as in Section 2, and we identify orientations up to sign. More concretely, for n even an orientation is an ordering of the edges, while for n odd an orientation is an odering of the set of half-edges and vertices. As discussed before, the presence of the orientation renders graphs with odd symmetries zero

The following is an examples of a graph in $\mathrm{Graphs}_n(5)$.



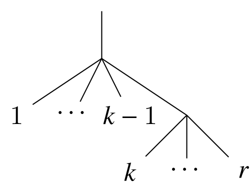
The space $\mathrm{Graphs}_n(r)$ is equipped with a differential by edge contraction, schematically:

Furthermore, we have a commutative product by gluing two graphs along the external vertices.



It is clear that $\mathrm{Graphs}_n(r)$ is free as a graded commutative algebra, generated by graphs that are internally connected, i.e., connected after removal of the external vertices.

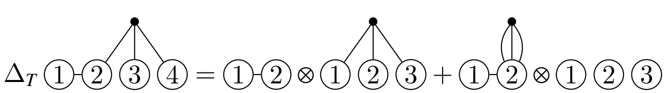
Furthermore there is cooperad structure on the collection Graphs_n, with the coproduct being the contraction of subgraphs. More precisely, for the generating cocomposition Δ_T corresponding to a tree



we have that

$$\Delta_T(\Gamma) = \sum_{\gamma} \Gamma/\gamma \otimes \gamma, \tag{9}$$

where the sum is over all subgraphs $\gamma \subset \Gamma$ containing the external vertices $k, \dots, r$ and no other external vertices, and the graph Γ/γ is obtained by contracting γ to one external vertex. Here is an example for $r = 4$ and $k = 2$:



In this formulas, and more generally (9) there is a natural way to define an orientation on the graphs on the right-hand side of the equation, given an orientation on the left-hand side, thus fixing the signs.

Finally, we note that for $n \geq 2$ we have a map of dg Hopf cooperads

$$\mathrm{Graphs}_n \to H(\mathrm{D}_n) = \mathrm{e}_n^c,$$

which is defined by sending any graph with internal vertices to zero, and sending a graph Γ without internal vertices and edges $(i_1, j_1), \dots, (i_k, j_k)$ to

$$\omega_{i_1 j_1} \cdots \omega_{i_k j_k},$$

cf. Theorem 4. Kontsevich and Lambrechts-Volić have then shown:

Proposition 10 (Kontsevich [1999] and Loday and Vallette [2012]). The map of dg Hopf cooperads $\mathrm{Graphs}_n \to \mathrm{e}_n^c$ above is a quasi-isomorphism.

The advantage of the dg Hopf cooperad Graphs_n over the smaller weakly equivalent cooperad e_n^c is that it has a large group of automorphism. More precisely we may consider the dg Lie algebra

$$\mathbb{Q}L \ltimes \mathrm{GC}_n, \tag{10}$$

where the generator L on the left acts on a graph by multiplication with the loop order.

$$[L, \gamma] = (\#\mathrm{loops}) \cdot \gamma$$

The statement is now that the dg Lie algebra (10) acts on the Hopf cooperad Graphs_n by biderivations, i.e., compatibly with both the cooperad and the dg commutative algebra structures. More concretely, the action of the generator L on a graph $\Gamma \in \mathrm{Graphs}_n$ is by

$$L \cdot \Gamma = (\#(\mathrm{edges}) - \#(\mathrm{internal\ vertices}))\Gamma.$$

The action of $\gamma \in \mathrm{GC}_n$ on $\Gamma \in \mathrm{Graphs}_n$ can be defined combinatorially as the contraction of subgraphs of shape γ in Γ, see Willwacher [2015b] for more details and the explicit formula.

3.5 A sketch of a proof of Theorem 6. As an illustration of the connection between the graph complexes GC_n of Section 2 we sketch here a proof of our intrinsic formality theorem (Theorem 6 above). We deviate slightly from the original reference Fresse and Willwacher [2015], where a different approach was used, using Bousfield's obstruction theory. The proof proceeds along the following sequence of steps.

1. As for most algebraic objects, we can define a deformation complex $\mathrm{Def}(\mathfrak{C}, \mathfrak{D})$ for Hopf cooperads $\mathfrak{C}$ and $\mathfrak{D}$, governing maps between $\mathfrak{C}$ and $\mathfrak{D}$. More concretely, $\mathrm{Def}(\mathfrak{C}, \mathfrak{D})$ is a dg Lie or L_∞-algebra, whose Maurer-Cartan elements correspond to maps from a cofibrant replacement of $\mathfrak{C}$ to a fibrant replacement of $\mathfrak{D}$. In particular $H^2(\mathrm{Def}(\mathfrak{C}, \mathfrak{D}))$ is a space of potential obstructions to constructing such maps. Furthermore, given a Hopf operad map $f : \mathfrak{C} \to \mathfrak{D}$ and the corresponding Maurer-Cartan element α_f, the twisted dg Lie algebra $\mathrm{Def}(\mathfrak{C} \xrightarrow{f} \mathfrak{D}) := \mathrm{Def}(\mathfrak{C}, \mathfrak{D})^{\alpha_f}$ governs deformations of the map f. We refer to Fresse, Turchin, and Willwacher [2017b, sections 3, 5] for details.

   We are interested in particular in $\mathrm{Def}(\mathrm{e}_n^c) := \mathrm{Def}(\mathrm{e}_n^c \xrightarrow{\mathrm{id}} \mathrm{e}_n^c)$, governing automorphisms of $\mathrm{e}_n^c = H(\mathrm{D}_n)$. If $\mathfrak{D}$ is a Hopf cooperad with $H(\mathfrak{D}) = \mathrm{e}_n^c$, then $H^2(\mathrm{Def}(\mathrm{e}_n^c))$ appears as a space of potential obstructions of lifting the cohomology map $\mathrm{e}_n^c \xrightarrow{=} H(\mathfrak{C})$ to a weak equivalence of Hopf cooperads between e_n^c and $\mathfrak{C}$. Our goal henceforth is to understand the space $H^2(\mathrm{Def}(\mathrm{e}_n^c))$, obstructing the intrinsic formality of the little n-disks operad.

2. If $\mathfrak{g}$ is a dg Lie algebra acting on e_n^c, or a quasi-isomorphic object, we obtain a map $H(\mathfrak{g}) \to H(\mathrm{Def}(\mathrm{e}_n^c))[1]$. It turns out that in the case of $\mathfrak{g} = \mathbb{Q}L \ltimes \mathrm{GC}_n$ acting on $\mathrm{Graphs}_n \simeq \mathrm{e}_n^c$ as described above the resulting map

$$\mathbb{Q}L \oplus H(\mathrm{GC}_n) \to H(\mathrm{Def}(\mathrm{e}_n^c))[1]$$

   is an isomorphism. This means in particular that the space of (potential) obstructions to intrinsic formality is given precisely by $H^1(\mathrm{GC}_n)$.

3. By the degree counting result (6) we hence see that for $n \geq 3$ the only possible obstructions are given by the graph cohomology classes represented by multiples of the loop graphs (4) appearing in (5). These graphs live in degree 1 only if n is divisible by 4. The intrinsic formality statment hence follows for $n \geq 3$ not divisible by 4.

4. Suppose next that $n \geq 3$ is divisible by 4. One can check that the $O(n)$ action on E_n is such that conjugation with the involution $S \in O(n)$ flipping the sign of one of the coordinates amounts to a multiplication of graphs in GC_n by $(-1)^{\#\mathrm{loops}}$. One can hence conclude that under the additional requirement of the presence of an involution on the operad as in Theorem 6, the relevant obstructions to intrinsic formality lie in the even loop order part $H(\mathrm{GC}_n)^{\mathbb{Z}_2}$. Hence the one-loop graphs cannot contribute.

By a similar analysis one can also make statements about the homotopy automorphisms of e_n^c for $n \geq 3$. Infinitesimally, they are governed by $\mathbb{Q}L \ltimes H^0(\mathrm{GC}_n)$. The piece $\mathbb{Q}L$ corresponds to the "trivial" automorphisms $S_\lambda : \mathsf{e}_n^c \to \mathsf{e}_n^c$ which just rescale the Lie cobracket by the factor $\lambda \in \mathbb{Q}^\times$. By invoking again the degree counting result 6 we see that (for $n \geq 3$) $H^0(\mathrm{GC}_n) = 0$ if $n \neq 3 \mod 4$ and otherwise $H^0(\mathrm{GC}_n)$ is one-dimensional, spanned by L_n. Hence one can say that for $n \geq 3$ the rationalization of the little n-disks operad has non-trivial homotopy automorphisms only if $n = 4k + 3$, and then only a 1-parameter family of such. Note that this is in striking contrast to the case of $n = 2$, where the homotopy automorphisms form the infinite dimensional Grothendieck-Teichmüller group, cf. Fresse [n.d.] or Theorem 1.

4 Mapping spaces and long knots

Let us turn again to the computation of the rational homotopy type of the space of long knots. Using the result (3) from the Goodwillie-Weiss embedding calculus we see that the quantity to evaluate is the mapping space $\mathrm{Map}^h_{op}(E_m, E_n)$. We are interested in the rationalization of this space. By Fresse, Turchin, and Willwacher [2017b, Theorem 15 and Proposition 6.1] the rationalization is weakly equivalent to the space

$$\mathrm{Map}^h_{op}(E_m, E_n^{\mathbb{Q}}) \simeq \mathrm{Map}^h_{\text{Hopf-Op}^c}(\Omega_\sharp E_n, \Omega_\sharp E_m) \simeq \mathrm{Map}^h_{\text{Hopf-Op}^c}(\mathsf{e}_n^c, \mathsf{e}_m^c)$$

if $n - m \geq 3$. For the last equivalence one uses the formality result of the previous section.

The space on the right-hand side of the above equation can be expressed through purely combinatorial data, and shown to be weakly equivalent to the nerve (Maurer-Cartan space) of the Lie algebra of hairy graphs $\mathrm{HGC}_{m,n}$.

Theorem 11 (Fresse, Turchin, and Willwacher [ibid.]). For $n \geq m \geq 2$ we have that

$$\mathrm{Map}^h_{\text{Hopf-Op}^c}(\mathsf{e}_n^c, \mathsf{e}_m^c) \simeq MC_\bullet(\mathrm{HGC}_{m,n}) := MC(\mathrm{HGC}\hat{\otimes}\Omega_{poly}(\Delta^\bullet))$$

where the hairy graph complex $\mathrm{HGC}_{m,n}$ is equipped with the Lie algebra structure of Section 2.1.

In fact, the same statement continues to hold for $m = 1$, if one modifies the Lie algebra structure on $\mathrm{HGC}_{1,n}$ to an L_∞-algebra structure described in Willwacher [2015a].

Theorem 11 states in particular that the real homotopy type of the spaces of long knots in codimension $n - m \geq 3$ is fully expressed through combinatorial data encoded in the graph complexes. In particular one finds that for $k \geq 0$ and $n-m \geq 3$ (see also Arone and Turchin [2015] for an earlier but weaker result)

$$\mathbb{Q} \otimes \pi_k(\overline{\mathrm{Emb}}_\partial(\mathbb{R}^m, \mathbb{R}^n)) \cong H^{-k-m}(\mathrm{HGC}_{m,n}).$$

Since the cohomology of the graph complex $\mathrm{HGC}_{m,n}$ can be explicitly computed in low degrees as described in Section 2.1, this result allows us to compute rational homotopy groups for low degrees k explicitly. As one application, let us consider here the case $k = 0$, detecting nontrivial knottings of $\mathbb{R}^m$ in $\mathbb{R}^n$. From the degree bound (8) we conclude that the only possible contribution can come from graphs in loop order 0, and those graph cohomology classes are listed in (7). Concretely the "line" graph of degree $n-m-2$ occurring for $n-m$ even produces nontrivial knottings if $n = 4j-1$ and $m = 2j$ for some j. Similarly the tripod graph of degree $2(n-m)-3$ occurring for $n-m$ odd yields nontrivial zeroth homotopy $n = 6j$ and $m = 4j-1$ for some j, see Fresse, Turchin, and Willwacher [2017b, Corollary 20]. In particular one hence recovers Haefliger's classical result Haefliger [1965] on the existence of non-trivial knots of dimension $4j-1$ in $6j$-space.

5 Outlook, extensions and open problems

Above we have seen that a rational version of the Goodwillie-Weiss manifold calculus can be used to compute the rational homotopy type of the space of higher dimensional long knots through the combinatorial structure of the graph complexes $\mathrm{HGC}_{m,n}$. Evidently, one can similarly hope to attack arbitrary embedding spaces $\mathrm{Emb}(M,N)$ via the rationalized Goodwillie-Weiss calculus. To complete this program one in particular needs to understand the rational homotopy types of all spaces and operads involved. As of today, at least over the reals, we understand the real homotopy types of (unframed) configuration spaces of points on compact orientable manifolds through the works Campos and Willwacher [2016] and Idrissi [2016]. Also, we understand the real homotopy type of the framed little disks operads Khoroshkin and Willwacher [2017]. The main open problem is the following.

Open Problem 12. Determine the real or rational homotopy type of the n-framed configuration spaces of points on a manifold M as a right E_n^{fr}-module, where $n \leq \dim M$.

This problem is also closely related to Open Open Problem 9 above.

After the real or rational homotopy types of the aforementioned objects are understood there should be no principle obstacle for generalizing the mapping space

space computations we reviewed here to arbitrary M and N. I can even describe the expected form of the graph complexes replacing the hairy graph complexes $\mathrm{HGC}_{m,n}$ in this setting. The relevant graphs should be hairy graphs as before, except that the hairs are additionaly decorated by a dgca model for the source space M, and the internal vertices may be decorated by the homology of the target N as in Campos and Willwacher [2016].

Unfortunately, the embedding calculus is fully applicable only in codimensions $\dim N - \dim M \geq 3$. In lower codimension one still has the map (2) (from left to right), but one can not assert it to be a weak equivalence. Nevertheless I expect that valuable information about the left-hand side can be obtained from the right-hand side. For example, in codimension 0, we have a map into the homotopy automorphisms of right framed-little disks (co)modules

$$\mathrm{Diff}(M) \to \mathrm{Aut}^h_{\Omega(E_n^{fr})\text{-comod}}(\Omega(\mathrm{conf}_M)). \tag{11}$$

I claim that the right-hand side can be computed and expressed through graph complexes. This then provides an arena in which one can study diffeomorphism groups, although the map (11) is generally not (expected to be) a rational homotopy equivalence.

REPRESENTATION THEORY OF W-ALGEBRAS AND HIGGS BRANCH CONJECTURE

TOMOYUKI ARAKAWA (荒川知幸)

Abstract

We survey a number of results regarding the representation theory of W-algebras and their connection with the resent development of the four dimensional $N = 2$ superconformal field theories.

1 Introduction

(Affine) W-algebras appeared in 80's in the study of the two-dimensional conformal field theory in physics. They can be regarded as a generalization of infinite-dimensional Lie algebras such as affine Kac-Moody algebras and the Virasoro algebra, although W-algebras are not Lie algebras but vertex algebras in general. W-algebras may be also considered as an affinizaton of finite W-algebras introduced by Premet [2002] as a natural quantization of Slodowy slices. W-algebras play important roles not only in conformal field theories but also in integrable systems (e.g. V. G. Drinfeld and Sokolov [1984], De Sole, V. G. Kac, and Valeri [2013], and Bakalov and Milanov [2013]), the geometric Langlands program (e.g. E. Frenkel [2007], Gaitsgory [2016], Tan [2016], and Aganagic, E. Frenkel, and Okounkov [2017]) and four-dimensional gauge theories (e.g. Alday, Gaiotto, and Tachikawa [2010], Schiffmann and Vasserot [2013], Maulik and Okounkov [2012], and Braverman, Finkelberg, and Nakajima [2016a]).

In this note we survey the resent development of the representation theory of W-algebras. One of the fundamental problems in W-algebras was the Frenkel-Kac-Wakimoto conjecture E. Frenkel, V. Kac, and Wakimoto [1992] that stated the existence and construction of rational W-algebras, which generalizes the integrable representations of affine Kac-Moody algebras and the minimal series representations of the Virasoro algebra. The notion of the associated varieties of vertex algebras played a crucial role in the proof of the Frenkel-Kac-Wakimoto conjecture, and has revealed an unexpected connection of vertex algebras with the geometric invariants called the Higgs branches in the four dimensional $N = 2$ superconformal field theories.

2 Vertex algebras

A *vertex algebra* consists of a vector space V with a distinguished vacuum vector $|0\rangle \in V$ and a vertex operation, which is a linear map $V \otimes V \to V((z))$, written $a \otimes b \mapsto a(z)b = (\sum_{n\in\mathbb{Z}} a_{(n)} z^{-n-1})b$, such that the following are satisfied:

- (Unit axioms) $(|0\rangle)(z) = 1_V$ and $a(z)|0\rangle \in a + zV[[z]]$ for all $a \in V$.
- (Locality) $(z-w)^n [a(z), b(w)] = 0$ for a sufficiently large n for all $a, b \in V$.

The operator $T : a \mapsto a_{(-2)}|0\rangle$ is called the translation operator and it satisfies $(Ta)(z) = [T, a(z)] = \partial_z a(z)$. The operators $a_{(n)}$ are called *modes*.

For elements a, b of a vertex algebra V we have the following *Borcherds identity* for any $m, n \in \mathbb{Z}$:

$$(1)\qquad [a_{(m)}, b_{(n)}] = \sum_{j\geq 0} \binom{m}{j} (a_{(j)}b)_{(m+n-j)},$$

$$(2)\qquad (a_{(m)}b)_{(n)} = \sum_{j\geq 0} (-1)^j \binom{m}{j} (a_{(m-j)}b_{(n+j)} - (-1)^m b_{(m+n-j)}a_{(j)}).$$

By regarding the Borcherds identity as fundamental relations, representations of a vertex algebra are naturally defined (see V. Kac [1998] and E. Frenkel and Ben-Zvi [2004] for the details).

One of the basic examples of vertex algebras are universal affine vertex algebras. Let G be a simply connected simple algebraic group, $\mathfrak{g} = \mathrm{Lie}(G)$. Let $\widehat{\mathfrak{g}} = \mathfrak{g}[t, t^{-1}] \oplus \mathbb{C}K$ be the affine Kac-Moody algebra associated with $\mathfrak{g}$. The commutation relations of $\widehat{\mathfrak{g}}$ are given by

$$(3)\quad [xt^m, yt^n] = [x, y]t^{m+n} + m\delta_{m+n,0}(x|y)K, \quad [K, \widehat{\mathfrak{g}}] = 0 \quad (x, y \in \mathfrak{g},\ m, n \in \mathbb{Z}),$$

where $(\ |\ )$ is the normalized invariant inner product of $\mathfrak{g}$, that is, $(\ |\ ) = 1/2h^\vee \times$Killing form and $h^\vee$ is the dual Coxeter number of $\mathfrak{g}$. For $k \in \mathbb{C}$, let

$$V^k(\mathfrak{g}) = U(\widehat{\mathfrak{g}}) \otimes_{U(\mathfrak{g}[t]\oplus\mathbb{C}K)} \mathbb{C}_k,$$

where $\mathbb{C}_k$ is the one-dimensional representation of $\mathfrak{g}[t] \oplus \mathbb{C}K$ on which $\mathfrak{g}[t]$ acts trivially and K acts as multiplication by k. There is a unique vertex algebra structure on $V^k(\mathfrak{g})$ such that $|0\rangle = 1 \otimes 1$ is the vacuum vector and

$$x(z) = \sum_{n \in \mathbb{Z}} (xt^n) z^{-n-1} \quad (x \in \mathfrak{g}).$$

Here on the left-hand-side $\mathfrak{g}$ is considered as a subspace of $V^k(\mathfrak{g})$ by the embedding $\mathfrak{g} \hookrightarrow V^k(\mathfrak{g})$, $x \mapsto (xt^{-1})|0\rangle$. $V^k(\mathfrak{g})$ is called the *universal affine vertex algebra associated with* $\mathfrak{g}$ *at a level* k. The Borcherds identity (1) for $x, y \in \mathfrak{g} \subset V^k(\mathfrak{g})$ is identical to the commutation relation (3) with $K = k$ id, and hence, any $V^k(\mathfrak{g})$-module is a $\widehat{\mathfrak{g}}$-module of level k. Conversely, any smooth $\widehat{\mathfrak{g}}$-module of level k is naturally a $V^k(\mathfrak{g})$-module, and therefore, the category $V^k(\mathfrak{g})$ -Mod of $V^k(\mathfrak{g})$-modules is the same as the category of smooth $\widehat{\mathfrak{g}}$-modules of level k. Let $L_k(\mathfrak{g})$ be the unique simple graded quotient of $V^k(\mathfrak{g})$, which is isomorphic to the irreducible highest weight representation $L(k\Lambda_0)$ with highest weight $k\Lambda_0$ as a $\widehat{\mathfrak{g}}$-module. The vertex algebra $L_k(\mathfrak{g})$ is called the *simple affine vertex algebra* associated with $\mathfrak{g}$ at level k, and $L_k(\mathfrak{g})$ -Mod forms a full subcategory of $V^k(\mathfrak{g})$ -Mod, the category of smooth $\widehat{\mathfrak{g}}$-modules of level k.

A vertex algebra V is called *commutative* if both sides of (1) are zero for all $a, b \in V$, $m, n \in \mathbb{Z}$. If this is the case, V can be regarded as a *differential algebra* (=a unital commutative algebra with a derivation) by the multiplication $a.b = a_{(-1)}b$ and the derivation T. Conversely, any differential algebra can be naturally equipped with the structure of a commutative vertex algebra. Hence, commutative vertex algebras are the same[1] as differential algebras (Borcherds [1986]).

Let X be an affine scheme, $J_\infty X$ the *arc space* of X that is defined by the functor of points $\mathrm{Hom}(\mathrm{Spec}\, R, J_\infty X) = \mathrm{Hom}(\mathrm{Spec}\, R[[t]], X)$. The ring $\mathbb{C}[J_\infty X]$ is naturally a differential algebra, and hence is a commutative vertex algebra. In the case that X is a Poisson scheme $\mathbb{C}[J_\infty X]$ has the structure of *Poisson vertex algebra* (Arakawa [2012b]), which is a vertex algebra analogue of Poisson algebra (see E. Frenkel and Ben-Zvi [2004] and V. Kac [2015] for the precise definition).

It is known by Haisheng Li [2005] that any vertex algebra V is canonically filtered, and hence can be regarded[2] as a quantization of the associated graded Poisson vertex algebra $\mathrm{gr}\, V = \bigoplus_p F^pV/F^{p+1}V$, where $F^\bullet V$ is the canonical filtration of V. By definition,

$$F^pV = \mathrm{span}_{\mathbb{C}}\{(a_1)_{(-n_1-1)} \dots (a_r)_{(-n_r-1)}|0\rangle \mid a_i \in V,\ n_i \geq 0,\ \sum_i n_i \geq p\}.$$

[1]However, the modules of a commutative vertex algebra are not the same as the modules as a differential algebra.

[2]This filtration is separated if V is non-negatively graded, which we assume.

The subspace

$$R_V := V/F^1V = F^0V/F^1V \subset \operatorname{gr} V$$

is called *Zhu's C_2-algebra of V*. The Poisson vertex algebra structure of gr V restricts to the Poisson algebra structure of R_V, which is given by

$$\bar{a}.\bar{b} = \overline{a_{(-1)}b}, \quad \{\bar{a}, \bar{b}\} = \overline{a_{(0)}b}.$$

The Poisson variety

$$X_V = \operatorname{Specm}(R_V)$$

called the *associated variety* of V (Arakawa [2012b]). We have Li [2005] the inclusion

(4) $$\operatorname{Specm}(\operatorname{gr} V) \subset J_\infty X_V.$$

A vertex algebra V is called *finitely strongly generated* if R_V is finitely generated. In this note all vertex algebras are assumed to be finitely strongly generated. V is called *lisse* (or *C_2-cofinite*) if $\dim X_V = 0$. By (4), it follows that V is lisse if and only if $\dim \operatorname{Spec}(\operatorname{gr} V) = 0$ (Arakawa [2012b]). Hence lisse vertex algebras can be regarded as an analogue of finite-dimensional algebras.

For instance, consider the case $V = V^k(\mathfrak{g})$. We have $F^1V^k(\mathfrak{g})) = \mathfrak{g}[t^{-1}]t^{-2}V^k(\mathfrak{g})$, and there is an isomorphism of Poisson algebras

$$\mathbb{C}[\mathfrak{g}^*] \xrightarrow{\sim} R_V, \quad x_1 \dots x_r \mapsto \overline{(x_1t^{-1}) \dots (x_rt^{-1})|0\rangle} \quad (x_i \in \mathfrak{g}).$$

Hence

(5) $$X_{V^k(\mathfrak{g})} \cong \mathfrak{g}^*.$$

Also, we have the isomorphism $\operatorname{Spec}(\operatorname{gr} V^k(\mathfrak{g})) \cong J_\infty \mathfrak{g}^*$. By (5), we have $X_{L_k(\mathfrak{g})} \subset \mathfrak{g}^*$, which is G-invariant and conic. It is known Dong and Mason [2006] that

(6) $$L_k(\mathfrak{g}) \text{ is lisse} \iff L_k(\mathfrak{g}) \text{ is integrable as a } \widehat{\mathfrak{g}}\text{-module } (\iff k \in \mathbb{Z}_{\geq 0}).$$

Hence the lisse condition may be regarded as a generalization of the integrability condition to an arbitrary vertex algebra.

A vertex algebra is called *conformal* if there exists a vector ω, called the *conformal vector*, such that the corresponding field $\omega(z) = \sum_{n \in \mathbb{Z}} L_n z^{-n-2}$ satisfies the following conditions. (1) $[L_m, L_n] = (m-n)L_{m+n} + \frac{m^3-m}{12}\delta_{m+n,0} c \operatorname{id}_V$, where c is a constant called the central charge of V; (2) L_0 acts semisimply on V; (3) $L_{-1} = T$. For a conformal vertex algebra V we set $V_\Delta = \{v \in V \mid L_0 v = \Delta V\}$, so that $V = \bigoplus_\Delta V_\Delta$. The universal affine vertex algebra $V^k(\mathfrak{g})$ is conformal by the Sugawara construction provided that $k \neq -h^\vee$. A *positive energy representation* M of a conformal vertex algebra V is a V-module M on which L_0 acts diagonally and the L_0-eivenvalues on M is bounded from below. An *ordinary representation* is a positive energy representation such that each L_0-eivenspaces are finite-dimensional. For a finitely generated ordinary representation M, the normalized character

$$\chi_V(q) = \mathrm{tr}_V(q^{L_0 - c/24})$$

is well-defined.

For a conformal vertex algebra $V = \bigoplus_\Delta V_\Delta$, one defines *Zhu's algebra* I. B. Frenkel and Zhu [1992] $\mathrm{Zhu}(V)$ of V by

$$\mathrm{Zhu}(V) = V/V \circ V, \quad V \circ V = \mathrm{span}_{\mathbb{C}}\{a \circ b \mid a, b \in V\},$$

where $a \circ b = \sum_{i \geq 0} \binom{\Delta_a}{i} a_{(i-2)} b$ for $a \in \Delta_a$. $\mathrm{Zhu}(V)$ is a unital associative algebra by the multiplication $a * b = \sum_{i \geq 0} \binom{\Delta_a}{i} a_{(i-1)} b$. There is a bijection between the isomorphism classes $\mathrm{Irrep}(V)$ of simple positive energy representation of V and that of simple $\mathrm{Zhu}(V)$-modules (I. B. Frenkel and Zhu [1992] and Zhu [1996]). The grading of V gives a filtration on $\mathrm{Zhu}(V)$ which makes it quasi-commutative, and there is a surjective map

$$R_V \twoheadrightarrow \mathrm{gr}\,\mathrm{Zhu}(V) \tag{7}$$

of Poisson algebras. Hence, if V is lisse then $\mathrm{Zhu}(V)$ is finite-dimensional, so there are only finitely many irreducible positive energy representations of V. Moreover, the lisse condition implies that any simple V-module is a positive energy representation (Abe, Buhl, and Dong [2004]).

A conformal vertex algebra is called *rational* if any positive energy representation of V is completely reducible. For instance, the simple affine vertex algebra $L_k(\mathfrak{g})$ is rational if and only if $L_k(\mathfrak{g})$ is integrable, and if this is the case $L_k(\mathfrak{g})$ -Mod is exactly the category of integrable representations of $\widehat{\mathfrak{g}}$ at level k. A theorem of Y. Zhu [1996] states that if V is a rational, lisse, $\mathbb{Z}_{\geq 0}$-graded conformal vertex algebra such that $V_0 = \mathbb{C}|0\rangle$, then the character $\chi_M(e^{2\pi i \tau})$ converges to a holomorphic functor on the upper half plane for any $M \in \mathrm{Irrep}(V)$. Moreover, the space spanned by the characters $\chi_M(e^{2\pi i \tau})$, $M \in \mathrm{Irrep}(V)$, is invariant under the natural action of $SL_2(\mathbb{Z})$. This theorem was strengthened in Dong, Lin, and Ng [2015] to the fact that $\{\chi_M(e^{2\pi i \tau}) \mid M \in \mathrm{Irrep}(V)\}$ forms a vector valued modular function by showing the congruence property. Furthermore, it has been shown in Huang [2008] that the category of V-modules form a modular tensor category.

3 W-algebras

W-algebras are defined by the method of the *quantized Drinfeld-Sokolov reduction* that was discovered by Feigin and E. Frenkel [1990]. In the most general definition of W-algebras given by V. Kac, Roan, and Wakimoto [2003], W-algebras are associated with the pair $(\mathfrak{g}, f)$ of a simple Lie algebra $\mathfrak{g}$ and a nilpotent element $f \in \mathfrak{g}$. The corresponding W-algebra is a one-parameter family of vertex algebra denoted by $\mathcal{W}^k(\mathfrak{g}, f)$, $k \in \mathbb{C}$. By definition,

$$\mathcal{W}^k(\mathfrak{g}, f) := H^0_{DS,f}(V^k(\mathfrak{g})),$$

where $H^{\bullet}_{DS,f}(M)$ denotes the BRST cohomology of the quantized Drinfeld-Sokolov reduction associated with $(\mathfrak{g}, f)$ with coefficient in a $V^k(\mathfrak{g})$-module M, which is defined as follows. Let $\{e, h, f\}$ be an $\mathfrak{sl}_2$-triple associated with f, $\mathfrak{g}_j = \{x \in \mathfrak{g} \mid [h, x] = 2j\}$, so that $\mathfrak{g} = \bigoplus_{j \in \frac{1}{2}\mathbb{Z}} \mathfrak{g}_j$. Set $\mathfrak{g}_{\geq 1} = \bigoplus_{j \geq 1} \mathfrak{g}_j$, $\mathfrak{g}_{>0} = \bigoplus_{j \geq 1/2} \mathfrak{g}_j$. Then $\chi : \mathfrak{g}_{\geq 1}[t, t^{-1}] \to \mathbb{C}$, $xt^n \mapsto \delta_{n,-1}(f|x)$, defines a character. Let $F_\chi = U(\mathfrak{g}_{>0}[t, t^{-1}]) \otimes_{U(\mathfrak{g}_{>0}[t] + \mathfrak{g}_{\geq 1}[t, t^{-1}])} \mathbb{C}_\chi$, where $\mathbb{C}_\chi$ is the one-dimensional representation of $\mathfrak{g}_{>0}[t] + \mathfrak{g}_{\geq 1}[t, t^{-1}]$ on which $\mathfrak{g}_{\geq 1}[t, t^{-1}]$ acts by the character χ and $\mathfrak{g}_{>0}[t]$ acts triviality. Then, for a $V^k(\mathfrak{g})$-module M,

$$H^{\bullet}_{DS,f}(M) = H^{\frac{\infty}{2}+\bullet}(\mathfrak{g}_{>0}[t, t^{-1}], M \otimes F_\chi),$$

where $H^{\frac{\infty}{2}+\bullet}(\mathfrak{g}_{>0}[t, t^{-1}], N)$ is the semi-infinite $\mathfrak{g}_{>0}[t, t^{-1}]$-cohomology Feĭgin [1984] with coefficient in a $\mathfrak{g}_{>0}[t, t^{-1}]$-module N. Since it is defined by a BRST cohomology, $\mathcal{W}^k(\mathfrak{g}, f)$ is naturally a vertex algebra, which is called *W-algebra associated with* $(\mathfrak{g}, f)$ *at level* k. By E. Frenkel and Ben-Zvi [2004] and V. G. Kac and Wakimoto [2004], we know that $H^i_{DS,f}(V^k(\mathfrak{g})) = 0$ for $i \neq 0$. If $f = 0$ we have by definition $\mathcal{W}^k(\mathfrak{g}, f) = V^k(\mathfrak{g})$. The W-algebra $\mathcal{W}^k(\mathfrak{g}, f)$ is conformal provided that $k \neq -h^\vee$.

Let $\mathcal{S}_f = f + \mathfrak{g}^e \subset \mathfrak{g} \cong \mathfrak{g}^*$, the *Slodowy slice* at f, where $\mathfrak{g}^e$ denotes the centralizer of e in $\mathfrak{g}$. The affine variety $\mathcal{S}_f$ has a Poisson structure obtained from that of $\mathfrak{g}^*$ by Hamiltonian reduction (Gan and Ginzburg [2002]). We have

$$X_{\mathcal{W}^k(\mathfrak{g},f)} \cong \mathcal{S}_f, \quad \operatorname{Spec}(\operatorname{gr} \mathcal{W}^k(\mathfrak{g}, f)) \cong J_\infty \mathcal{S}_f \tag{8}$$

(De Sole and V. G. Kac [2006] and Arakawa [2015a]). Also, we have

$$\operatorname{Zhu}(\mathcal{W}^k(\mathfrak{g}, f)) \cong U(\mathfrak{g}, f)$$

(Arakawa [2007] and De Sole and V. G. Kac [2006]), where $U(\mathfrak{g}, f)$ is the *finite W-algebra* associated with $(\mathfrak{g}, f)$ (Premet [2002]). Therefore, the W-algebra $\mathcal{W}^k(\mathfrak{g}, f)$ can be regarded as an affinization of the finite W-algebra $U(\mathfrak{g}, f)$. The map (7) for $\mathcal{W}^k(\mathfrak{g}, f)$

is an isomorphism, which recovers the fact Premet [2002] and Gan and Ginzburg [2002] that $U(\mathfrak{g}, f)$ is a quantization of the Slodowy slice $\mathcal{S}_f$. The definition of $\mathcal{W}^k(\mathfrak{g}, f)$ naturally extends V. Kac, Roan, and Wakimoto [2003] to the case that $\mathfrak{g}$ is a (basic classical) Lie superalgebra and f is a nilpotent element in the even part of $\mathfrak{g}$.

We have $\mathcal{W}^k(\mathfrak{g}, f) \cong \mathcal{W}^k(\mathfrak{g}, f')$ if f and f' belong to the same nilpotent orbit of $\mathfrak{g}$. The W-algebra associated with a minimal nilpotent element f_{mim} and a principal nilpotent element f_{prin} are called a minimal W-algebra and a principal W-algebra, respectively. For $\mathfrak{g} = \mathfrak{sl}_2$, these two coincide and are isomorphic to the Virasoro vertex algebra of central charge $1-6(k-1)^2/(k+2)$ provided that $k \neq -2$. In V. Kac, Roan, and Wakimoto [ibid.] it was shown that almost every superconformal algebra appears as the minimal W-algebra $\mathcal{W}^k(\mathfrak{g}, f_{min})$ for some Lie superalgebra $\mathfrak{g}$, by describing the generators and the relations (OPEs) of minimal W-algebras. Except for some special cases, the presentation of $\mathcal{W}^k(\mathfrak{g}, f)$ by generators and relations is not known for other nilpotent elements.

Historically, the principal W-algebras were first extensively studied (see Bouwknegt and Schoutens [1995]). In the case that $\mathfrak{g} = \mathfrak{sl}_n$, the non-critical principal W-algebras is isomorphic to the Fateev-Lukyanov's W_n-algebra Fateev and Lykyanov [1988] (Feigin and E. Frenkel [1990] and E. Frenkel and Ben-Zvi [2004]). The critical principal W-algebra $\mathcal{W}^{-h^\vee}(\mathfrak{g}, f_{prin})$ is isomorphic to the Feigin-Frenkel center $\mathfrak{z}(\widehat{\mathfrak{g}})$ of $\widehat{\mathfrak{g}}$, that is the center of the critical affine vertex algebra $V^{-h^\vee}(\mathfrak{g})$ (Feigin and E. Frenkel [1992]). For a general f, we have the isomorphism

$$\mathfrak{z}(\widehat{\mathfrak{g}}) \cong Z(\mathcal{W}^{-h^\vee}(\mathfrak{g}, f)),$$

(Arakawa [2012a] and Arakawa and Moreau [2018a]), where $Z(\mathcal{W}^{-h^\vee}(\mathfrak{g}, f))$ denotes the center of $\mathcal{W}^{-h^\vee}(\mathfrak{g}, f)$. This fact has an application to *Vinberg's Problem* for the centralizer $\mathfrak{g}^e$ of e in $\mathfrak{g}$ Arakawa and Premet [2017].

4 Representation theory of W-algebras

The definition of $\mathcal{W}^k(\mathfrak{g}, f)$ by the quantized Drinfeld-Sokolov reduction gives rise to a functor

$$V^k(\mathfrak{g})\text{-Mod} \rightarrow \mathcal{W}^k(\mathfrak{g}, f)\text{-Mod}$$
$$M \mapsto H^0_{DS,f}(M).$$

Let $\mathcal{O}_k$ be the category $\mathcal{O}$ of $\widehat{\mathfrak{g}}$ at level k. Then $\mathcal{O}_k$ is naturally considered as a full subcategory of $V^k(\mathfrak{g})$-Mod. For a weight λ of $\widehat{\mathfrak{g}}$ of level k, let $L(\lambda)$ be the irreducible highest weight representations of $\widehat{\mathfrak{g}}$ with highest weight λ.

Theorem 1 (Arakawa [2005]). *Let $f_{min} \in \mathbb{O}_{min}$ and let k be an arbitrary complex number.*

i. *We have $H^i_{DS,f_{min}}(M) = 0$ for any $M \in \mathcal{O}_k$ and $i \in \mathbb{Z}\backslash\{0\}$. Therefore, the functor*

$$\mathcal{O}_k \to \mathcal{W}^k(\mathfrak{g}, f_{min})\text{-Mod}, \quad M \mapsto H^0_{DS,f_{min}}(M)$$

is exact.

ii. *For a weight λ of $\widehat{\mathfrak{g}}$ of level k, $H^0_{DS,f_{min}}(L(\lambda))$ is zero or isomorphic to an irreducible highest weight representation of $\mathcal{W}^k(\mathfrak{g}, f_{min})$. Moreover, any irreducible highest weight representation the minimal W-algebra $\mathcal{W}^k(\mathfrak{g}, f_{min})$ arises in this way.*

By Theorem 1 and the Euler-Poincaré principal, the character $\operatorname{ch} H^0_{DS,f_\theta}(L(\lambda))$ is expressed in terms of $\operatorname{ch} L(\lambda)$. Since $\operatorname{ch} L(\lambda)$ is known Kashiwara and Tanisaki [2000] for all non-critical weight λ, Theorem 1 determines the character of all non-critical irreducible highest weight representation of $\mathcal{W}^k(\mathfrak{g}, f_{min})$. In the case that k is critical the character of irreducible highest weight representation of $\mathcal{W}^k(\mathfrak{g}, f_{min})$ is determined by the Lusztig-Feigin-Frenkel conjecture (Lusztig [1991], Arakawa and Fiebig [2012], and E. Frenkel and Gaitsgory [2009]).

Remark 2. Theorem 1 holds in the case that $\mathfrak{g}$ is a basic classical Lie superalgebra as well. In particular one obtains the character of irreducible highest weight representations of superconformal algebras that appear as $\mathcal{W}^k(\mathfrak{g}, f_{min})$ once the character of irreducible highest weight representations of $\widehat{\mathfrak{g}}$ is given.

Let KL_k be the full subcategory of $\mathcal{O}_k$ consisting of objects on which $\mathfrak{g}[t]$ acts locally finitely. Altough the functor

$$\mathcal{O}_k \to \mathcal{W}^k(\mathfrak{g}, f)\text{-Mod}, \quad M \mapsto H^0_{DS,f}(M) \tag{9}$$

is not exact for a general nilpotent element f, we have the following result.

Theorem 3 (Arakawa [2015a]). *Let f, k be arbitrary. We have $H^i_{DS,f_{min}}(M) = 0$ for any $M \in \mathrm{KL}_k$ and $i \neq 0$. Therefore, the functor*

$$\mathrm{KL}_k \to \mathcal{W}^k(\mathfrak{g}, f_{min})\text{-Mod}, \quad M \mapsto H^0_{DS,f_{min}}(M)$$

is exact.

In the case that f is a principal nilpotent element, Theorem 3 has been proved in E. Frenkel and Gaitsgory [2010] using Theorem 4 below.

The restriction of the quantized Drinfeld-Sokolv reduction functor to KL_k does not produce all the irreducible highest weight representations of $\mathcal{W}^k(\mathfrak{g}, f)$. However, one can modify the functor (9) to the "$-$"-reduction functor $H^0_{-,f}(?)$ (defined in E. Frenkel, V. Kac, and Wakimoto [1992]) to obtain the following result for the principal W-algebras.

Theorem 4 (Arakawa [2007])**.** *Let f be a principal nilpotent element, and let k be an arbitrary complex number.*

i. *We have $H^i_{-,f_{prin}}(M) = 0$ for any $M \in \mathcal{O}_k$ and $i \in \mathbb{Z}\backslash\{0\}$. Therefore, the functor*

$$\mathcal{O}_k \to \mathcal{W}^k(\mathfrak{g}, f_{prin})\text{-Mod}, \quad M \mapsto H^0_{-,f_{prin}}(M)$$

is exact.

ii. *For a weight λ of $\widehat{\mathfrak{g}}$ of level k, $H^0_{-,f_{prin}}(L(\lambda))$ is zero or isomorphic to an irreducible highest weight representation of $\mathcal{W}^k(\mathfrak{g}, f_{prin})$. Moreover, any irreducible highest weight representation the principal W-algebra $\mathcal{W}^k(\mathfrak{g}, f_{prin})$ arises in this way.*

In type A we can derive the similar result as Theorem 4 for any nilpotent element f using the work of Brundan and Kleshchev [2008] on the representation theory of finite W-algebras (Arakawa [2011]). In particular the character of all ordinary irreducible representations of $\mathcal{W}^k(\mathfrak{sl}_n, f)$ has been determined for a non-critical k.

5 BRST reduction of associated varieties

Let $\mathcal{W}_k(\mathfrak{g}, f)$ be the unique simple graded quotient of $\mathcal{W}^k(\mathfrak{g}, f)$. The associated variety $X_{\mathcal{W}_k(\mathfrak{g},f)}$ is a subvariety of $X_{\mathcal{W}^k(\mathfrak{g},f)} = \mathcal{S}_f$, which is invariant under the natural $\mathbb{C}^*$-action on $\mathcal{S}_f$ that contracts to the point $f \in \mathcal{S}_f$. Therefore $\mathcal{W}_k(\mathfrak{g}, f)$ is lisse if and only if $X_{\mathcal{W}_k(\mathfrak{g},f)} = \{f\}$.

By Theorem 3, $\mathcal{W}_k(\mathfrak{g}, f)$ is a quotient of the vertex algebra $H^0_{DS,f}(L_k(\mathfrak{g}))$, provided that it is nonzero.

Theorem 5 (Arakawa [2015a])**.** *For any $f \in \mathfrak{g}$ and $k \in \mathbb{C}$ we have*

$$X_{H^0_{DS,f}(L_k(\mathfrak{g}))} \cong X_{L_k(\mathfrak{g})} \cap \mathcal{S}_f.$$

Therefore,

i. *$H^0_{DS,f}(L_k(\mathfrak{g})) \neq 0$ if and only if $\overline{G.f} \subset X_{L_k(\mathfrak{g})}$;*

ii. *If* $X_{L_k(\mathfrak{g})} = \overline{G.f}$ *then* $X_{H^0_{DS,f}(L_k(\mathfrak{g}))} = \{f\}$. *Hence* $H^0_{DS,f}(L_k(\mathfrak{g}))$ *is lisse, and thus, so is its quotient* $\mathcal{W}_k(\mathfrak{g}, f)$.

Theorem 5 can be regarded as a vertex algebra analogue of the corresponding result Losev [2011] and Ginzburg [2009] for finite W-algebras.

Note that if $L_k(\mathfrak{g})$ is integrable we have $H^0_{DS,f}(L_k(\mathfrak{g})) = 0$ by (6). Therefore we need to study more general representations of $\widehat{\mathfrak{g}}$ to obtain lisse W-algebras using Theorem 5.

Recall that the irreducible highest weight representation $L(\lambda)$ of $\widehat{\mathfrak{g}}$ is called *admissible* V. G. Kac and Wakimoto [1989] (1) if λ is regular dominant, that is, $\langle \lambda + \rho, \alpha^\vee \rangle \notin -\mathbb{Z}_{\geq 0}$ for any $\alpha \in \Delta^{re}_+$, and (2) $\mathbb{Q}\Delta(\lambda) = \mathbb{Q}\Delta^{re}$. Here Δ^{re} is the set of real roots of $\widehat{\mathfrak{g}}$, Δ^{re}_+ the set of positive real roots of $\widehat{\mathfrak{g}}$, and $\Delta(\lambda) = \{\alpha \in \Delta^{re} \mid \langle \lambda + \rho, \alpha^\vee \rangle \in \mathbb{Z}\}$, the set of integral roots of λ. Admissible representations are (conjecturally all) modular invariant representations of $\widehat{\mathfrak{g}}$, that is, the characters of admissible representations are invariant under the natural action of $SL_2(\mathbb{Z})$ (V. G. Kac and Wakimoto [1988]). The simple affine vertex algebra $L_k(\mathfrak{g})$ is admissible as a $\widehat{\mathfrak{g}}$-module if and only if

$$k + h^\vee = \frac{p}{q}, \quad p, q \in \mathbb{N},\ (p,q) = 1,\ p \geq \begin{cases} h^\vee & \text{if } (q, r^\vee) = 1, \\ h & \text{if } (q, r^\vee) = r^\vee \end{cases} \tag{10}$$

(V. G. Kac and Wakimoto [2008]). Here h is the Coxeter number of $\mathfrak{g}$ and $r^\vee$ is the lacity of $\mathfrak{g}$. If this is the case k is called an *admissible number* for $\widehat{\mathfrak{g}}$ and $L_k(\mathfrak{g})$ is called an *admissible affine vertex algebra*.

Theorem 6 (Arakawa [2015a])**.** *Let* $L_k(\mathfrak{g})$ *be an admissible affine vertex algebra.*

i. *(Feigin-Frenkel conjectrue) We have* $X_{L_k(\mathfrak{g})} \subset \mathfrak{N}$, *the nilpotent cone of* $\mathfrak{g}$.

ii. *The variety* $X_{L_k(\mathfrak{g})}$ *is irreducible. That is, there exists a nilpotent orbit* $\mathbb{O}_k$ *of* $\mathfrak{g}$ *such that*

$$X_{L_k(\mathfrak{g})} = \overline{\mathbb{O}_k}.$$

iii. *More precisely, let* k *be an admissible number of the form* (10)*. Then*

$$X_{L_k(\mathfrak{g})} = \begin{cases} \{x \in \mathfrak{g} \mid (\operatorname{ad} x)^{2q} = 0\} & \text{if } (q, r^\vee) = 1, \\ \{x \in \mathfrak{g} \mid \pi_{\theta_s}(x)^{2q/r^\vee} = 0\} & \text{if } (q, r^\vee) = r^\vee, \end{cases}$$

where θ_s *is the highest short root of* $\mathfrak{g}$ *and* π_{θ_s} *is the irreducible finite-dimensional representation of* $\mathfrak{g}$ *with highest weight* θ_s.

From Theorem 5 and Theorem 6 we immediately obtain the following assertion, which was (essentially) conjectured by V. G. Kac and Wakimoto [2008].

Theorem 7 (Arakawa [2015a]). *Let $L_k(\mathfrak{g})$ be an admissible affine vertex algebra, and let $f \in \mathbb{O}_k$. Then the simple affine W-algebra $\mathcal{W}_k(\mathfrak{g}, f)$ is lisse.*

In the case that $X_{L_k(\mathfrak{g})} = \overline{G.f_{prin}}$, the lisse W-algebras obtained in Theorem 7 is the *minimal series* principal W-algebras studied in E. Frenkel, V. Kac, and Wakimoto [1992]. In the case that $\mathfrak{g} = \mathfrak{sl}_2$, these are exactly the minimal series Virasoro vertex algebras (Feĭgin and Fuchs [1984], Beilinson, Belavin, V. Drinfeld, and et al. [2004], and Wang [1993]). The Frenkel-Kac-Wakimoto conjecture states that these minimal series principal W-algebras are rational. More generally, all the lisse W-algebras $\mathcal{W}_k(\mathfrak{g}, f)$ that appear in Theorem 7 are conjectured to be rational (V. G. Kac and Wakimoto [2008] and Arakawa [2015a]).

6 The rationality of minimal series principal W-algebras

An admissible affine vertex algebra $L_k(\mathfrak{g})$ is called *non-degenearte* (E. Frenkel, V. Kac, and Wakimoto [1992]) if

$$X_{L_k(\mathfrak{g})} = \mathfrak{N} = \overline{G.f_{prin}}.$$

If this is the case k is called a *non-degenerate admissible number* for $\widehat{\mathfrak{g}}$. By Theorem 6 (iii), "most" admissible affine vertex algebras are non-degenerate. More precisely, an admissible number k of the form (10) is non-degenerate if and only if

$$q \geq \begin{cases} h & \text{if } (q, r^\vee) = 1, \\ r^\vee {}^L h^\vee & \text{if } (q, r^\vee) = r^\vee \end{cases}$$

where ${}^L h^\vee$ is the dual Coxeter number of the Langlands dual Lie algebra ${}^L\mathfrak{g}$. For a non-degenerate admissible number k, the simple principal W-algebra $\mathcal{W}_k(\mathfrak{g}, f_{prin})$ is lisse by Theorem 7.

The following assertion settles the Frenkel-Kac-Waimoto conjecture E. Frenkel, V. Kac, and Wakimoto [ibid.] in full generality.

Theorem 8 (Arakawa [2015b]). *Let k be a non-degenerate admissible number. Then the simple principal W-algebra $\mathcal{W}_k(\mathfrak{g}, f_{prin})$ is rational.*

The proof of Theorem 8 based on Theorem 4, Theorem 7, and the following assertion on admissible affine vertex algebras, which was conjectured by Adamović and Milas [1995].

Theorem 9 (Arakawa [2016]). *Let $L_k(\mathfrak{g})$ be an admissible affine vertex algebra. Then $L_k(\mathfrak{g})$ is rational in the category $\mathcal{O}$, that is, any $L_k(\mathfrak{g})$-module that belongs to $\mathcal{O}$ is completely reducible.*

The following assertion, which has been widely believed since V. G. Kac and Wakimoto [1990] and E. Frenkel, V. Kac, and Wakimoto [1992], gives a yet another realization of minimal series principal W-algebras.

Theorem 10 (Arakawa, Creutzig, and Linshaw [2018]). *Let $\mathfrak{g}$ be simply laced. For an admissible affine vertex algebra $L_k(\mathfrak{g})$, the vertex algebra $(L_k(\mathfrak{g}) \otimes L_1(\mathfrak{g}))^{\mathfrak{g}[t]}$ is isomorphic to a minimal series principal W-algebra. Conversely, any minimal series principal W-algebra associated with $\mathfrak{g}$ appears in this way.*

In the case that $\mathfrak{g} = \mathfrak{sl}_2$ and k is a non-negative integer, the statement of Theorem 10 is well-known as the GKO construction of the discrete series of the Virasoro vertex algebras Goddard, Kent, and Olive [1986]. Some partial results have been obtained previously in Arakawa, Lam, and Yamada [2017] and Arakawa and Jiang [2018]. From Theorem 10, it follows that the minimal series principal W-algebra $\mathcal{W}_{p/q-h^\vee}(\mathfrak{g}, f_{prin})$ of ADE type is unitary, that is, any simple $\mathcal{W}_{p/q-h^\vee}(\mathfrak{g}, f_{prin})$-module is unitary in the sense of Dong and Lin [2014], if and only if $|p-q| = 1$.

7 Four-dimensional $N = 2$ superconformal algebras, Higgs branch conjecture and the class $\mathcal{S}$ chiral algebras

In the study of four-dimensional $N = 2$ superconformal field theories in physics, Beem, Lemos, Liendo, Peelaers, Rastelli, and van Rees Beem, Lemos, Liendo, Peelaers, Rastelli, and van Rees [2015] have constructed a remarkable map

(11) $$\Phi : \{\text{4d } N = 2 \text{ SCFTs}\} \to \{\text{vertex algebras}\}$$

such that, among other things, the character of the vertex algebra $\Phi(\mathcal{T})$ coincides with the *Schur index* of the corresponding 4d $N = 2$ SCFT $\mathcal{T}$, which is an important invariant of the theory $\mathcal{T}$.

How do vertex algebras coming from 4d $N = 2$ SCFTs look like? According to Beem, Lemos, Liendo, Peelaers, Rastelli, and van Rees [ibid.], we have

$$c_{2d} = -12 c_{4d},$$

where c_{4d} and c_{2d} are central charges of the 4d $N = 2$ SCFT and the corresponding vertex algebra, respectively. Since the central charge is positive for a unitary theory, this implies that the vertex algebras obtained by Φ are never unitary. In particular integrable affine vertex algebras never appear by this correspondence.

The main examples of vertex algebras considered in Beem, Lemos, Liendo, Peelaers, Rastelli, and van Rees [ibid.] are the affine vertex algebras $L_k(\mathfrak{g})$ of types D_4, F_4, E_6, E_7,

E_8 at level $k = -h^\vee/6-1$, which are non-rational, non-admissible affine vertex algebras studies in Arakawa and Moreau [2016]. One can find more examples in the literature, see e.g. Beem, Peelaers, Rastelli, and van Rees [2015], Xie, Yan, and Yau [2016], Córdova and Shao [2016], and Song, Xie, and Yan [2017].

Now, there is another important invariant of a 4d $N = 2$ SCFT $\mathcal{T}$, called the *Higgs branch*, which we denote by $Higgs_{\mathcal{T}}$. The Higgs branch $Higgs_{\mathcal{T}}$ is an affine algebraic variety that has the hyperKähler structure in its smooth part. In particular, $Higgs_{\mathcal{T}}$ is a (possibly singular) symplectic variety.

Let $\mathcal{T}$ be one of the 4d $N = 2$ SCFTs studied in Beem, Lemos, Liendo, Peelaers, Rastelli, and van Rees [2015] such that that $\Phi(\mathcal{T}) = L_k(\mathfrak{g})$ with $k = h^\vee/6-1$ for types D_4, F_4, E_6, E_7, E_8 as above. It is known that $Higgs_{\mathcal{T}} = \overline{\mathbb{O}_{min}}$, and this equals Arakawa and Moreau [2016] to the the associated variety $X_{\Phi(\mathcal{T})}$. It is expected that this is not just a coincidence.

Conjecture 11 (Beem and Rastelli [2017])**.** For a 4d $N = 2$ SCFT $\mathcal{T}$, we have

$$Higgs_{\mathcal{T}} = X_{\Phi(\mathcal{T})}.$$

So we are expected to recover the Higgs branch of a 4d $N = 2$ SCFT from the corresponding vertex algebra, which is a purely algebraic object.

We note that Conjecture 11 is a physical conjecture since the Higgs branch is not a mathematical defined object at the moment. The Schur index is not a mathematical defined object either. However, in view of (11) and Conjecture 11, one can try to define both Higgs branches and Schur indices of 4d $N = 2$ SCFTs using vertex algebras. We note that there is a close relationship between Higgs branches of 4d $N = 2$ SCFTs and *Coulomb branches* of three-dimensional $N = 4$ gauge theories whose mathematical definition has been given by Braverman, Finkelberg, and Nakajima [2016b].

Although Higgs branches are symplectic varieties, the associated variety X_V of a vertex algebra V is only a Poisson variety in general. A vertex algebra V is called *quasi-lisse* (Arakawa and Kawasetsu [n.d.]) if X_V has only finitely many symplectic leaves. If this is the case symplectic leaves in X_V are algebraic (Brown and Gordon [2003]). Clearly, lisse vertex algebras are quasi-lisse. The simple affine vertex algebra $L_k(\mathfrak{g})$ is quasi-lisse if and only if $X_{L_k(\mathfrak{g})} \subset \mathfrak{N}$. In particular, admissible affine vertex algebras are quasi-lisse. See Arakawa and Moreau [2016, 2017, 2018b] for more examples of quasi-lisse vertex algebras. Physical intuition expects that vertex algebras that come from 4d $N = 2$ SCFTs via the map Φ are quasi-lisse.

By extending Zhu's argument Zhu [1996] using a theorem of Etingof and Schelder Etingof and Schedler [2010], we obtain the following assertion.

Theorem 12 (Arakawa and Kawasetsu [n.d.])**.** *Let V be a quasi-lisse $\mathbb{Z}_{\geq 0}$-graded conformal vertex algebra such that $V_0 = \mathbb{C}$. Then there only finitely many simple ordinary*

V-modules. Moreover, for an ordinary V-module M, the character $\chi_M(q)$ satisfies a modular linear differential equation.

Since the space of solutions of a modular linear differential equation is invariant under the action of $SL_2(\mathbb{Z})$, Theorem 12 implies that a quasi-lisse vertex algebra possesses a certain modular invariance property, although we do not claim that the normalized characters of ordinary V-modules span the space of the solutions. Note that Theorem 12 implies that the Schur indices of 4d $N = 2$ SCFTs have some modular invariance property. This is something that has been conjectured by physicists (Beem and Rastelli [2017]).

There is a distinct class of four-dimensional $N = 2$ superconformal field theories called the *theory of class* $\mathcal{S}$ (Gaiotto [2012] and Gaiotto, Moore, and Neitzke [2013]), where $\mathcal{S}$ stands for 6. The vertex algebras obtained from the theory of class $\mathcal{S}$ is called the *chiral algebras of class* $\mathcal{S}$ (Beem, Peelaers, Rastelli, and van Rees [2015]). The Moore-Tachikawa conjecture Moore and Tachikawa [2012], which was recently proved in Braverman, Finkelberg, and Nakajima [2017], describes the Higgs branches of the theory of class $\mathcal{S}$ in terms of two-dimensional topological quantum field theories.

Let $\mathbb{V}$ be the category of vertex algebras, whose objects are semisimple groups, and $\mathrm{Hom}(G_1, G_2)$ is the isomorphism classes of conformal vertex algebras V with a vertex algebra homomorphism

$$V^{-h_1^\vee}(\mathfrak{g}_1) \otimes V^{-h_2^\vee}(\mathfrak{g}_2) \to V$$

such that the action of $\mathfrak{g}_1[t] \oplus \mathfrak{g}_2[t]$ on V is locally finite. Here $\mathfrak{g}_i = \mathrm{Lie}(G_i)$ and $h_i^\vee$ is the dual Coxeter number of $\mathfrak{g}_i$ in the case that $\mathfrak{g}_i$ is simple. If $\mathfrak{g}_i$ is not simple we understand $V^{-h_i^\vee}(\mathfrak{g}_i)$ to be the tensor product of the critical level universal affine vertex algebras corresponding to all simple components of $\mathfrak{g}_i$. The composition $V_1 \circ V_2$ of $V_1 \in \mathrm{Hom}(G_1, G_2)$ and $V_2 \in \mathrm{Hom}(G_1, G_2)$ is given by the relative semi-infinite cohomology

$$V_1 \circ V_2 = H^{\frac{\infty}{2}+\bullet}(\widehat{\mathfrak{g}}_2, \mathfrak{g}_2, V_1 \otimes V_2),$$

where $\widehat{\mathfrak{g}}_2$ denotes the direct sum of the affine Kac-Moody algebra associated with the simple components of $\mathfrak{g}_2$. By a result of Arkhipov and Gaitsgory [2002], one finds that the identity morphism id_G is the algebra $\mathfrak{D}_G^{ch}$ of *chiral differential operators* on G (Malikov, Schechtman, and Vaintrob [1999] and Beilinson and V. Drinfeld [2004]) at the critical level, whose associated variety is canonically isomorphic to T^*G.

The following theorem, which was conjectured in Beem, Lemos, Liendo, Peelaers, Rastelli, and van Rees [2015] (see Tachikawa [n.d.(a),(b)]) for mathematical expositions), describes the chiral algebras of class $\mathcal{S}$.

Theorem 13 (Arakawa [n.d.]). *Let $\mathbb{B}_2$ the category of 2-bordisms. There exists a unique monoidal functor $\eta_G : \mathbb{B}_2 \to \mathbb{V}$ which sends (1) the object S^1 to G, (2) the cylinder,* *which is the identity morphism* id_{S^1}, *to the identity morphism* $\mathrm{id}_G = \mathfrak{D}_G^{ch}$, *and (3) the cap to* $H^0_{DS,f_{prin}}(\mathfrak{D}_G^{ch})$. *Moreover, we have* $X_{\eta_G(B)} \cong \eta_G^{BFN}(B)$ *for any 2-bordism* B, *where* η_G^{BFN} *is the functor form* $\mathbb{B}_2$ *to the category of symplectic variaties constructed in Braverman, Finkelberg, and Nakajima [2017].*

The last assertion of the above theorem confirms the Higgs branch conjecture for the theory of class $\mathcal{S}$.

DOUBLE AFFINE GRASSMANNIANS AND COULOMB BRANCHES OF $3d\,\mathcal{N}=4$ QUIVER GAUGE THEORIES

Michael Finkelberg

Abstract

We propose a conjectural construction of various slices for double affine Grassmannians as Coulomb branches of 3-dimensional $\mathcal{N}=4$ supersymmetric affine quiver gauge theories. It generalizes the known construction for the usual affine Grassmannians, and makes sense for arbitrary symmetric Kac-Mody algebras.

1 Introduction

1.1 Historical background. The geometric Satake equivalence Lusztig [1983], Ginzburg [1995], Beilinson and Drinfeld [2000], and Mirković and Vilonen [2007] proposed by V. Drinfeld for the needs of the Geometric Langlands Program proved very useful for the study of representation theory of reductive algebraic groups (starting from G. Lusztig's construction of q-analogues of weight multiplicities). About 15 years ago, I. Frenkel and I. Grojnowski envisioned an extension of the geometric Satake equivalence to the case of loop groups. The affine Grassmannians (the main objects of the geometric Satake equivalence) are ind-schemes of ind-finite type. Their loop analogues (double affine Grassmannians) are much more infinite, beyond our current technical abilities. We are bound to settle for some provisional substitutes, such as transversal slices to the smaller strata in the closures of bigger strata. These substitutes still carry quite powerful geometric information.

Following I. Frenkel's suggestion, some particular slices for the double affine Grassmannians were constructed in terms of Uhlenbeck compactifications of instanton moduli spaces on Kleinian singularities about 10 years ago. More recently, H. Nakajima's approach to Coulomb branches of 3-dimensional $\mathcal{N}=4$ supersymmetric gauge theories, applied to affine quiver gauge theories, paved a way for the construction of the most general slices.

MSC2010: primary 22E46; secondary 14J60, 14J81.

1.2 Contents. We recall the geometric Satake equivalence in Section 2. The (generalized) slices for the affine Grassmannians are reviewed in Section 3. The problem of constructing (the slices for) the double affine Grassmannians is formulated in Section 4. The mathematical construction of Coulomb branches of $3d$ $\mathcal{N}=4$ gauge theories and its application to slices occupies Section 5. Some more applications are mentioned in Section 6.

Acknowledgments. This report is based mostly on the works of A. Braverman and H. Nakajima, some joint with the author. I was incredibly lucky to have an opportunity to learn mathematics from them. Before meeting them, I was introduced to some semiinfinite ideas sketched below by A. Beilinson, V. Drinfeld, B. Feigin, V. Ginzburg and I. Mirković. It is also a pleasure to acknowledge my intellectual debt to R. Bezrukavnikov, D. Gaiotto, D. Gaitsgory, J. Kamnitzer and V. Pestun.

2 Geometric Satake equivalence

Let $\mathcal{O}$ denote the formal power series ring $\mathbb{C}[[z]]$, and let $\mathcal{K}$ denote its fraction field $\mathbb{C}((z))$. Let G be an almost simple complex algebraic group with a Borel and a Cartan subgroup $G \supset B \supset T$, and with the Weyl group W_{fin} of (G,T). Let Λ be the coweight lattice, and let $\Lambda^+ \subset \Lambda$ be the submonoid of dominant coweights. Let also $\Lambda_+ \subset \Lambda$ be the submonoid spanned by the simple coroots α_i, $i \in I$. We denote by $G^\vee \supset T^\vee$ the Langlands dual group, so that Λ is the weight lattice of $G^\vee$.

The affine Grassmannian $\mathrm{Gr}_G = G_{\mathcal{K}}/G_{\mathcal{O}}$ is an ind-projective scheme, the union $\bigsqcup_{\bar\lambda\in\Lambda^+}\mathrm{Gr}_G^{\bar\lambda}$ of $G_{\mathcal{O}}$-orbits. The closure of $\mathrm{Gr}_G^{\bar\lambda}$ is a projective variety $\overline{\mathrm{Gr}}_G^{\bar\lambda} = \bigsqcup_{\bar\mu\le\bar\lambda}\mathrm{Gr}_G^{\bar\mu}$. The fixed point set Gr_G^T is naturally identified with the coweight lattice Λ; and $\bar\mu\in\Lambda$ lies in $\mathrm{Gr}_G^{\bar\lambda}$ iff $\bar\mu \in W_{\text{fin}}\bar\lambda$.

One of the cornerstones of the Geometric Langlands Program initiated by V. Drinfeld is an equivalence $\mathbb{S}$ of the tensor category $\mathrm{Rep}(G^\vee)$ and the category $\mathrm{Perv}_{G_{\mathcal{O}}}(\mathrm{Gr}_G)$ of $G_{\mathcal{O}}$-equivariant perverse constructible sheaves on Gr_G equipped with a natural monoidal convolution structure $\star$ and a fiber functor $H^\bullet(\mathrm{Gr}_G,-)$ Lusztig [1983], Ginzburg [1995], Beilinson and Drinfeld [2000], and Mirković and Vilonen [2007]. It is a categorification of the classical Satake isomorphism between $K(\mathrm{Rep}(G^\vee)) = \mathbb{C}[T^\vee]^{W_{\text{fin}}}$ and the spherical affine Hecke algebra of G. The geometric Satake equivalence $\mathbb{S}$ sends an irreducible $G^\vee$-module $V^{\bar\lambda}$ with highest weight $\bar\lambda$ to the Goresky-MacPherson sheaf $\mathrm{IC}(\overline{\mathrm{Gr}}_G^{\bar\lambda})$.

In order to construct a commutativity constraint for $(\mathrm{Perv}_{G_{\mathcal{O}}}(\mathrm{Gr}_G),\star)$, Beilinson and Drinfeld introduced a relative version $\mathrm{Gr}_{G,BD}$ of the Grassmannian over the Ran space of a smooth curve X, and a fusion monoidal structure Ψ on $\mathrm{Perv}_{G_{\mathcal{O}}}(\mathrm{Gr}_G)$ (isomorphic to $\star$). One of the main discoveries of Mirković and Vilonen [2007] was a Λ-grading of the fiber functor $H^\bullet(\mathrm{Gr}_G, \mathcal{F}) = \bigoplus_{\bar\lambda\in\Lambda} \Phi_{\bar\lambda}(\mathcal{F})$ by the hyperbolic stalks at T-fixed points. For a $G^\vee$-module V, its weight space $V_{\bar\lambda}$ is canonically isomorphic to the hyperbolic stalk $\Phi_{\bar\lambda}(\mathbb{S}V)$.

Various geometric structures of a perverse sheaf $\mathbb{S}V$ reflect some fine representation theoretic structures of V, such as Brylinski-Kostant filtration and the action of dynamical Weyl group, see Ginzburg and Riche [2015]. One of the important technical tools of studying $\mathrm{Perv}_{G_\mathcal{O}}(\mathrm{Gr}_G)$ is the embedding $\mathrm{Gr}_G \hookrightarrow \mathbf{Gr}_G$ into Kashiwara infinite type scheme $\mathbf{Gr}_G = G_{\mathbb{C}((z^{-1}))}/G_{\mathbb{C}[z]}$ Kashiwara [1989] and Kashiwara and Tanisaki [1995]. The quotient $G_{\mathbb{C}[[z^{-1}]]}\backslash\mathbf{Gr}_G$ is the moduli stack $\mathrm{Bun}_G(\mathbb{P}^1)$ of G-bundles on the projective line $\mathbb{P}^1$. The $G_{\mathbb{C}[[z^{-1}]]}$-orbits on $\mathbf{Gr}_G$ are of finite codimension; they are also numbered by the dominant coweights of G, and the image of an orbit $\mathbf{Gr}_G^{\bar\lambda}$ in $\mathrm{Bun}_G(\mathbb{P}^1)$ consists of G-bundles of isomorphism type $\bar\lambda$ Grothendieck [1957]. The stratifications $\mathrm{Gr}_G = \bigsqcup_{\bar\lambda\in\Lambda^+} \mathrm{Gr}_G^{\bar\lambda}$ and $\mathbf{Gr}_G = \bigsqcup_{\bar\lambda\in\Lambda^+} \mathbf{Gr}_G^{\bar\lambda}$ are transversal, and their intersections and various generalizations thereof are the subject of the next section.

3 Generalized slices

3.1 The dominant case. We denote by K_1 the first congruence subgroup of $G_{\mathbb{C}[[z^{-1}]]}$: the kernel of the evaluation projection $\mathrm{ev}_\infty\colon G_{\mathbb{C}[[z^{-1}]]} \twoheadrightarrow G$. The transversal slice $\mathcal{W}_{\bar\mu}^{\bar\lambda}$ (resp. $\overline{\mathcal{W}}_{\bar\mu}^{\bar\lambda}$) is defined as the intersection of $\mathrm{Gr}_G^{\bar\lambda}$ (resp. $\overline{\mathrm{Gr}}_G^{\bar\lambda}$) and $K_1\cdot\bar\mu$ in $\mathbf{Gr}_G$. It is known that $\overline{\mathcal{W}}_{\bar\mu}^{\bar\lambda}$ is nonempty iff $\bar\mu \le \bar\lambda$, and $\dim \overline{\mathcal{W}}_{\bar\mu}^{\bar\lambda}$ is an affine irreducible variety of dimension $\langle 2\bar\rho^\vee, \bar\lambda - \bar\mu\rangle$. Following an idea of I. Mirković, Kamnitzer, Webster, Weekes, and Yacobi [2014] proved that $\overline{\mathcal{W}}_{\bar\mu}^{\bar\lambda} = \bigsqcup_{\bar\mu\le\bar\nu\le\bar\lambda} \mathcal{W}_{\bar\mu}^{\bar\nu}$ is the decomposition of $\overline{\mathcal{W}}_{\bar\mu}^{\bar\lambda}$ into symplectic leaves of a natural Poisson structure.

The only T-fixed point of $\overline{\mathcal{W}}_{\bar\mu}^{\bar\lambda}$ is $\bar\mu$. We consider the cocharacter $2\bar\rho\colon \mathbb{C}^\times \to T$, and denote by $R_{\bar\mu}^{\bar\lambda} \subset \overline{\mathcal{W}}_{\bar\mu}^{\bar\lambda}$ the corresponding repellent: the closed affine subvariety formed by all the points that flow into $\bar\mu$ under the action of $2\bar\rho(t)$, as t goes to ∞. Let r stand for the closed embedding of $R_{\bar\mu}^{\bar\lambda}$ into $\overline{\mathcal{W}}_{\bar\mu}^{\bar\lambda}$, and let ι stand for the closed embedding of $\bar\mu$ into $R_{\bar\mu}^{\bar\lambda}$. Then the hyperbolic stalk $\Phi_{\bar\mu}^{\bar\lambda}\mathcal{F}$ of a T-equivariant constructible complex $\mathcal{F}$ on $\overline{\mathcal{W}}_{\bar\mu}^{\bar\lambda}$ is defined as $\iota^! r^*\mathcal{F}$, see Braden [2003] and Drinfeld and Gaitsgory [2014].

Recall that the geometric Satake equivalence takes an irreducible $G^\vee$-module $V^{\bar\lambda}$ to the IC-sheaf $\mathrm{IC}(\overline{\mathrm{Gr}}_G^{\bar\lambda})$, and the weight space $V_{\bar\mu}^{\bar\lambda}$ is realized as $V_{\bar\mu}^{\bar\lambda} = \Phi_{\bar\mu}\mathrm{IC}(\overline{\mathrm{Gr}}_G^{\bar\lambda}) = \Phi_{\bar\mu}^{\bar\lambda}\mathrm{IC}(\overline{\mathcal{W}}_{\bar\mu}^{\bar\lambda})$. The usual stalks of both $\mathrm{IC}(\overline{\mathrm{Gr}}_G^{\bar\lambda})$ and $\mathrm{IC}(\overline{\mathcal{W}}_{\bar\mu}^{\bar\lambda})$ at $\bar\mu$ are isomorphic up to shift to the associated graded $\mathrm{gr}\, V_{\bar\mu}^{\bar\lambda}$ with respect to the Brylinski-Kostant filtration.

3.2 The general case. If we want to reconstruct the whole of $V^{\bar{\lambda}}$ from the various slices $\overline{\mathcal{W}}^{\bar{\lambda}}_{\bar{\mu}}$, we are missing the weight spaces $V^{\bar{\lambda}}_{\bar{\mu}}$ with nondominant $\bar{\mu}$. To take care of the remaining weight spaces, for arbitrary $\bar{\mu}$ we consider the moduli space $\overline{\mathcal{W}}^{\bar{\lambda}}_{\bar{\mu}}$ of the following data:

(a) A G-bundle $\mathcal{P}$ on $\mathbb{P}^1$.

(b) A trivialization $\sigma\colon \mathcal{P}_{\mathrm{triv}}|_{\mathbb{P}^1\setminus\{0\}} \xrightarrow{\sim} \mathcal{P}|_{\mathbb{P}^1\setminus\{0\}}$ having a pole of degree $\leq \bar{\lambda}$ at $0 \in \mathbb{P}^1$ (that is defining a point of $\overline{\mathrm{Gr}}^{\bar{\lambda}}_G$).

(c) A B-structure ϕ on $\mathcal{P}$ of degree $w_0\bar{\mu}$ with the fiber $B_- \subset G$ at $\infty \in \mathbb{P}^1$ (with respect to the trivialization σ of $\mathcal{P}$ at $\infty \in \mathbb{P}^1$). Here $G \supset B_- \supset T$ is the Borel subgroup opposite to B, and $w_0 \in W_{\mathrm{fin}}$ is the longest element.

This construction goes back to Finkelberg and Mirković [1999]. The space $\overline{\mathcal{W}}^{\bar{\lambda}}_{\bar{\mu}}$ is nonempty iff $\bar{\mu} \leq \bar{\lambda}$. In this case it is an irreducible affine normal Cohen-Macaulay variety of dimension $\langle 2\bar{\rho}^\vee, \bar{\lambda} - \bar{\mu}\rangle$, see Braverman, Finkelberg, and Nakajima [2016a]. In case $\bar{\mu}$ is dominant, the two definitions of $\overline{\mathcal{W}}^{\bar{\lambda}}_{\bar{\mu}}$ agree. At the other extreme, if $\bar{\lambda} = 0$, then $\overline{\mathcal{W}}^{0}_{-\alpha}$ is nothing but the open zastava space $\mathring{Z}^{-w_0\alpha}$. The T-fixed point set $(\overline{\mathcal{W}}^{\bar{\lambda}}_{\bar{\mu}})^T$ is nonempty iff the weight space $V^{\bar{\lambda}}_{\bar{\mu}}$ is not 0; in this case $(\overline{\mathcal{W}}^{\bar{\lambda}}_{\bar{\mu}})^T$ consists of a single point denoted $\bar{\mu}$. We consider the repellent $R^{\bar{\lambda}}_{\bar{\mu}} \subset \overline{\mathcal{W}}^{\bar{\lambda}}_{\bar{\mu}}$. It is a closed subvariety of dimension $\langle \bar{\rho}^\vee, \bar{\lambda} - \bar{\mu}\rangle$ (equidimensional). We have $V^{\bar{\lambda}}_{\bar{\mu}} = \Phi_{\bar{\mu}} \mathrm{IC}(\overline{\mathrm{Gr}}^{\bar{\lambda}}_G) = \Phi^{\bar{\lambda}}_{\bar{\mu}} \mathrm{IC}(\overline{\mathcal{W}}^{\bar{\lambda}}_{\bar{\mu}})$, so that $V^{\bar{\lambda}} = \bigoplus_{\bar{\mu}\in\Lambda} \Phi^{\bar{\lambda}}_{\bar{\mu}} \mathrm{IC}(\overline{\mathcal{W}}^{\bar{\lambda}}_{\bar{\mu}})$ (see Krylov [2017]). Similarly to Braverman and Gaitsgory [2001], one can introduce a crystal structure on the set of irreducible components $\bigsqcup_{\bar{\mu}\in\Lambda} \mathrm{Irr}\, R^{\bar{\lambda}}_{\bar{\mu}}$ (see Krylov [2017]), so that the resulting crystal is isomorphic to the integrable crystal $\mathbf{B}(\bar{\lambda})$ (for a beautiful survey on crystals, see Kashiwara [1995]).

3.3 Beilinson-Drinfeld slices. Let $\underline{\bar{\lambda}} = (\bar{\lambda}_1, \ldots, \bar{\lambda}_N)$ be a collection of dominant coweights of G. We consider the moduli space $\underline{\overline{\mathcal{W}}}^{\underline{\bar{\lambda}}}_{\bar{\mu}}$ of the following data:

(a) A collection of points $(z_1, \ldots, z_N) \in \mathbb{A}^N$ on the affine line $\mathbb{A}^1 \subset \mathbb{P}^1$.

(b) A G-bundle $\mathcal{P}$ on $\mathbb{P}^1$.

(c) A trivialization $\sigma\colon \mathcal{P}_{\mathrm{triv}}|_{\mathbb{P}^1\setminus\{z_1,\ldots,z_N\}} \xrightarrow{\sim} \mathcal{P}|_{\mathbb{P}^1\setminus\{z_1,\ldots,z_N\}}$ with a pole of degree $\leq \sum_{s=1}^N \bar{\lambda}_s \cdot z_s$ on the complement.

(d) A B-structure ϕ on $\mathcal{P}$ of degree $w_0\bar{\mu}$ with the fiber $B_- \subset G$ at $\infty \in \mathbb{P}^1$ (with respect to the trivialization σ of $\mathcal{P}$ at $\infty \in \mathbb{P}^1$).

$\underline{\overline{\mathcal{W}}}^{\underline{\bar{\lambda}}}_{\bar{\mu}}$ is nonempty iff $\bar{\mu} \leq \bar{\lambda} := \sum_{s=1}^N \bar{\lambda}_s$. In this case it is an irreducible affine normal Cohen-Macaulay variety flat over $\mathbb{A}^N$ of relative dimension $\langle 2\bar{\rho}^\vee, \bar{\lambda} - \bar{\mu}\rangle$, see Braverman, Finkelberg, and Nakajima [2016a]. The fiber over $N \cdot 0 \in \mathbb{A}^N$ is nothing but $\overline{\mathcal{W}}^{\bar{\lambda}}_{\bar{\mu}}$. We can consider the Verdier specialization $\mathrm{Sp}\,\mathrm{IC}(\underline{\overline{\mathcal{W}}}^{\bar\lambda}_{\bar\mu})$ to the special fiber $\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$. It is a perverse sheaf on $\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}\times\mathbb{A}^N$ smooth along the diagonal stratification of $\mathbb{A}^N$. We denote by $\Psi\mathrm{IC}(\underline{\overline{\mathcal{W}}}^{\bar\lambda}_{\bar\mu})$ its restriction to $\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}\times\underline{z}$ where $\underline{z}$ is a point of $\mathbb{A}^N_{\mathbb{R}}$ such that $z_1>\ldots>z_N$. Then

$$\Psi\mathrm{IC}(\underline{\overline{\mathcal{W}}}^{\bar\lambda}_{\bar\mu})\simeq\bigoplus_{\bar\mu\le\bar\nu\le\bar\lambda,\ \bar\nu\in\Lambda^+}M^{\underline{\bar\lambda}}_{\bar\nu}\otimes\mathrm{IC}(\overline{\mathcal{W}}^{\bar\nu}_{\bar\mu}),$$

where $M^{\underline{\bar\lambda}}_{\bar\nu}$ is the multiplicity $\mathrm{Hom}_{G^\vee}(V^{\bar\nu},V^{\bar\lambda_1}\otimes\ldots\otimes V^{\bar\lambda_N})$.

3.4 Convolution diagram over slices. In the setup of Section 3.3 we consider the moduli space $\underline{\widetilde{\mathcal{W}}}^{\bar\lambda}_{\bar\mu}$ of the following data:

(a) A collection of points $(z_1,\ldots,z_N)\in\mathbb{A}^N$ on the affine line $\mathbb{A}^1\subset\mathbb{P}^1$.

(b) A collection of G-bundles $(\mathcal{P}_1,\ldots,\mathcal{P}_N)$ on $\mathbb{P}^1$.

(c) A collection of isomorphisms $\sigma_s\colon\mathcal{P}_{s-1}|_{\mathbb{P}^1\setminus\{z_s\}}\xrightarrow{\sim}\mathcal{P}_s|_{\mathbb{P}^1\setminus\{z_s\}}$ with a pole of degree $\le\bar\lambda_s$ at z_s. Here $1\le s\le N$, and $\mathcal{P}_0:=\mathcal{P}_{\mathrm{triv}}$.

(d) A B-structure ϕ on $\mathcal{P}_N$ of degree $w_0\bar\mu$ with the fiber $B_-\subset G$ at $\infty\in\mathbb{P}^1$ (with respect to the trivialization $\sigma_N\circ\ldots\circ\sigma_1$ of $\mathcal{P}_N$ at $\infty\in\mathbb{P}^1$).

A natural projection $\varpi\colon\underline{\widetilde{\mathcal{W}}}^{\bar\lambda}_{\bar\mu}\to\underline{\overline{\mathcal{W}}}^{\bar\lambda}_{\bar\mu}$ sends $(\mathcal{P}_1,\ldots,\mathcal{P}_N,\sigma_1,\ldots,\sigma_N)$ to $(\mathcal{P}_N,\sigma_N\circ\ldots\circ\sigma_1)$. We denote $\varpi^{-1}(\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu})$ by $\widetilde{\mathcal{W}}^{\underline{\bar\lambda}}_{\bar\mu}$. Then $\varpi\colon\widetilde{\mathcal{W}}^{\underline{\bar\lambda}}_{\bar\mu}\to\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$ is stratified semismall, and

$$\varpi_*\mathrm{IC}(\widetilde{\mathcal{W}}^{\underline{\bar\lambda}}_{\bar\mu})=\bigoplus_{\bar\mu\le\bar\nu\le\bar\lambda,\ \bar\nu\in\Lambda^+}M^{\underline{\bar\lambda}}_{\bar\nu}\otimes\mathrm{IC}(\overline{\mathcal{W}}^{\bar\nu}_{\bar\mu}).$$

4 Double affine Grassmannian

In this section G is assumed to be a simply connected almost simple complex algebraic group.

4.1 The affine group and its Langlands dual. We consider the minimal integral even positive definite W_{fin}-invariant symmetric bilinear form $(\cdot,\cdot)$ on the coweight lattice Λ. It gives rise to a central extension $\widehat{G}$ of the polynomial version $G_{\mathbb{C}[t^{\pm1}]}$ of the loop group:

$$1\to\mathbb{C}^\times\to\widehat{G}\to G_{\mathbb{C}[t^{\pm1}]}\to 1.$$

The loop rotation group $\mathbb{C}^\times$ acts naturally on $G_{\mathbb{C}[t^{\pm1}]}$, and this action lifts to $\widehat{G}$. We denote the corresponding semidirect product $\mathbb{C}^\times\ltimes\widehat{G}$ by G_{aff}. It is an untwisted affine Kac-Moody group ind-scheme.

We denote by $G_{\mathrm{aff}}^{\vee}$ the corresponding Langlands dual group. Note that if G is not simply laced, then $G_{\mathrm{aff}}^{\vee}$ is a twisted affine Kac-Moody group, not to be confused with $(G^{\vee})_{\mathrm{aff}}$. However, we have a canonical embedding $G^{\vee} \hookrightarrow G_{\mathrm{aff}}^{\vee}$.

We fix a Cartan torus $\mathbb{C}^{\times} \times T \times \mathbb{C}^{\times} \subset G_{\mathrm{aff}}$ and its dual Cartan torus $\mathbb{C}^{\times} \times T^{\vee} \times \mathbb{C}^{\times} \subset G_{\mathrm{aff}}^{\vee}$. Here the first copy of $\mathbb{C}^{\times}$ is the central $\mathbb{C}^{\times}$, while the second copy is the loop rotation $\mathbb{C}^{\times}$. Accordingly, the weight lattice Λ_{aff} of $G_{\mathrm{aff}}^{\vee}$ is $\mathbb{Z} \oplus \Lambda \oplus \mathbb{Z}$: the first copy of $\mathbb{Z}$ is the central charge (level), and the second copy is the energy. A typical element $\lambda \in \Lambda_{\mathrm{aff}}$ will be written as $\lambda = (k, \bar{\lambda}, n)$. The subset of dominant weights $\Lambda_{\mathrm{aff}}^{+} \subset \Lambda_{\mathrm{aff}}$ consists of all the triples $(k, \bar{\lambda}, n)$ such that $\bar{\lambda} \in \Lambda^{+}$ and $\langle \bar{\lambda}, \bar{\theta}^{\vee} \rangle \leq k$. Here $\bar{\theta}^{\vee} = \sum_{i \in I} a_i \alpha_i^{\vee}$ is the highest root of $G \supset B \supset T$. We denote by $\Lambda_{\mathrm{aff},k}^{+} \subset \Lambda_{\mathrm{aff}}^{+}$ the finite subset of dominant weights of level k; we also denote by $\Lambda_{\mathrm{aff},k} \subset \Lambda_{\mathrm{aff}}$ the subset of all the weights of level k. We say that $\lambda \geq \mu$ if $\lambda - \mu$ is an element of the submonoid generated by the positive roots of $G_{\mathrm{aff}}^{\vee}$ (in particular, λ and μ must have the same level). Finally, let $\bar{\omega}_i$, $i \in I$, be the fundamental coweights of G, and $\rho := (1, 0, 0) + \sum_{i \in I} (a_i, \bar{\omega}_i, 0) \in \Lambda_{\mathrm{aff}}$.

The affine Weyl group W_{aff} is the semidirect product $W_{\mathrm{fin}} \ltimes \Lambda$. For $k \in \mathbb{Z}_{>0}$, we also consider its version $W_{\mathrm{aff},k} = W_{\mathrm{fin}} \ltimes k\Lambda$; it acts naturally on $\Lambda_{\mathrm{aff},k} = \{k\} \times \Lambda \oplus \mathbb{Z}$ (trivially on $\mathbb{Z}$). Every $W_{\mathrm{aff},k}$-orbit on $\Lambda_{\mathrm{aff},k}$ contains a unique representative in $\Lambda_{\mathrm{aff},k}^{+}$. It follows that if we denote by Γ_k the group of roots of unity of order k, then there is a natural isomorphism $\Lambda_{\mathrm{aff},k}^{+}/\mathbb{Z} = W_{\mathrm{aff},k} \backslash \Lambda \xrightarrow{\sim} \mathrm{Hom}(\Gamma_k, G)/\mathrm{Ad}_G$.

4.2 The quest. We would like to have a double affine Grassmannian $\mathrm{Gr}_{G_{\mathrm{aff}}}$ and a geometric Satake equivalence between the category of integrable representations $\mathrm{Rep}(G_{\mathrm{aff}}^{\vee})$ and an appropriate category of perverse sheaves on $\mathrm{Gr}_{G_{\mathrm{aff}}}$. Note that the affine Satake isomorphism at the level of functions is established in Braverman and Kazhdan [2013] and Braverman, Kazhdan, and Patnaik [2016] (and in Gaussent and Rousseau [2014] for arbitrary Kac-Moody groups).

Such a quest was formulated by I. Grojnowski in his talk at ICM-2006 in Madrid. At approximately the same time, I. Frenkel suggested that the integrable representations of level k should be realized in cohomology of certain instanton moduli spaces on $\mathbb{A}^2/\Gamma_k$. Here Γ_k acts on $\mathbb{A}^2$ in a hyperbolic way: $\zeta(x, y) = (\zeta x, \zeta^{-1} y)$.

Note that the set of dominant coweights Λ^{+} is well ordered, which reflects the fact that the affine Grassmannian Gr_G is an ind-projective scheme. However, the set of affine dominant coweights $\Lambda_{\mathrm{aff}}^{+}$ is not well ordered: it does not have a minimal element. In fact, it has an automorphism group $\mathbb{Z}$ acting by the energy shifts: $(k, \bar{\lambda}, n) \mapsto (k, \bar{\lambda}, n + n')$ (we add a multiple of the minimal imaginary coroot δ). This indicates that the sought for double affine Grassmannian $\mathrm{Gr}_{G_{\mathrm{aff}}}$ is an object of semiinfinite nature.

At the moment, the only technical possibility of dealing with semiinfinite spaces is via transversal slices to strata. Following I. Frenkel's suggestion, in the series Braverman and

Finkelberg [2010, 2012, 2013] we developed a partial affine analogue of slices of Section 3 defined in terms of Uhlenbeck spaces $\mathfrak{U}_G(\mathbb{A}^2/\Gamma_k)$.

4.3 Dominant slices via Uhlenbeck spaces. The Uhlenbeck space $\mathfrak{U}_G^d(\mathbb{A}^2)$ is a partial closure of the moduli space $\mathrm{Bun}_G^d(\mathbb{A}^2)$ of G-bundles of second Chern class d on the projective plane $\mathbb{P}^2$ trivialized at the infinite line $\mathbb{P}^1_\infty \subset \mathbb{P}^2$, see Braverman, Finkelberg, and Gaitsgory [2006]. It is known that $\mathrm{Bun}_G^d(\mathbb{A}^2)$ is smooth quasiaffine, and $\mathfrak{U}_G^d(\mathbb{A}^2)$ is a connected affine variety of dimension $2dh_G^\vee$ (where $h_G^\vee$ is the dual Coxeter number of G). Conjecturally, $\mathfrak{U}_G^d(\mathbb{A}^2)$ is normal; in this case $\mathfrak{U}_G^d(\mathbb{A}^2)$ is the affinization of $\mathrm{Bun}_G^d(\mathbb{A}^2)$.

The group $G \times \mathrm{GL}(2)$ acts naturally on $\mathfrak{U}_G^d(\mathbb{A}^2)$: the first factor via the change of trivialization at $\mathbb{P}^1_\infty$, and the second factor via its action on $(\mathbb{P}^2, \mathbb{P}^1_\infty)$. The group Γ_k is embedded into GL(2). Given $\mu = (k, \bar{\mu}, m) \in \Lambda^+_{\mathrm{aff},k}$ we choose its lift to a homomorphism from Γ_k to G; thus Γ_k embeds diagonally into $G \times \mathrm{GL}(2)$ and acts on $\mathrm{Bun}_G^d(\mathbb{A}^2)$. The fixed point subvariety $\mathrm{Bun}_G^d(\mathbb{A}^2)^{\Gamma_k}$ consists of Γ_k-equivariant bundles and is denoted $\mathrm{Bun}_{G,\mu}^d(\mathbb{A}^2/\Gamma_k)$; another choice of lift above leads to an isomorphic subvariety. Since $0 \in \mathbb{A}^2$ is a Γ_k-fixed point, for any Γ_k-equivariant G-bundle $\mathcal{P} \in \mathrm{Bun}_{G,\mu}^d(\mathbb{A}^2/\Gamma_k)$ the group Γ_k acts on the fiber $\mathcal{P}_0$. This action defines an element of $\mathrm{Hom}(\Gamma_k, G)/\mathrm{Ad}_G$ to be denoted $[\mathcal{P}_0]$.

Now given $\lambda = (k, \bar{\lambda}, l) \in \Lambda^+_{\mathrm{aff},k}$ we define $\mathrm{Bun}_{G,\mu}^\lambda(\mathbb{A}^2/\Gamma_k)$ as the subvariety of $\mathrm{Bun}_{G,\mu}^d(\mathbb{A}^2/\Gamma_k)$ formed by all $\mathcal{P}$ such that the class $[\mathcal{P}_0] \in \mathrm{Hom}(\Gamma_k, G)/\mathrm{Ad}_G$ is the image of λ, and $d = k(l-m) + \frac{(\bar{\lambda},\bar{\lambda})-(\bar{\mu},\bar{\mu})}{2}$. It is a union of connected components of $\mathrm{Bun}_{G,\mu}^d(\mathbb{A}^2/\Gamma_k)$. Conjecturally, $\mathrm{Bun}_{G,\mu}^\lambda(\mathbb{A}^2/\Gamma_k)$ is connected. This conjecture is proved if $G = \mathrm{SL}(N)$, or $k = 1$, or k is big enough for arbitrary G and fixed $\bar{\lambda}, \bar{\mu}$.

Finally, we define the dominant slice $\overline{\mathcal{W}}{}_\mu^\lambda$ as the closure $\mathfrak{U}_{G,\mu}^\lambda(\mathbb{A}^2/\Gamma_k)$ of $\mathrm{Bun}_{G,\mu}^\lambda(\mathbb{A}^2/\Gamma_k)$ in the Uhlenbeck space $\mathfrak{U}_G^d(\mathbb{A}^2)$.

4.4 (Hyperbolic) stalks. The Cartan torus $T_{\mathrm{aff}} = \mathbb{C}^\times \times T \times \mathbb{C}^\times$ maps into $G \times \mathrm{GL}(2)$. Here the first copy of $\mathbb{C}^\times$ goes to the diagonal torus of $\mathrm{SL}(2) \subset \mathrm{GL}(2)$, while the second copy of $\mathbb{C}^\times$ goes to the center of GL(2). So T_{aff} acts on $\overline{\mathcal{W}}{}_\mu^\lambda$, and we denote by $\mu \in \overline{\mathcal{W}}{}_\mu^\lambda$ the only fixed point. The corresponding repellent R_μ^λ is the closed affine subvariety formed by all the points that flow into μ under the action of $2\rho(t)$, as t goes to ∞. The corresponding hyperbolic stalk $\Phi_\mu^\lambda \mathrm{IC}(\overline{\mathcal{W}}{}_\mu^\lambda)$ is conjecturally isomorphic to the weight space V_μ^λ of the integrable $G_{\mathrm{aff}}^\vee$-module V^λ with highest weight λ. In type A this conjecture follows from the identification of $\overline{\mathcal{W}}{}_\mu^\lambda$ with a Nakajima cyclic quiver variety and I. Frenkel's level-rank duality between the weight multiplicities and the tensor product multiplicities Frenkel [1982], Nakajima [2002, 2009], and Braverman and Finkelberg

[2010]. In type ADE at level 1 this conjecture follows from Braverman, Finkelberg, and Nakajima [2016b]. Also, as the notation suggests, the hyperbolic stalk $\Phi^\lambda_\mu \mathrm{IC}(\overline{\mathcal{W}}^\lambda_\mu)$ is isomorphic to the vanishing cycles of $\mathrm{IC}(\overline{\mathcal{W}}^\lambda_\mu)$ at μ with respect to a general function vanishing at μ Finkelberg and Kubrak [2015]. The usual stalk of $\mathrm{IC}(\overline{\mathcal{W}}^\lambda_\mu)$ at μ is conjecturally isomorphic to the associated graded of V^λ_μ with respect to the the affine Brylinski-Kostant filtration Slofstra [2012]. At level 1, this conjecture follows from the computation of the IC-stalks of Uhlenbeck spaces in Braverman, Finkelberg, and Gaitsgory [2006].

The affine analogs of generalized slices of Sections 3.2, 3.3, 3.4 were constructed in type A in Braverman and Finkelberg [2012, 2013] in terms of Nakajima cyclic quiver varieties mentioned above. For arbitrary G, the desired generalized slices are expected to be the Uhlenbeck partial compactifications of the moduli spaces of Γ_k-equivariant G_c-instantons (where $G_c \subset G$ is a maximal compact subgroup) on multi Taub-NUT spaces (for a physical explanation via a supersymmetric conformal field theory in 6 dimensions, see Witten [2010]). Unfortunately, we are still lacking a modular definition of the Uhlenbeck compactification Baranovsky [2015], and the existing *ad hoc* constructions are not flexible enough. Another approach via the Coulomb branches of framed affine quiver gauge theories following Nakajima [2016a] and Braverman, Finkelberg, and Nakajima [2016c,a, 2017] is described in the remaining sections. For a beautiful short introduction to the Coulomb branches, the reader may consult Nakajima [2016b, 2015].

5 Coulomb branches of $3d$ $\mathcal{N} = 4$ quiver gauge theories

5.1 General setup. Let $\mathbf{N}$ be a finite dimensional representation of a complex connected reductive group G (having nothing to do with G of previous sections). We consider the moduli space $\mathcal{R}_{\mathsf{G},\mathbf{N}}$ of triples $(\mathcal{P}, \sigma, s)$ where $\mathcal{P}$ is a G-bundle on the formal disc $D = \operatorname{Spec} \mathcal{O}$; σ is a trivialization of $\mathcal{P}$ on the punctured formal disc $D^* = \operatorname{Spec} \mathcal{K}$; and s is a section of the associated vector bundle $\mathcal{P}_{\mathrm{triv}} \overset{\mathsf{G}}{\times} \mathbf{N}$ on D^* such that s extends to a regular section of $\mathcal{P}_{\mathrm{triv}} \overset{\mathsf{G}}{\times} \mathbf{N}$ on D, and $\sigma(s)$ extends to a regular section of $\mathcal{P} \overset{\mathsf{G}}{\times} \mathbf{N}$ on D. In other words, s extends to a regular section of the vector bundle associated to the G-bundle glued from $\mathcal{P}$ and $\mathcal{P}_{\mathrm{triv}}$ on the non-separated formal scheme glued from 2 copies of D along D^* (*raviolo*). The group $\mathsf{G}_\mathcal{O}$ acts on $\mathcal{R}_{\mathsf{G},\mathbf{N}}$ by changing the trivialization σ, and we have an evident $\mathsf{G}_\mathcal{O}$-equivariant projection $\mathcal{R}_{\mathsf{G},\mathbf{N}} \to \mathrm{Gr}_\mathsf{G}$ forgetting s. The fibers of this projection are profinite dimensional vector spaces: the fiber over the base point is $\mathbf{N} \otimes \mathcal{O}$, and all the other fibers are subspaces in $\mathbf{N} \otimes \mathcal{O}$ of finite codimension. One may say that $\mathcal{R}_{\mathsf{G},\mathbf{N}}$ is a $\mathsf{G}_\mathcal{O}$-equvariant "constructible profinite dimensional vector bundle" over Gr_G. The $\mathsf{G}_\mathcal{O}$-equivariant Borel-Moore homology $H^{\mathsf{G}_\mathcal{O}}_\bullet(\mathcal{R}_{\mathsf{G},\mathbf{N}})$ is well-defined, and forms an associative algebra with respect to a convolution operation. This algebra is commutative, finitely generated and integral, and its spectrum $\mathcal{M}_C(\mathsf{G}, \mathbf{N}) = \operatorname{Spec} H_\bullet^{\mathsf{G}_\mathcal{O}}(\mathcal{R}_{\mathsf{G},\mathbf{N}})$ is an irreducible normal affine variety of dimension $2\,\mathrm{rk}(\mathsf{G})$, the *Coulomb branch*. It is supposed to be a (singular) hyper-Kähler manifold Seiberg and Witten [1997].

Let $\mathsf{T} \subset \mathsf{G}$ be a Cartan torus with Lie algebra $\mathfrak{t} \subset \mathfrak{g}$. Let $\mathsf{W} = N_\mathsf{G}(\mathsf{T})/\mathsf{T}$ be the corresponding Weyl group. Then the equivariant cohomology $H^\bullet_{\mathsf{G}_\mathcal{O}}(\mathrm{pt}) = \mathbb{C}[\mathfrak{t}/\mathsf{W}]$ forms a subalgebra of $H_\bullet^{\mathsf{G}_\mathcal{O}}(\mathcal{R}_{\mathsf{G},\mathbf{N}})$ (a *Cartan subalgebra*), so we have a projection $\Pi\colon \mathcal{M}_C(\mathsf{G}, \mathbf{N}) \to \mathfrak{t}/\mathsf{W}$.

Finally, the algebra $H_\bullet^{\mathsf{G}_\mathcal{O}}(\mathcal{R}_{\mathsf{G},\mathbf{N}})$ comes equipped with quantization: a $\mathbb{C}[\hbar]$-deformation $\mathbb{C}_\hbar[\mathcal{M}_C(\mathsf{G}, \mathbf{N})] = H_\bullet^{\mathbb{C}^\times \ltimes \mathsf{G}_\mathcal{O}}(\mathcal{R}_{\mathsf{G},\mathbf{N}})$ where $\mathbb{C}^\times$ acts by loop rotations, and $\mathbb{C}[\hbar] = H^\bullet_{\mathbb{C}^\times}(\mathrm{pt})$. It gives rise to a Poisson bracket on $\mathbb{C}[\mathcal{M}_C(\mathsf{G}, \mathbf{N})]$ with an open symplectic leaf, so that Π becomes an integrable system: $\mathbb{C}[\mathfrak{t}/\mathsf{W}] \subset \mathbb{C}[\mathcal{M}_C(\mathsf{G}, \mathbf{N})]$ is a Poisson-commutative polynomial subalgebra with $\mathrm{rk}(\mathsf{G})$ generators.

5.2 Flavor symmetry. Suppose we have an extension $1 \to \mathsf{G} \to \tilde{\mathsf{G}} \to \mathsf{G}_F \to 1$ where G_F is a connected reductive group (a *flavor group*), and the action of G on $\mathbf{N}$ is extended to an action of $\tilde{\mathsf{G}}$. Then the action of $\mathsf{G}_\mathcal{O}$ on $\mathcal{R}_{G,\mathbf{N}}$ extends to an action of $\tilde{\mathsf{G}}_\mathcal{O}$, and the convolution product defines a commutative algebra structure on the equivariant Borel-Moore homology $H_\bullet^{\tilde{\mathsf{G}}_\mathcal{O}}(\mathcal{R}_{\mathsf{G},\mathbf{N}})$. We have the restriction homomorphism $H_\bullet^{\tilde{\mathsf{G}}_\mathcal{O}}(\mathcal{R}_{\mathsf{G},\mathbf{N}}) \to H_\bullet^{\mathsf{G}_\mathcal{O}}(\mathcal{R}_{\mathsf{G},\mathbf{N}}) = H_\bullet^{\tilde{\mathsf{G}}_\mathcal{O}}(\mathcal{R}_{\mathsf{G},\mathbf{N}}) \otimes_{H^\bullet_{\mathsf{G}_F}(\mathrm{pt})} \mathbb{C}$. In other words, $\underline{\mathcal{M}}_C(\mathsf{G}, \mathbf{N}) := \operatorname{Spec} H_\bullet^{\tilde{\mathsf{G}}_\mathcal{O}}(\mathcal{R}_{\mathsf{G},\mathbf{N}})$ is a deformation of $\mathcal{M}_C(\mathsf{G}, \mathbf{N})$ over $\operatorname{Spec} H^\bullet_{\mathsf{G}_F}(\mathrm{pt}) = \mathfrak{t}_F/\mathsf{W}_F$.

We will need the following version of this construction. Let $\mathsf{Z} \subset \mathsf{G}_F$ be a torus embedded into the flavor group. We denote by $\tilde{\mathsf{G}}^\mathsf{Z}$ the pullback extension $1 \to \mathsf{G} \to \tilde{\mathsf{G}}^\mathsf{Z} \to \mathsf{Z} \to 1$. We define $\underline{\mathcal{M}}_C^\mathsf{Z}(\mathsf{G}, \mathbf{N}) := \operatorname{Spec} H_\bullet^{\tilde{\mathsf{G}}^\mathsf{Z}_\mathcal{O}}(\mathcal{R}_{\mathsf{G},\mathbf{N}})$: a deformation of $\mathcal{M}_C(\mathsf{G}, \mathbf{N})$ over $\mathfrak{z} := \operatorname{Spec} H^\bullet_\mathsf{Z}(\mathrm{pt})$.

Since $\mathcal{M}_C(\mathsf{G}, \mathbf{N})$ is supposed to be a hyper-Kähler manifold, its flavor deformation should come together with a (partial) resolution. To construct it, we consider the obvious projection $\tilde{\pi}\colon \mathcal{R}_{\tilde{\mathsf{G}},\mathbf{N}} \to \mathrm{Gr}_{\tilde{\mathsf{G}}} \to \mathrm{Gr}_{\mathsf{G}_F}$. Given a dominant coweight $\lambda_F \in \Lambda_F^+ \subset \mathrm{Gr}_{\mathsf{G}_F}$, we set $\mathcal{R}^{\lambda_F}_{\tilde{\mathsf{G}},\mathbf{N}} := \tilde{\pi}^{-1}(\lambda_F)$, and consider the equivariant Borel-Moore homology $H_\bullet^{\tilde{\mathsf{G}}^\mathsf{Z}_\mathcal{O}}(\mathcal{R}^{\lambda_F}_{\tilde{\mathsf{G}},\mathbf{N}})$. It carries a convolution module structure over $H_\bullet^{\tilde{\mathsf{G}}^\mathsf{Z}_\mathcal{O}}(\mathcal{R}_{\mathsf{G},\mathbf{N}})$. We consider

$$\underline{\widetilde{\mathcal{M}}}_C^{\mathsf{Z},\lambda_F}(\mathsf{G}, \mathbf{N}) := \operatorname{Proj}\Big(\bigoplus_{n\in\mathbb{N}} H_\bullet^{\tilde{\mathsf{G}}^\mathsf{Z}_\mathcal{O}}(\mathcal{R}^{n\lambda_F}_{\tilde{\mathsf{G}},\mathbf{N}})\Big) \xrightarrow{\varpi} \underline{\mathcal{M}}_C^\mathsf{Z}(\mathsf{G}, \mathbf{N}).$$

We denote $\varpi^{-1}(\mathfrak{M}_C(\mathsf{G},\mathbf{N}))$ by $\widetilde{\mathfrak{M}}_C^{\lambda_F}(\mathsf{G},\mathbf{N})$. We have

$$\widetilde{\mathfrak{M}}_C^{\lambda_F}(\mathsf{G},\mathbf{N}) = \operatorname{Proj}(\bigoplus_{n\in\mathbb{N}} H_\bullet^{\mathsf{G}_\mathcal{O}}(\mathcal{R}_{\tilde{\mathsf{G}},\mathbf{N}}^{n\lambda_F})).$$

More generally, for a strictly convex (i.e. not containing nontrivial subgroups) cone $\mathsf{V}\subset\Lambda_F^+$, we consider the multi projective spectra

$$\widetilde{\underline{\mathfrak{M}}}_C^{\mathsf{Z},\mathsf{V}}(\mathsf{G},\mathbf{N}) := \operatorname{Proj}(\bigoplus_{\lambda_F\in\mathsf{V}} H_\bullet^{\tilde{\mathsf{G}}_\mathcal{O}^{\mathsf{Z}}}(\mathcal{R}_{\tilde{\mathsf{G}},\mathbf{N}}^{\lambda_F})) \xrightarrow{\varpi} \underline{\mathfrak{M}}_C^{\mathsf{Z}}(\mathsf{G},\mathbf{N})$$

and

$$\widetilde{\mathfrak{M}}_C^{\mathsf{V}}(\mathsf{G},\mathbf{N}) := \operatorname{Proj}(\bigoplus_{\lambda_F\in\mathsf{V}} H_\bullet^{\mathsf{G}_\mathcal{O}}(\mathcal{R}_{\tilde{\mathsf{G}},\mathbf{N}}^{\lambda_F})) \xrightarrow{\varpi} \mathfrak{M}_C(\mathsf{G},\mathbf{N}).$$

5.3 Quiver gauge theories. Let Q be a quiver with Q_0 the set of vertices, and Q_1 the set of arrows. An arrow $e\in Q_1$ goes from its tail $t(e)\in Q_0$ to its head $h(e)\in Q_0$. We choose a Q_0-graded vector spaces $V := \bigoplus_{j\in Q_0} V_j$ and $W := \bigoplus_{j\in Q_0} W_j$. We set $\mathsf{G} = \mathrm{GL}(V) := \prod_{j\in Q_0}\mathrm{GL}(V_j)$. We choose a second grading $W = \bigoplus_{s=1}^N W^{(s)}$ compatible with the Q_0-grading of W. We set G_F to be a Levi subgroup $\prod_{s=1}^N\prod_{j\in Q_0}\mathrm{GL}(W_j^{(s)})$ of $\mathrm{GL}(W)$, and $\tilde{\mathsf{G}} := \mathsf{G}\times\mathsf{G}_F$. Finally, we define a central subgroup $\mathsf{Z}\subset\mathsf{G}_F$ as follows: $\mathsf{Z} := \prod_{s=1}^N\Delta_{\mathbb{C}^\times}^{(s)} \subset \prod_{s=1}^N\prod_{j\in Q_0}\mathrm{GL}(W_j^{(s)})$, where $\mathbb{C}^\times\cong\Delta_{\mathbb{C}^\times}^{(s)}\subset\prod_{j\in Q_0}\mathrm{GL}(W_j^{(s)})$ is the diagonally embedded subgroup of scalar matrices. The reductive group $\tilde{\mathsf{G}}$ acts naturally on $\mathbf{N} := \bigoplus_{e\in Q_1}\mathrm{Hom}(V_{t(e)},V_{h(e)})\oplus\bigoplus_{j\in Q_0}\mathrm{Hom}(W_j,V_j)$.

The Higgs branch of the corresponding quiver gauge theory is the Nakajima quiver variety $\mathfrak{M}_H(\mathsf{G},\mathbf{N}) = \mathfrak{M}(V,W)$. We are interested in the Coulomb branch $\mathfrak{M}_C(\mathsf{G},\mathbf{N})$.

5.4 Back to slices in an affine Grassmannian. Let now G be an adjoint simple simply laced algebraic group. We choose an orientation Ω of its Dynkin graph (of type ADE), and denote by I its set of vertices. Given an I-graded vector space W we encode its dimension by a dominant coweight $\bar{\lambda} := \sum_{i\in I}\dim(W_i)\bar{\omega}_i \in \Lambda^+$ of G. Given an I-graded vector space V we encode its dimension by a positive coroot combination $\alpha := \sum_{i\in I}\dim(V_i)\alpha_i \in \Lambda_+$. We set $\bar{\mu} := \bar{\lambda}-\alpha\in\Lambda$. Given a direct sum decomposition $W = \bigoplus_{s=1}^N W^{(s)}$ compatible with the I-grading of W as in Section 5.3, we set $\bar{\lambda}_s := \sum_{i\in I}\dim(W_i^{(s)})\bar{\omega}_i\in\Lambda^+$, and finally, $\underline{\bar{\lambda}} := (\bar{\lambda}_1,\dots,\bar{\lambda}_N)$.

Recall the notations of Section 5.2. Since the flavor group G_F is a Levi subgroup of $\mathrm{GL}(W)$, its weight lattice is naturally identified with $\mathbb{Z}^{\dim W}$. More precisely, we choose a basis $w_1,\dots,w_{\dim W}$ of W such that any W_i, $i\in I$, and $W^{(s)}$, $1\le s\le N$, is spanned by a subset of the basis, and we assume the following monotonicity condition: if for $1 \leq a < b < c \leq \dim W$ we have $w_a, w_b \in W^{(s)}$ for certain s, then $w_b \in W^{(s)}$ as well. We define a strictly convex cone $\mathsf{V} = \{(n_1, \dots, n_{\dim W})\} \subset \Lambda_F^+ \subset \mathbb{Z}^{\dim W}$ by the following conditions: (a) if $w_k \in W^{(s)}$, $w_l \in W^{(t)}$, and $s < t$, then $n_k \geq n_l \geq 0$; (b) if $w_k, w_l \in W^{(s)}$, then $n_k = n_l$. The following isomorphisms are constructed in Braverman, Finkelberg, and Nakajima [2016a] (notations of Section 3):

$$\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu} \xrightarrow{\sim} \mathfrak{M}_C(\mathsf{G}, \mathbf{N}),\ \underline{\overline{\mathcal{W}}}^{\bar\lambda}_{\bar\mu} \xrightarrow{\sim} \underline{\mathfrak{M}}^{\mathsf{Z}}_C(\mathsf{G}, \mathbf{N}),$$

(we learned of their existence from V. Pestun). We also expect the following isomorphisms:

$$\underline{\widetilde{\mathcal{W}}}^{\bar\lambda}_{\bar\mu} \xrightarrow{\sim} \underline{\widetilde{\mathfrak{M}}}^{\mathsf{Z},\mathsf{V}}_C(\mathsf{G}, \mathbf{N}),\ \widetilde{\mathcal{W}}^{\bar\lambda}_{\bar\mu} \xrightarrow{\sim} \widetilde{\mathfrak{M}}^{\mathsf{V}}_C(\mathsf{G}, \mathbf{N}).$$

In case G is an adjoint simple non simply laced algebraic group, it can be obtained by folding from a simple simply laced group $\tilde G$ (i.e. as the fixed point set of an outer automorphism of $\tilde G$). The corresponding automorphism of the Dynkin quiver of $\tilde G$ acts on the above Coulomb branches, and the slices for G can be realized as the fixed point sets of these Coulomb branches.

5.5 Back to slices in a double affine Grassmannian. We choose an orientation of an *affine* Dynkin graph of type $A^{(1)}, D^{(1)}, E^{(1)}$ with the set of vertices $\tilde I = I \sqcup \{i_0\}$, and repeat the construction of Section 5.4 for an affine dominant coweight $\lambda = \sum_{i \in \tilde I} \dim(W_i)\omega_i = (k, \bar\lambda, 0) \in \Lambda^+_{\mathrm{aff}}$, a positive coroot combination $\alpha = \sum_{i \in \tilde I} \dim(V_i)\alpha_i \in \Lambda_{\mathrm{aff},+}$, and $\mu := \lambda - \alpha = (k, \bar\mu, n) \in \Lambda_{\mathrm{aff}}$.

We define the slices in $\mathrm{Gr}_{G_{\mathrm{aff}}}$ (where G is the corresponding adjoint simple simply laced algebraic group) as

$$\overline{\mathcal{W}}^{\lambda}_{\mu} := \mathfrak{M}_C(\mathsf{G}, \mathbf{N}),\ \underline{\overline{\mathcal{W}}}^{\lambda}_{\mu} := \underline{\mathfrak{M}}^{\mathsf{Z}}_C(\mathsf{G}, \mathbf{N}),\ \underline{\widetilde{\mathcal{W}}}^{\lambda}_{\mu} := \underline{\widetilde{\mathfrak{M}}}^{\mathsf{Z},\mathsf{V}}_C(\mathsf{G}, \mathbf{N}),\ \widetilde{\mathcal{W}}^{\lambda}_{\mu} := \widetilde{\mathfrak{M}}^{\mathsf{V}}_C(\mathsf{G}, \mathbf{N}).$$

If μ is dominant, the slices $\overline{\mathcal{W}}^{\lambda}_{\mu}$ conjecturally coincide with the ones of Section 4.3. In type A this conjecture follows from the computation Nakajima and Takayama [2017] of Coulomb branches of the cyclic quiver gauge theories and their identification with the Nakajima cyclic quiver varieties.

Note that $\pi_0(\mathcal{R}_{\mathsf{G},\mathbf{N}}) = \pi_0(\mathrm{Gr}_{\mathrm{GL}(V)}) = \pi_1(\mathrm{GL}(V)) = \mathbb{Z}^{\tilde I}$, so that $H^{\mathsf{G}_\mathcal{O}}_\bullet(\mathcal{R}_{\mathsf{G},\mathbf{N}}) = \mathbb{C}[\mathfrak{M}_C(\mathsf{G}, \mathbf{N})] = \mathbb{C}[\overline{\mathcal{W}}^{\lambda}_{\mu}]$ is $\mathbb{Z}^{\tilde I}$-graded. We identify $\mathbb{Z}^{\tilde I}$ with the root lattice of $T_{\mathrm{aff}} \subset G_{\mathrm{aff}}\colon \mathbb{Z}^{\tilde I} = \mathbb{Z}\langle\alpha_i^\vee\rangle_{i \in \tilde I}$. Then the $\mathbb{Z}^{\tilde I}$-grading on $\mathbb{C}[\overline{\mathcal{W}}^{\lambda}_{\mu}]$ corresponds to a T_{aff}-action on $\overline{\mathcal{W}}^{\lambda}_{\mu}$. Composing with the cocharacter $2\rho\colon \mathbb{C}^\times \to T_{\mathrm{aff}}$, we obtain an action of $\mathbb{C}^\times$ on $\overline{\mathcal{W}}^{\lambda}_{\mu}$. Conjecturally, the fixed point set $(\overline{\mathcal{W}}^{\lambda}_{\mu})^{\mathbb{C}^\times}$ is nonempty iff the $V^{\lambda}_{\mu} \neq 0$, and in this case the fixed point set consists of a single point denoted by μ. We consider the corresponding repellent $R^\lambda_\mu \subset \overline{\mathcal{W}}^\lambda_\mu$ and the hyperbolic stalk $\Phi^\lambda_\mu \mathrm{IC}(\overline{\mathcal{W}}^\lambda_\mu)$.

Similarly to Section 5.4, in case G is an adjoint simple non simply laced group, the Dynkin diagram of its affinization can be obtained by folding of a Dynkin graph of type $A^{(1)}, D^{(1)}, E^{(1)}$, and the above slices for G are defined as the fixed point sets of the corresponding slices for the unfolding of G. The repellents and the hyperbolic stalks are thus defined for arbitrary simple G too, and we expect the conclusions of Sections 3.2, 3.3, 3.4 to hold in the affine case as well.

5.6 Warning. In order to formulate the statements about multiplicities for fusion and convolution as in 3.3 and 3.4, we must have closed embeddings of slices $\overline{\mathcal{W}}^{\lambda'}_\mu \hookrightarrow \overline{\mathcal{W}}^\lambda_\mu$ for $\lambda' \le \lambda \in \Lambda^+_{\mathrm{aff}}$. Certainly we do have the natural closed embeddings of generalized slices in $\mathrm{Gr}_G : \overline{\mathcal{W}}^{\bar\lambda'}_{\bar\mu} \hookrightarrow \overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$, $\bar\lambda' \le \bar\lambda \in \Lambda^+$, but these embeddings have no manifest interpretation in terms of Coulomb branches (see Section 6.4 below for a partial advance, though). For a slice in Gr_G, the collection of closures of symplectic leaves in $\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$ coincides with the collection of smaller slices $\overline{\mathcal{W}}^{\bar\lambda'}_{\bar\mu} \subset \overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$, $\bar\mu \le \bar\lambda' \le \bar\lambda$, $\bar\lambda' \in \Lambda^+$. However, in the affine case, in general there are *more* symplectic leaves in $\overline{\mathcal{W}}^\lambda_\mu$ than the cardinality of $\{\lambda' \in \Lambda^+_{\mathrm{aff}} : \mu \le \lambda' \le \lambda\}$. For example, if $k = 1$, and $\mu = 0$, so that $\overline{\mathcal{W}}^\lambda_\mu \simeq \mathcal{U}^d_G(\mathbb{A}^2)$, the symplectic leaves are numbered by the partitions of size $\le d$: they are all of the form $\mathcal{S} \times \mathrm{Bun}^{d'}_G(\mathbb{A}^2)$ where $0 \le d' \le d$, and $\mathcal{S}$ is a stratum of the diagonal stratification of $\mathrm{Sym}^{d-d'} \mathbb{A}^2$.

Thus we expect that the slice $\overline{\mathcal{W}}^{\lambda'}_\mu$ for $\lambda' \in \Lambda^+_{\mathrm{aff}}$, $\mu \le \lambda' \le \lambda$, is isomorphic to the closure of a symplectic leaf in $\overline{\mathcal{W}}^\lambda_\mu$. We also do expect the multiplicity of $\mathrm{IC}(\overline{\mathcal{W}}^{\lambda'}_\mu)$ in $\Psi\mathrm{IC}(\underline{\overline{\mathcal{W}}}^{\underline{\lambda}}_\mu) = \varpi_*\mathrm{IC}(\widetilde{\mathcal{W}}^{\underline{\lambda}}_\mu)$ to be $M^{\underline{\lambda}}_{\lambda'} = \mathrm{Hom}_{G^\vee_{\mathrm{aff}}}(V^{\lambda'}, V^{\lambda_1} \otimes \ldots \otimes V^{\lambda_N})$ for any $\lambda' \in \Lambda^+_{\mathrm{aff}}$ such that $\mu \le \lambda' \le \lambda$. However, it is possible that the IC sheaves of *other* symplectic leaves' closures also enter $\Psi\mathrm{IC}(\underline{\overline{\mathcal{W}}}^{\underline{\lambda}}_\mu) = \varpi_*\mathrm{IC}(\widetilde{\mathcal{W}}^{\underline{\lambda}}_\mu)$ with nonzero multiplicities. We should understand the representation-theoretic meaning of these extra multiplicities, cf. Nakajima [2009, Theorem 5.15 and Remark 5.17(3)] for G of type A.

Also, the closed embeddings of slices (for Levi subgroups of G_{aff}) seem an indispensable tool for constructing a $\mathfrak{g}^\vee_{\mathrm{aff}}$-action on $\bigoplus_\mu \Phi^\lambda_\mu \mathrm{IC}(\overline{\mathcal{W}}^\lambda_\mu)$ or a structure of $\mathfrak{g}^\vee_{\mathrm{aff}}$-crystal on $\bigsqcup_\mu \mathrm{Irr}(R^\lambda_\mu)$ (via reduction to Levi subgroups), cf. Krylov [2017].

5.7 Further problems. Note that the construction of Section 5.5 uses no specific properties of the affine Dynkin graphs, and works in the generality of arbitrary graph Q without edge loops and the corresponding Kac-Moody Lie algebra $\mathfrak{g}_Q$. We still expect the conclusions of Sections 3.2, 3.3, 3.4 to hold in this generality, see Braverman, Finkelberg, and Nakajima [2016a, 3(x)].

The only specific feature of the affine case is as follows. Recall that the category $\mathrm{Rep}_k(G^\vee_{\mathrm{aff}})$ of integrable $G^\vee_{\mathrm{aff}}$-modules at level $k \in \mathbb{Z}_{>0}$ is equipped with a braided balanced tensor *fusion* structure Moore and Seiberg [1989] and Bakalov and Kirillov [2001]. Unfortunately, I have no clue how this structure is reflected in the geometry of $\mathrm{Gr}_{G_{\mathrm{aff}}}$. I believe this is one of the most pressing problems about $\mathrm{Gr}_{G_{\mathrm{aff}}}$.

6 Applications

6.1 Hikita conjecture. We already mentioned in Section 5.5 that in case $V^\lambda_\mu \neq 0$ we expect the fixed point set $(\overline{\mathcal{W}}^\lambda_\mu)^{T_{\mathrm{aff}}}$ to consist of a single point μ. This point is the support of a nilpotent scheme $\boldsymbol{\mu}$ defined as follows: we choose a T_{aff}-equivariant embedding $\overline{\mathcal{W}}^\lambda_\mu \hookrightarrow \mathbb{A}^N$ into a representation of T_{aff}, and define $\boldsymbol{\mu}$ as the scheme-theoretic intersection of $\overline{\mathcal{W}}^\lambda_\mu$ with the zero weight subspace $\mathbb{A}^N_0$ inside $\mathbb{A}^N$. The resulting subscheme $\boldsymbol{\mu} \subset \overline{\mathcal{W}}^\lambda_\mu$ is independent of the choice of a T_{aff}-equivariant embedding $\overline{\mathcal{W}}^\lambda_\mu \hookrightarrow \mathbb{A}^N$. According to the Hikita conjecture Hikita [2017], the ring $\mathbb{C}[\boldsymbol{\mu}]$ is expected to be isomorphic to the cohomology ring $H^\bullet(\mathfrak{M}(V,W))$ of the corresponding Nakajima affine quiver variety, see Section 5.3. This is an instance of *symplectic duality* ($3d$ mirror symmetry) between Coulomb and Higgs branches. The Hikita conjecture for the slices $\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$ in Gr_G and the corresponding finite type Nakajima quiver varieties is proved in Kamnitzer, Tingley, Webster, Weekes, and Yacobi [2015] for types A, D (and conditionally for types E).

6.2 Monopole formula. We return to the setup of Section 5.1. Recall that $\mathcal{R}_{\mathbb{G},\mathbf{N}}$ is a union of (profinite dimensional) vector bundles over $\mathbb{G}_{\mathcal{O}}$-orbits in $\mathrm{Gr}_{\mathbb{G}}$. The corresponding Cousin spectral sequence converging to $H^{\mathbb{G}_{\mathcal{O}}}_\bullet(\mathcal{R}_{\mathbb{G},\mathbf{N}})$ degenerates and allows to compute the equivariant Poincaré polynomial (or rather Hilbert series)

$$P^{\mathbb{G}_{\mathcal{O}}}_t(\mathcal{R}_{\mathbb{G},\mathbf{N}}) = \sum_{\theta \in \Lambda^+_{\mathbb{G}}} t^{d_\theta - 2\langle \rho_{\mathbb{G}}, \theta\rangle} P_{\mathbb{G}}(t;\theta). \tag{1}$$

Here $\deg(t) = 2$, $P_{\mathbb{G}}(t;\theta) = \prod (1-t^{d_i})^{-1}$ is the Hilbert series of the equivariant cohomology $H^\bullet_{\mathrm{Stab}_{\mathbb{G}}(\theta)}(\mathrm{pt})$ (d_i are the degrees of generators of the ring of $\mathrm{Stab}_{\mathbb{G}}(\theta)$-invariant functions on its Lie algebra), and $d_\theta = \sum_{\chi \in \Lambda^\vee_{\mathbb{G}}} \max(-\langle \chi, \theta\rangle, 0) \dim \mathbf{N}_\chi$. This is a slight variation of the *monopole formula* of Cremonesi, Hanany, and Zaffaroni [2014]. Note that the series (1) may well diverge (even as a formal Laurent series: the space of homology of given degree may be infinite-dimensional), e.g. this is always the case for unframed quiver gauge theories. To ensure its convergence (as a formal Taylor series with the constant term 1) one has to impose the so called 'good' or 'ugly' assumption on the theory. In this case the resulting $\mathbb{N}$-grading on $H_\bullet^{\mathbb{G}_\mathcal{O}}(\mathcal{R}_{\mathbb{G},\mathbf{N}})$ gives rise to a $\mathbb{C}^\times$-action on $\mathfrak{M}_C(\mathbb{G},\mathbf{N})$, making it a conical variety with a single (attracting) fixed point.

Now recall the setup of Sections 5.3, 5.4; in particular, the isomorphism $\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu} \xrightarrow{\sim} \mathfrak{M}_C(\mathbb{G},\mathbf{N})$. In case $\bar\mu$ is dominant, the slice $\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu} \subset \mathrm{Gr}_G$ is conical with respect to the loop rotation $\mathbb{C}^\times$-action. However, this action is *not* the one of the previous paragraph. They differ by a hamiltonian $\mathbb{C}^\times$-action (preserving the Poisson structure). The Hilbert series of $\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$ graded by the loop rotation $\mathbb{C}^\times$-action is given by

$$P_t(\mathbb{C}[\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}]) = \sum_{\theta\in\Lambda^+_{\mathbb{G}}} t^{d_\theta - 2\langle\rho_{\mathbb{G}},\theta\rangle - \frac{1}{2}\bar\theta^\dagger\cdot\det\mathbf{N}_{\mathrm{hor}} + \frac{1}{2}\bar\theta^\dagger\cdot C\cdot\alpha} P_{\mathbb{G}}(t;\theta). \tag{2}$$

Here $\deg(t) = 1$; $\alpha = \bar\lambda - \bar\mu \in \Lambda_+ = \mathbb{N}^I$; $\bar\theta$ is the class of $\theta \in \Lambda_{\mathbb{G}} = \Lambda_{\mathrm{GL}(V)}$ in $\pi_0\mathrm{Gr}_{\mathrm{GL}(V)} = \mathbb{Z}^I$; $\bar\theta^\dagger$ is the transposed row-vector; C is the $I\times I$ Cartan matrix of G; and $\mathbf{N}_{\mathrm{hor}} = \bigoplus_{i\to j\in\Omega}\mathrm{Hom}(V_i,V_j)$ is the "horizontal" summand of $\mathrm{GL}(V)$-module $\mathbf{N}$, so that $\det\mathbf{N}_{\mathrm{hor}}$ is a character of $\mathrm{GL}(V)$, i.e. an element of $\mathbb{Z}^I$.

Finally, we consider a double affine Grassmannian slice $\overline{\mathcal{W}}^\lambda_\mu$ with dominant μ as in Section 4.3. The analogue of the loop rotation action of the previous paragraph is the action of the second copy of $\mathbb{C}^\times$ (the center of $\mathrm{GL}(2)$) in Section 4.4. We expect that the Hilbert series of $\overline{\mathcal{W}}^\lambda_\mu$ graded by this $\mathbb{C}^\times$-action is given by the evident affine analogue of the formula (2) (with the $\tilde I\times\tilde I$ Cartan matrix C_{aff} of G_{aff} replacing C). In particular, in case of level 1, this gives a formula for the Hilbert series of the coordinate ring $\mathbb{C}[\mathcal{U}^d_G(\mathbb{A}^2)]$ of the Uhlenbeck space proposed in Cremonesi, Mekareeya, Hanany, and Ferlito [2014]. Note that the latter formula works for arbitrary G, not necessarily simply laced one. In type A it follows from the results of Nakajima and Takayama [2017].

6.3 Zastava.

Let us consider the Coulomb branch $\mathfrak{M}_C(\mathbb{G},\mathbf{N})$ of an *unframed* quiver gauge theory for an ADE type quiver: $W_i = 0\ \forall i\in I$, so that $\mathbf{N} = \mathbf{N}_{\mathrm{hor}}$. An isomorphism $\mathfrak{M}_C(\mathbb{G},\mathbf{N}) \xrightarrow{\sim} \mathring{Z}^\alpha$ with the open zastava[1] (the moduli space of degree α based maps from the projective line $\mathbb{P}^1 \ni \infty$ to the flag variety $\mathcal{B} \ni B_-$ of G, where $\alpha = \sum_{i\in I}(\dim V_i)\alpha_i$), is constructed in Braverman, Finkelberg, and Nakajima [2016a] (we learned of its existence from V. Pestun). As the name suggests, the open zastava is a (dense smooth symplectic) open subvariety in the zastava space Z^α, a normal Cohen-Macaulay affine Poisson variety.

Note that there is another version of zastava $\mathbf{Z}^\alpha$ that is the solution of a moduli problem (G-bundles on $\mathbb{P}^1$ with a generalized B-structure and an extra U_--structure transversal at $\infty \in \mathbb{P}^1$) Braverman, Finkelberg, Gaitsgory, and Mirković [2002] given by a scheme cut out by the Plücker equations. This scheme is not reduced in general (the first example

[1] Zastava = *flags* in Croatian.

occurs in type A_4) E. Feigin and Makedonskyi [2017], and Z^α is the corresponding variety: $Z^\alpha := \mathbf{Z}^\alpha_{\mathrm{red}}$.

We already mentioned that the open zastava is a particular case of a generalized slice: $\mathring{Z}^\alpha = \overline{\mathcal{W}}^0_{w_0\alpha}$. The zastava space Z^α is the limit of slices in the following sense: for any $\bar\lambda \geq \bar\mu$ such that $w_0\bar\mu - w_0\bar\lambda = \alpha$, there is a loop rotation equivariant regular birational morphism $s^{\bar\lambda}_{\bar\mu}\colon \overline{\mathcal{W}}^{-w_0\bar\lambda}_{-w_0\bar\mu} \to Z^\alpha$, and for any $N \in \mathbb{N}$ and big enough dominant $\bar\mu$, the corresponding morphism of the coordinate rings graded by the loop rotations $(s^{\bar\lambda}_{\bar\mu})^*\colon \mathbb{C}[Z^\alpha] \to \mathbb{C}[\overline{\mathcal{W}}^{-w_0\bar\lambda}_{-w_0\bar\mu}]$ is an isomorphism in degrees $\leq N$ (both $\mathbb{C}[Z^\alpha]$ and $\mathbb{C}[\overline{\mathcal{W}}^{-w_0\bar\lambda}_{-w_0\bar\mu}]$ for dominant $\bar\mu$ are positively graded).

Now $\mathbb{C}[Z^\alpha]$ is obtained by the following version of the Coulomb branch construction. Given a vector space U we define the positive part of the affine Grassmannian $\mathrm{Gr}^+_{GL(U)} \subset \mathrm{Gr}_{GL(U)}$ as the moduli space of vector bundles $\mathcal{U}$ on the formal disc $D = \mathrm{Spec}(\mathcal{O})$ equipped with trivialization $\sigma\colon \mathcal{U}|_{D^*} \xrightarrow{\sim} U \otimes \mathcal{O}_{D^*}$ on the formal punctured disc $D^* = \mathrm{Spec}(\mathcal{K})$ such that σ extends through the puncture as an embedding $\sigma\colon \mathcal{U} \hookrightarrow U \otimes \mathcal{O}_D$. Since $\mathbb{G} = \mathrm{GL}(V) = \prod_{i\in I} \mathrm{GL}(V_i)$, we have $\mathrm{Gr}_{\mathrm{GL}(V)} = \prod_{i\in I} \mathrm{Gr}_{\mathrm{GL}(V_i)}$, and we define $\mathrm{Gr}^+_{\mathrm{GL}(V)} = \prod_{i\in I} \mathrm{Gr}^+_{\mathrm{GL}(V_i)}$. Finally, we define $\mathcal{R}^+_{\mathbb{G},\mathbf{N}}$ as the preimage of $\mathrm{Gr}^+_{\mathrm{GL}(V)} \subset \mathrm{Gr}_{\mathrm{GL}(V)}$ under $\mathcal{R}_{\mathbb{G},\mathbf{N}} \to \mathrm{Gr}_{\mathrm{GL}(V)}$. Then $H^{\mathbb{G}_\mathcal{O}}_\bullet(\mathcal{R}^+_{\mathbb{G},\mathbf{N}})$ forms a convolution subalgebra of $H^{\mathbb{G}_\mathcal{O}}_\bullet(\mathcal{R}_{\mathbb{G},\mathbf{N}})$, and an isomorphism $\mathcal{M}^+_C(\mathbb{G},\mathbf{N}) := \mathrm{Spec}\, H^{\mathbb{G}_\mathcal{O}}_\bullet(\mathcal{R}^+_{\mathbb{G},\mathbf{N}}) \xrightarrow{\sim} Z^\alpha$ is constructed in Braverman, Finkelberg, and Nakajima [2016a].

An analogue of the monopole formula (2) gives the character of the $T \times \mathbb{C}^\times$-module $\mathbb{C}[Z^\alpha]$:

$$\chi(\mathbb{C}[Z^\alpha]) = \sum_{\Lambda^{++}_{\mathbb{G}}} z^{\bar\theta} t^{d_\theta - 2\langle\rho_{\mathbb{G}},\theta\rangle - \frac{1}{2}\bar\theta^\dagger\cdot\det\mathbf{N} + \frac{1}{2}\bar\theta^\dagger\cdot C\cdot\alpha} P_{\mathbb{G}}(t;\theta). \tag{3}$$

Here $\Lambda^{++}_{\mathbb{G}}$ is the set of I-tuples of partitions; i-th partition having length at most $\dim V_i$ (recall that the cone of dominant coweights $\Lambda^+_{\mathbb{G}}$ is formed by the I-tuples of nonincreasing sequences $(\lambda^{(i)}_1 \geq \lambda^{(i)}_2 \geq \ldots \geq \lambda^{(i)}_{\dim V_i})$ of integers, and for $\Lambda^{++}_{\mathbb{G}} \subset \Lambda^+_{\mathbb{G}}$ we require these integers to be nonnegative). Also, z denotes the coordinates on the Cartan torus $T \subset G$ identified with $(\mathbb{C}^\times)^I$ via $z_i = \alpha^\vee_i$.

The character of the $T \times \mathbb{C}^\times$-module $\mathbb{C}[Z^\alpha]$ for G of type ADE was also computed in Braverman and Finkelberg [2014]. Namely, it is given by the *fermionic formula* of B. Feigin, E. Feigin, Jimbo, Miwa, and Mukhin [2009], and the generating function of these characters for all $\alpha \in \Lambda_+$ is an eigenfunction of the q-difference Toda integrable system. It would be interesting to find a combinatorial relation between the monopole and fermionic formulas.

In the affine case, the zastava space $Z^\alpha_{\mathfrak{g}_{\mathrm{aff}}}$ was introduced in Braverman, Finkelberg, and Gaitsgory [2006]. It is an irreducible affine algebraic variety containing a (dense smooth symplectic) open subvariety $\mathring{Z}^\alpha_{\mathfrak{g}_{\mathrm{aff}}}$: the moduli space of degree α based maps from the projective line $\mathbb{P}^1$ to the Kashiwara flag scheme $\mathbf{Fl}_{\mathfrak{g}_{\mathrm{aff}}}$. Contrary to the finite case, the open subvariety $\mathring{Z}^\alpha_{\mathfrak{g}_{\mathrm{aff}}}$ is not affine, but only quasiaffine, and we denote by $\underline{\mathring{Z}}^\alpha_{\mathfrak{g}_{\mathrm{aff}}}$ its affine closure. We do not know if the open embedding $\mathring{Z}^\alpha_{\mathfrak{g}_{\mathrm{aff}}} \hookrightarrow Z^\alpha_{\mathfrak{g}_{\mathrm{aff}}}$ extends to an open embedding $\underline{\mathring{Z}}^\alpha_{\mathfrak{g}_{\mathrm{aff}}} \hookrightarrow Z^\alpha_{\mathfrak{g}_{\mathrm{aff}}}$: it depends on the normality property of $Z^\alpha_{\mathfrak{g}_{\mathrm{aff}}}$ that is established only for $\mathfrak{g}$ of types A, C Braverman and Finkelberg [2014] and Finkelberg and Rybnikov [2014] at the moment (but is expected for all types). For an $A^{(1)}, D^{(1)}, E^{(1)}$ type quiver and an unframed quiver gauge theory with $\alpha = \sum_{i \in \tilde{I}} (\dim V_i)\alpha_i$, we have an isomorphism $\mathcal{M}_C(\mathsf{G}, \mathbf{N}) \xrightarrow{\sim} \underline{\mathring{Z}}^\alpha_{\mathfrak{g}_{\mathrm{aff}}}$ Braverman, Finkelberg, and Nakajima [2016a]. If $Z^\alpha_{\mathfrak{g}_{\mathrm{aff}}}$ is normal, this isomorphism extends to $\mathcal{M}_C^+(\mathsf{G}, \mathbf{N}) \xrightarrow{\sim} Z^\alpha_{\mathfrak{g}_{\mathrm{aff}}}$, and the fermionic formula for the character $\chi(\mathbb{C}[Z^\alpha])$ holds true.

Finally, for an arbitrary quiver Q without edge loops we can consider an unframed quiver gauge theory, and a coroot $\alpha := \sum_{i \in Q_0} (\dim V_i)\alpha_i$ of the corresponding Kac-Moody Lie algebra $\mathfrak{g}_Q$. The moduli space $\mathring{Z}^\alpha_{\mathfrak{g}_Q}$ of based maps from $\mathbb{P}^1$ to the Kashiwara flag scheme $\mathbf{Fl}_{\mathfrak{g}_Q}$ was studied in Braverman, Finkelberg, and Gaitsgory [2006]. It is a smooth connected variety. We expect that it is quasiaffine, and its affine closure $\underline{\mathring{Z}}^\alpha_{\mathfrak{g}_Q}$ is isomorphic to the Coulomb branch $\mathcal{M}_C(\mathsf{G}, \mathbf{N})$. It would be interesting to find a modular interpretation of $\mathcal{M}_C^+(\mathsf{G}, \mathbf{N})$ and its stratification into symplectic leaves. In the affine case such an interpretation involves Uhlenbeck spaces $\mathfrak{U}^d_G(\mathbb{A}^2)$.

The Jordan quiver corresponds to the Heisenberg Lie algebra. The computations of Finkelberg, Ginzburg, Ionov, and Kuznetsov [2016] suggest that the Uhlenbeck compactification of the Calogero-Moser phase space plays the role of zastava for the Heisenberg Lie algebra.

6.4 Multiplication and quantization. The multiplication of slices in the affine Grassmannian $\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu} \times \overline{\mathcal{W}}^{\bar\lambda'}_{\bar\mu'} \to \overline{\mathcal{W}}^{\bar\lambda+\bar\lambda'}_{\bar\mu+\bar\mu'}$ was constructed in Braverman, Finkelberg, and Nakajima [2016a] via multiplication of scattering matrices for singular monopoles (we learned of its existence from T. Dimofte, D. Gaiotto and J. Kamnitzer). The corresponding comultiplication $\mathbb{C}[\overline{\mathcal{W}}^{\bar\lambda+\bar\lambda'}_{\bar\mu+\bar\mu'}] \to \mathbb{C}[\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}] \otimes \mathbb{C}[\overline{\mathcal{W}}^{\bar\lambda'}_{\bar\mu'}]$ can not be seen directly from the Coulomb branch construction of slices. However, its quantization $\mathbb{C}_\hbar[\overline{\mathcal{W}}^{\bar\lambda+\bar\lambda'}_{\bar\mu+\bar\mu'}] \to \mathbb{C}_\hbar[\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}] \otimes \mathbb{C}_\hbar[\overline{\mathcal{W}}^{\bar\lambda'}_{\bar\mu'}]$ (recall from the end of Section 5.1 that $\mathbb{C}_\hbar[\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}]$ is the loop rotation equivariant Borel-Moore homology of the corresponding variety of triples) already can be realized in terms of Coulomb branches. The reason for this is that the quantized Coulomb branch $\mathbb{C}_\hbar[\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}]$ is likely to have a presentation by generators and relations of a *truncated shifted Yangian* $Y^{\bar\lambda}_{\bar\mu} \simeq \mathbb{C}_\hbar[\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}]$ of Braverman, Finkelberg, and Nakajima [ibid., Appendix B]. Also, it seems likely that the comultiplication of Finkelberg, Kamnitzer, Pham, Rybnikov, and

Weekes [2018] descends to a homomorphism $\Delta\colon Y^{\bar\lambda+\bar\lambda'}_{\bar\mu+\bar\mu'} \to Y^{\bar\lambda}_{\bar\mu} \otimes Y^{\bar\lambda'}_{\bar\mu'}$. Finally, we expect that the desired comultiplication $\mathbb{C}[\overline{\mathcal{W}}^{\bar\lambda+\bar\lambda'}_{\bar\mu+\bar\mu'}] \to \mathbb{C}[\overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}] \otimes \mathbb{C}[\overline{\mathcal{W}}^{\bar\lambda'}_{\bar\mu'}]$ is obtained by setting $\hbar = 0$ in Δ.

Returning to the question of constructing the closed embeddings of slices $\overline{\mathcal{W}}^{\bar\lambda'}_{\bar\mu} \hookrightarrow \overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$ in terms of Coulomb branches (see the beginning of Section 5.6), we choose dominant coweights $\bar\nu, \bar\nu', \bar\mu'$ such that $\bar\nu' + \bar\nu = \bar\lambda'$, $\bar\mu' + \bar\nu = \bar\lambda'$, and set $\bar\mu'' := \bar\mu - \bar\mu'$. Then we have the multiplication morphism $\overline{\mathcal{W}}^{\bar\nu}_{\bar\mu''} \times \overline{\mathcal{W}}^{\bar\nu'}_{\bar\mu'} \to \overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$, and we restrict it to $\overline{\mathcal{W}}^{\bar\nu}_{\bar\mu''} = \overline{\mathcal{W}}^{\bar\nu}_{\bar\mu''} \times \{\bar\mu'\} \to \overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$ where $\bar\mu' \in \overline{\mathcal{W}}^{\bar\nu'}_{\bar\mu'}$ is the fixed point. Then the desired closed subvariety $\overline{\mathcal{W}}^{\bar\lambda'}_{\bar\mu} \subset \overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$ is nothing but the closure of the image of $\overline{\mathcal{W}}^{\bar\nu}_{\bar\mu''} \to \overline{\mathcal{W}}^{\bar\lambda}_{\bar\mu}$.

The similar constructions are supposed to work for the slices in $\mathrm{Gr}_{G_{\mathrm{aff}}}$. They are based on the comultiplication for *affine Yangians* constructed in Guay, Nakajima, and Wendlandt [2017].

6.5 Affinization of KLR algebras. We recall the setup of Section 5.3, and set $W = 0$ (no framing). We choose a sequence $\mathbf{j} = (j_1, \dots, j_N)$ of vertices such that any vertex $j \in Q_0$ enters $\dim V_j$ times; thus, $N = \dim V$. The set of all such sequences is denoted $\mathbf{J}(V)$. We choose a Q_0-graded flag $V = V^0 \supset V^1 \supset \dots \supset V^N = 0$ such that V^{n-1}/V^n is a 1-dimensional vector space supported at the vertex j_n for any $n = 1, \dots, N$. It gives rise to the following flag of Q_0-graded lattices in $V_\mathcal{K} = V \otimes \mathcal{K}$: $\dots \supset L^{-1} \supset L^0 \supset L^1 \supset \dots$, where $L^{r+N} = zL^r$ for any $r \in \mathbb{Z}$; $L^0 = V_\mathcal{O}$, and $L^n/L^N = V^n \subset V = L^0/L^N$ for any $n = 1, \dots, N$. Let $\mathsf{I}_\mathbf{j} \subset \mathsf{G}_\mathcal{O}$ be the stabilizer of the flag $L^\bullet$ (an Iwahori subgroup). Then the $\mathsf{I}_\mathbf{j}$-module $\mathbf{N}_\mathcal{O}$ contains a submodule $\mathbf{N}_\mathbf{j}$ formed by the $\mathcal{K}$-linear homomorphisms $b_e\colon V_{t(e),\mathcal{K}} \to V_{h(e),\mathcal{K}}$ such that for any $e \in Q_1$ and $r \in \mathbb{Z}$, b_e takes $L^r_{t(e)}$ to $L^{r+1}_{h(e)}$.

We consider the following version of the variety of triples: $\mathcal{R}_{\mathbf{j},\mathbf{j}} := \{[g, s] \in \mathsf{G}_\mathcal{K} \overset{\mathsf{I}_\mathbf{j}}{\times} \mathbf{N}_\mathbf{j} : gs \in \mathbf{N}_\mathbf{j}\}$, cf. Braverman, Etingof, and Finkelberg [2016] and Webster [2016, Section 4]. Then the equivariant Borel-Moore homology $\mathcal{H}_{\mathbf{j},\mathbf{j}} := H^{\mathbb{C}^\times \ltimes \mathsf{I}_\mathbf{j}}_\bullet(\mathcal{R}_{\mathbf{j},\mathbf{j}})$ forms an associative algebra with respect to a convolution operation. Moreover, if we take another sequence $\mathbf{j}' \in \mathbf{J}(V)$ and consider $\mathcal{R}_{\mathbf{j}',\mathbf{j}} := \{[g, s] \in \mathsf{G}_\mathcal{K} \overset{\mathsf{I}_\mathbf{j}}{\times} \mathbf{N}_\mathbf{j} : gs \in \mathbf{N}_{\mathbf{j}'}\}$, then $\mathcal{H}_{\mathbf{j}',\mathbf{j}} := H^{\mathbb{C}^\times \ltimes \mathsf{I}_{\mathbf{j}'}}_\bullet(\mathcal{R}_{\mathbf{j},\mathbf{j}'})$ forms a $\mathcal{H}_{\mathbf{j}',\mathbf{j}'} - \mathcal{H}_{\mathbf{j},\mathbf{j}}$-bimodule with respect to convolution, and we have convolutions $\mathcal{H}_{\mathbf{j}'',\mathbf{j}'} \otimes \mathcal{H}_{\mathbf{j}',\mathbf{j}} \to \mathcal{H}_{\mathbf{j}'',\mathbf{j}}$. In other words, $\mathcal{H}_V := \bigoplus_{\mathbf{j},\mathbf{j}' \in \mathbf{J}(V)} \mathcal{H}_{\mathbf{j}',\mathbf{j}}$ forms a convolution algebra.

Furthermore, given $\mathbf{j}_1 \in \mathbf{J}(V)$, $\mathbf{j}_2 \in \mathbf{J}(V')$, the concatenated sequence $\mathbf{j}_1\mathbf{j}_2$ lies in $\mathbf{J}(V \oplus V')$, and one can define the morphisms $\mathcal{H}_{\mathbf{j}'_1,\mathbf{j}_1} \otimes \mathcal{H}_{\mathbf{j}'_2,\mathbf{j}_2} \to \mathcal{H}_{\mathbf{j}'_1\mathbf{j}'_2,\mathbf{j}_1\mathbf{j}_2}$ summing up to a homomorphism $\mathcal{H}_V \otimes \mathcal{H}_{V'} \to \mathcal{H}_{V \oplus V'}$.

Similarly to the classical theory of Khovanov-Lauda-Rouquier algebras (see a beautiful survey Rouquier [2012] and references therein), we expect that in case Q has no loop edges, the categories of finitely generated graded projective $\mathcal{H}_V$-modules provide a categorification of the positive part U_Q^{++} of the quantum toroidal algebra U_Q (where U_Q^{++} is defined as the subalgebra generated by the positive modes of the positive generators $e_{j,r} : j \in Q_0,\ r \geq 0$).

REPRESENTATIONS OF GALOIS ALGEBRAS

VYACHESLAV FUTORNY

Abstract

Galois algebras allow an effective study of their representation theory based on the invariant skew group structure. In particular, this leads to many remarkable results on Gelfand-Tsetlin representations of the general linear Lie algebra $\mathfrak{gl}_n$, quantum $\mathfrak{gl}_n$, Yangians of type A and finite W-algebras of type A.

1 Introduction

A classical problem of the representation theory of simple complex finite dimensional Lie algebras is the classification of simple modules. Today such a classification is known only for the Lie algebra $\mathfrak{sl}_2$ Block [1981]. Special attention is addressed to the study of so-called *weight* modules, i.e. those on which a certain Cartan subalgebra is diagonalizable. By the results of Fernando [1990] and Mathieu [2000], the classification of simple weight modules with finite dimensional weight subspaces is well known for any simple finite dimensional Lie algebra. On the other hand, a classification of simple modules remains open even in the category of weight modules with infinite dimensional weight subspaces. The largest subcategory of the category of weight module with some understanding of simple objects is the category of Gelfand-Tsetlin modules. The Gelfand-Tsetlin theory has attracted considerable interest in the last 40 years after the pioneering work of Gelfand and Cetlin [1950] and was developed in Drozd, Ovsienko, and Futorny [1991], Graev [2004], Graev [2007], Drozd, Ovsienko, and Futorny [1989], Mazorchuk [1998], Mazorchuk [2001], Molev [2006], Želobenko [1973], among the others. Gelfand-Tsetlin integrable systems were studied by Guillemin and Sternberg [1983], Kostant and Wallach [2006a], Kostant and Wallach [2006b], Colarusso and Evens [2010], Colarusso and Evens [2014].

Gelfand-Tsetlin theory can be viewed in a more general context of Harish-Chandra categories Drozd, Futorny, and Ovsienko [1994], Futorny and Ovsienko [2007] which play very important role in the representation theory. These are the categories of modules over

MSC2010: primary 17B10; secondary 17B05, 16G30.

a given algebra defined by the restriction onto a fixed subalgebra. General setting for the study of Harish-Chandra categories was established in Drozd, Futorny, and Ovsienko [1994]. Examples of Harish-Chandra categories include classical Harish-Chandra modules over a finite dimensional Lie algebra defined with respect to a reductive subalgebra (Dixmier [1974]), weight modules over semisimple finite dimensional Lie algebras with respect to a Cartan subalgebra, Gelfand-Tsetlin modules over $\mathfrak{gl}_n$ (Drozd, Ovsienko, and Futorny [1991]), certain representations of Yangians (Futorny, Molev, and Ovsienko [2005]) etc. In the case of generalized Weyl algebras of rank 1 this approach led to a complete classification of simple modules (Bavula [1992], Bavula and van Oystaeyen [2004]).

Developed techniques turned out to be very useful in the study of Gelfand-Tsetlin modules for the Lie algebra $\mathfrak{gl}_n$ (Drozd, Ovsienko, and Futorny [1991], Ovsienko [2002]). Gelfand-Tsetlin modules form the full subcategory of weight $\mathfrak{gl}_n$-modules which are sums of finite dimensional modules over the *Gelfand-Tsetlin subalgebra* Γ (certain maximal commutative subalgebra of the universal enveloping algebra of $\mathfrak{gl}_n$) Drozd, Ovsienko, and Futorny [1991], Futorny and Ovsienko [2010]. These modules are weight modules with respect to some Cartan subalgebra of $\mathfrak{gl}_n$ but they allow to have infinite dimensional weight spaces.

Gelfand-Tsetlin theory had a successful development in Ovsienko [2002], where it was shows that simple Gelfand-Tsetlin modules over $\mathfrak{gl}_n$ are parametrized up to some finiteness by the maximal ideals of Γ. Different explicit constructions of Gelfand-Tsetlin modules for $\mathfrak{gl}_n$ were recently obtained in Futorny, Grantcharov, and Ramirez [2014], Futorny, Grantcharov, and Ramirez [2015], Futorny, Grantcharov, and Ramirez [2016b], Futorny, Grantcharov, and Ramirez [2016a], Futorny, Ramirez, and Zhang [2016], Zadunaisky [2017], Vishnyakova [2018], Vishnyakova [2017], Ramírez and Zadunaisky [2017]. Nevertheless, the problem remains open.

As an attempt to unify the representation theories of the universal enveloping algebra of $\mathfrak{gl}_n$ and of the generalized Weyl algebras a new concept of Galois orders was introduced in Futorny and Ovsienko [2010]. These algebras have a hidden skew (semi)group structure. In particular, the universal enveloping algebra of $\mathfrak{gl}_n$ is an example of such algebra where invariant skew group structure comes from the Gelfand-Tsetlin formulas. Representation theory of Galois algebras was developed in Futorny and Ovsienko [2014]. It provides a new framework for the study of representation of various classes of algebras. Recent paper of Hartwig (Hartwig [2017a]) discovers new examples of Galois algebras for which the theory can be effectively applied.

2 Harish-Chandra modules

We recall basic facts about Harish-Chandra module categories following Drozd, Futorny, and Ovsienko [1994]. Let U be an associative algebra over $\mathbb{k}$, $\Gamma \subset U$ a subalgebra. The set of maximal ideals $\mathbf{m}$ of Γ such that $\dim \Gamma/\mathbf{m} < \infty$ will be called the *cofinite spectrum* $\operatorname{cfs}\Gamma$ of Γ. Then every $\mathbf{m} \in \operatorname{cfs}\Gamma$ defines a unique simple Γ-module of dimension $l(\mathbf{m})$ where $\Gamma/\mathbf{m} \simeq M_{l(\mathbf{m})}(\mathbb{k})$.

We say that M is a *Harish-Chandra module* (with respect to Γ) if M a finitely generated U-module such that

$$M = \bigoplus_{\mathbf{m}\in \operatorname{cfs}\Gamma} M(\mathbf{m}),$$

where

$$M(\mathbf{m}) = \{x \in M \mid \exists k,\ \mathbf{m}^k x = 0\}.$$

The support of a Harish-Chandra module M is a subset of $\operatorname{cfs}\Gamma$ consisting of those $\mathbf{m}$ for which $M(\mathbf{m}) \neq 0$.

We denote by $\mathbb{H}(U,\Gamma)$ the full subcategory consisting of all Harish-Chandra modules in $U -$ mod. It is closed under the operations of taking submodules, quotients and direct sums.

In Drozd, Futorny, and Ovsienko [ibid.] a concept of a Harish-Chandra subalgebra was introduced. For any $\mathbf{m} \in \operatorname{cfs}\Gamma$ denote by $L_{\mathbf{m}}$ the unique simple $\Gamma/\mathbf{m}$-module. We say that Γ is quasi-commutative if $\operatorname{Ext}^1(L_{\mathbf{m}}, L_{\mathbf{n}}) = 0$ for all $\mathbf{m} \neq \mathbf{n}$. We also say that Γ is quasi-central if for every $u \in U$, the Γ-bimodule $\Gamma u \Gamma$ is finitely generated as a left and as a right Γ-module. Clearly, for a noetherian Γ it is sufficiently to check this condition only for the generators of Γ (cf. Drozd, Futorny, and Ovsienko [ibid.], Proposition 8). A subalgebra Γ is called *Harish-Chandra* if it is quasi-central and quasi-commutative.

Example 2.1. *Let $\mathfrak{g}$ be a finite dimensional Lie algebra and $\mathfrak{F}$ its reductive Lie subalgebra. Then $\Gamma = U(\mathfrak{F})$ is a Harish-Chandra subalgebra of $U = U(\mathfrak{g})$. Indeed, Γ is quasi-commutative since any $\mathbf{m} \in \operatorname{cfs}\Gamma$ is cofinite. Also Γ is quasi-central since $\mathfrak{g}$ is finite dimensional.*

The concept of a Harish-Chandra subalgebra is essential for understanding the categories of Harish-Chandra modules. We address to Drozd, Futorny, and Ovsienko [ibid.] for further properties of Harish-Chandra subalgebras in the general setting. The most studied is the case of commutative Γ which we consider next.

2.1 Commutative Γ. Let U be an associative algebra and $\Gamma \subset U$ a noetherian commutative subalgebra. A natural idea is to try to parametrize simple modules in the Harish-Chandra category $\mathbb{H}(U,\Gamma)$ by simple Γ-modules. Since any simple Γ-module is 1-dimensional it defines a homomorphism from Γ to $\Bbbk$ which we call a *character* of Γ. The kernel of any such character is a maximal ideal of Γ, thus there is a one-to-one correspondence between the characters of Γ and elements of $\operatorname{Specm}\Gamma$. The following problem of extension of characters to simple modules in $\mathbb{H}(U,\Gamma)$ is of prime importance for description of possible supports of simple Harish-Chandra modules.

Problem 1. Given $\mathbf{m} \in \operatorname{Specm}\Gamma$ is there a (simple) module $M \in \mathbb{H}(U,\Gamma)$ such that $M(\mathbf{m}) \neq 0$.

Recall that in the classical setting when both U and Γ are commutative and extension $\Gamma \subset U$ is integral then we have a map between the sets of prime (maximal) ideals $\varphi : \operatorname{Spec} U \to \operatorname{Spec}\Gamma$ and the fiber $\varphi^{-1}(\mathfrak{p})$ is non-empty for every $\mathfrak{p} \in \operatorname{Spec} A$. In particular, every character of Γ can be extended to a character of U. Moreover, if U is finitely generated module over Γ then all fibers $\varphi^{-1}(\mathfrak{p})$ are finite and the number of different extensions of each character of Γ is finite. By the Hilbert-Noether theorem this is the case when $U = S(V)$ is the symmetric algebra of a finite dimensional vector space V and Γ is the subalgebra of G-invariants of U for some finite subgroup G of $GL(V)$.

If U is noncommutative then the restriction functor from the category $\mathbb{H}(U,\Gamma)$ to the category of torsion Γ-modules induces a map Φ from $\operatorname{Specm}\Gamma$ to the set of isomorphism classes $Irr(U)$ of simple U-modules in $\mathbb{H}(U,\Gamma)$. Given a maximal ideal $\mathbf{m} \in \operatorname{Specm}\Gamma$, $\Phi(\mathbf{m})$ consist of those simple $V \in \mathbb{H}(U,\Gamma)$ such that $V(\mathbf{m}) \neq 0$ (or left maximal ideals of U which contain $\mathbf{m}$).

Example 2.2. *(i) Let $\mathfrak{g}$ be a reductive Lie algebra with a Cartan subalgebra $\mathfrak{H}$, $U = U(\mathfrak{g})$ and $\Gamma = U(\mathfrak{H})$. Then for any weight $\lambda \in \mathfrak{H}^*$ the fiber $\Phi(\lambda)$ is infinite (even in the category $\mathcal{O}$ which is a subcategory of $\mathbb{H}(U,\Gamma)$).*

(ii) Let $U = U_n = \mathbb{C}[S_n]$, $U_1 \subset \ldots \subset U_n$, Z_k the center of $\mathbb{C}[U_k]$. Then $\Gamma =< Z_1,\ldots,Z_n >$ is maximal commutative. It is generated by the Jucys-Murphy elements $X_i = (1i)+\ldots+(i-1i)$, $i = 1,\ldots,n$. The elements of $\operatorname{Specm}\Gamma$ *parametrize the irreducible representations of the group S_n Okounkov and Vershik [1996].*

The freeness of U over Γ as a right module guarantees the lifting of characters of Γ (all examples above are of this kind). Finding sufficient conditions for the fiber $\Phi(\mathbf{m})$ to be non-empty for any point $\mathbf{m} \in \operatorname{Specm}\Gamma$ is a difficult problem in general. In particular, if U is a *special filtered* such conditions were obtained in Futorny and Ovsienko [2005] generalizing the Kostant's theorem (see further examples in Futorny and Ovsienko [ibid.] and Futorny, Molev, and Ovsienko [2005]).

3 Galois algebras

A class of Galois rings (orders) was introduced in Futorny and Ovsienko [2010] to deal with the problem of extension of characters of commutative subalgebras.

Let R be a ring, $\mathcal{M}$ a monoid acting on R by ring automorphisms. We will denote the action of $m \in \mathcal{M}$ on $r \in R$ by r^m. Consider the skew monoid ring $R * \mathcal{M}$. Any element of $R * \mathcal{M}$ can be written in the form $x = \sum_{m \in \mathcal{M}} x_m m$. Define $supp\, x$ as the set of those $m \in \mathcal{M}$ for which x_m is not zero.

Let G be a finite group acting on $\mathcal{M}$ by conjugation. Then we have an action of G on $R * \mathcal{M}$ by ring automorphisms: $g(rm) = g(r)g(m)$, $g \in G, r \in R, m \in \mathcal{M}$.

Assume now that Γ is an integral domain, K the field of fractions of Γ and L a finite Galois extension of K with the Galois group $G = \mathrm{Gal}(L/K)$. Consider the action of G by conjugation on $\mathrm{Aut}(L)$. Let $\mathcal{M}$ be any G-invariant submonoid of $\mathrm{Aut}(L)$. For our purposes we will always require $\mathcal{M}$ to be K-*separating*, that is $m_1|_K = m_2|_K \Rightarrow m_1 = m_2$ for $m_1, m_2 \in \mathcal{M}$. The action of G on L and on $\mathcal{M}$ (by conjugations) extends to the action of G on the skew monoid ring $L * \mathcal{M}$. Denote by $\mathcal{K} = (L * \mathcal{M})^G$ the subring of invariants.

Definition 3.1. *A finitely generated* Γ*-subring* U *of* $\mathcal{K}$ *is called a* Galois ring over Γ *if* $UK = KU = \mathcal{K}$.

We have the following characterization of Galois rings:

We will always assume that all Galois rings are $\Bbbk$-algebras. In this case we say that a Galois ring is a Galois algebra over Γ.

Example 3.1. *Let* $U = \Gamma(\sigma, a)$ *be a* generalized Weyl algebra *of rank* 1 *(Bavula [1992]), where* Γ *is a unital integral domain,* $a \in \Gamma$*,* σ *an automorphism of* Γ *of infinite order. It is generated over* Γ *by* X *and* Y *such that* $X\gamma = \sigma(\gamma)X$*,* $Y\gamma = \sigma^{-1}(\gamma)Y$*,* $YX = a$*,* $XY = \sigma(a)$*. Let* K *be the field of fractions of* Γ *and* $\mathcal{M} \simeq \mathbb{Z}$ *is a subgroup of* $\mathrm{Aut}\,\Gamma$ *generated by* σ*. Then* U *can be embedded into the skew group algebra* $K * \mathbb{Z}$ *when* $X \mapsto \sigma$ *and* $Y \mapsto a\sigma^{-1}$*. Clearly,* U *is a Galois algebra over* Γ*. Note that* $U \simeq \Gamma * \mathbb{Z}$ *if* a *is invertible in* Γ*.*

3.1 Galois orders.

Now we discuss a special class of Galois rings which are called *Galois orders*. Galois orders were introduced in Futorny and Ovsienko [2010] as a natural noncommutative generalization of a classical notion of order in skew group rings (cf. McConnell and Robson [1987]).

A Galois ring U over Γ. is *right (respectively left) Galois order*, if for any finite dimensional right (respectively left) K-subspace $W \subset U[S^{-1}]$ (respectively $W \subset [S^{-1}]U$), $W \cap U$ is a finitely generated right (respectively left) Γ-module. A Galois ring is *Galois order* if it is both right and left Galois order.

For a right Γ-submodule $M \subset U$ denote

$$\mathbb{D}_r(M) = \{u \in U \mid \exists \gamma \in \Gamma, \gamma \neq 0 \text{ such that } u \cdot \gamma \in M\}.$$

It follows immediately that $\mathbb{D}_r(M)$ is a Γ-module.

We have the following characterization of a Galois order.

Proposition 3.1 (Futorny and Ovsienko [2010], Corollary 5.1, 5.2)**.** *(i) A Galois ring U over a noetherian Γ is* right (left) Galois order *if and only if for every finitely generated right (left) Γ-module $M \subset U$, the right (left) Γ-module $\mathbb{D}_r(M)$ is finitely generated.*

(ii) If a Galois ring U over a noetherian domain Γ is projective as a right (left) Γ-module then U is a right (left) Galois order.

In the commutative case if K is the field of fractions of Γ, $U \subset K$ is finitely generated over Γ and the extension $\Gamma \subset U$ is integral then U is Galois order over Γ. Further examples of Galois orders include: generalized Weyl algebras over integral domains with infinite order automorphisms (e.g. the n-th Weyl algebra A_n, the quantum plane, the q-deformed Heisenberg algebra, quantized Weyl algebras, the Witten-Woronowicz algebra Bavula [1992]; the universal enveloping algebra of $\mathfrak{gl}_n$ over the Gelfand-Tsetlin subalgebra Drozd, Ovsienko, and Futorny [1991], Drozd, Futorny, and Ovsienko [1994], finite W-algebras Futorny, Molev, and Ovsienko [2005]).

There is a strong connection between Galois orders and maximality of Harish-Chandra subalgebras. Namely, we have

Theorem 3.1. *(i) Let Γ be a finitely generated domain over $\mathbb{k}$ and U a Galois order over Γ. Then Γ is a Harish-Chandra subalgebra in U.*

(ii) Let U be a Galois ring over finitely generated $\mathbb{k}$-algebra Γ and $\mathcal{M}$ be a group. If Γ is a Harish-Chandra subalgebra in U then U is a Galois order if and only if U_e is an integral extension of Γ.

(iii) Let U be a Galois ring over a normal noetherian Harish-Chandra subalgebra Γ and $\mathcal{M}$ be a group. Then U is a Galois order over Γ if and only if Γ is maximal commutative in U.

Proof. First item follows from [Futorny and Ovsienko [2010], Corollary 5.4]. Second item follows from [Futorny and Ovsienko [ibid.], Theorem 5.2, (2)]. Let U be a Galois ring over a normal noetherian Harish-Chandra subalgebra Γ. If Γ is maximal then applying [Futorny and Ovsienko [ibid.], Corollary 5.6, (2)] and the fact that U has no torsion as a Γ-module we conclude that U is a Galois order over Γ. To prove the converse, it is sufficient to show that $U \cap K = \Gamma$ by [Futorny and Ovsienko [ibid.], Theorem 4.1]. Since $U \cap K$ is an integral extension of Γ by the second item, the statement follows from the normality of Γ.

□

The problem of lifting of characters for Galois orders was studied in Futorny and Ovsienko [2014]. In particular, sufficient conditions for the fiber $\Phi(\mathbf{m})$ to be nontrivial and finite were established. Let $U \subset (L * \mathcal{M})^G$ be a Galois ring over Γ. Consider the integral closure $\bar{\Gamma}$ of Γ in L. It is a standard fact that if Γ is finitely generated as a $\Bbbk$-algebra then any character of Γ has finitely many extensions to characters of $\bar{\Gamma}$.

Let $\bar{\mathbf{m}}$ be any lifting of $\mathbf{m}$ to the integral closure of Γ in L, and $\mathcal{M}_{\mathbf{m}}$ the stabilizer of $\bar{\mathbf{m}}$ in $\mathcal{M}$. Note that the group $\mathcal{M}_{\mathbf{m}}$ is defined uniquely up to G-conjugation. Thus the cardinality of $\mathcal{M}_{\mathbf{m}}$ does not depend on the choice of the lifting. We denote it by $|\mathbf{m}|$.

For $\mathbf{m}, \mathbf{n} \in \operatorname{Specm} \Gamma$ set

$$S(\mathbf{m}, \mathbf{n}) = \{m \in \mathcal{M} \mid \bar{\mathbf{n}} \in GmG \cdot \bar{\mathbf{m}}\},$$

which is a G-invariant subset in $\mathcal{M}$. If $\mathcal{M}$ is a group then we have

$$|S(\mathbf{m}, \mathbf{n})/G| \leq |\{x \in \mathcal{M} \mid x\bar{\mathbf{m}} = \bar{\mathbf{n}}\}|.$$

Denote by $r(\mathbf{m}, \mathbf{n})$ the minimal number of generators of $U(S(\mathbf{m}, \mathbf{n}))$ as a right Γ-module.

Theorem 3.2. *[Futorny and Ovsienko [ibid.], Theorem A, , Theorem 8] Let Γ be a commutative domain which is finitely generated as a $\Bbbk$-algebra, $U \subset (L * \mathcal{M})^G$ a right Galois order over Γ, $\mathbf{m} \in \operatorname{Specm} \Gamma$. Suppose $|\mathbf{m}|$ is finite.*

(i) The fiber $\Phi(\mathbf{m})$ is non-empty.

(ii) If U is a Galois order over Γ, then the fiber $\Phi(\mathbf{m})$ is finite.

(iii) Let U be a Galois order over normal noetherian Γ, $M \in \mathbb{H}(U, \Gamma)$ a simple U-module and $\mathbf{m} \in \operatorname{Specm} \Gamma$. If U is free as a right Γ-module then for any $\mathbf{n}$

$$\dim_{\Bbbk} M(\mathbf{n}) \leq |S(\mathbf{m}, \mathbf{n})/G|.$$

3.2 Principal Galois orders. Further examples of Galois orders were recently constructed by Hartwig [2017a]. As before denote $\mathcal{K} = (L * \mathcal{M})^G$. Clearly, $\mathcal{K}$ is its own Galois subring over Γ. But, $\mathcal{K}$ is a Galois order if and only if $\Lambda = L$, where Λ is the integral closure of Γ in L [Hartwig [ibid.], Corollary 2.15].

Let $x = \sum_{\phi \in \mathcal{M}} x_\phi \phi \in L * \mathcal{M}$ and $a \in L$. Define the evaluation $x(a) := \sum_{\phi \in \mathcal{M}} x_\phi \phi(a)$ [Hartwig [ibid.], Definition 2.18]. Then we have

Theorem 3.3 (Hartwig [2017a], Theorem 2.21)**.**

$$\mathcal{K}_\Gamma = \{x \in \mathcal{K} \mid x(\gamma) \in \Gamma \textit{ for all } \gamma \in \Gamma\}$$

is a Galois order over Γ *in* $\mathcal{K}$.

One immediately sees that any Galois subring of $\mathcal{K}_\Gamma$ over Γ is a Galois order. Such orders are called *principal* Hartwig [ibid.].

A new class of principal Galois orders, *rational Galois orders*, was introduced in Hartwig [ibid.]. These structures are attached to an arbitrary finite reflection group and a set of difference operators with rational function coefficients. In particular, the parabolic subalgebras of finite W-algebras of type A are rational Galois orders [Hartwig [ibid.], Theorem 1.2]. This extends the result of Futorny, Molev, and Ovsienko [2005] for W-algebras of type A. Other examples of principal Galois orders include *orthogonal Gelfand-Tsetlin algebras* (Hartwig [2017a], Theorem 4.6) introduced in Mazorchuk [1999] and *quantum orthgonal Gelfand-Tsetlin algebras* (Hartwig [2017a], Theorem 5.6) introduced in Hartwig [2017b]. The family of quantum orthogonal Gelfand-Tsetlin algebras includes in particular quantized universal enveloping algebra $U_q(\mathfrak{gl}_n)$ and, as a consequence, implies the maximality of the Gelfand-Tsetlin subalgebra of $U_q(\mathfrak{gl}_n)$ when q is not a root of unity (this was conjectured by Mazorchuk and Turowska [2000]).

4 Gelfand-Tsetlin modules

Now we address the Lie algebra $\mathfrak{gl}_n$ consisting of all $n \times n$ complex matrices with the standard basis of elementary matrices $\{e_{i,j} \mid 1 \leq i, j \leq n\}$. For each $k \leqslant n$ denote by $\mathfrak{gl}_k$ the Lie subalgebra of $\mathfrak{gl}_n$ spanned by $\{e_{ij} \mid i, j = 1, \dots, k\}$. We have the following embeddings of Lie subalgebras

$$\mathfrak{gl}_1 \subset \mathfrak{gl}_2 \subset \dots \subset \mathfrak{gl}_n.$$

We have corresponding embeddings $U_1 \subset U_2 \subset \dots \subset U_n$ of the universal enveloping algebras $U_k = U(\mathfrak{gl}_k)$, $1 \leq k \leq n$. Set $U = U_n$.

Let Z_k be the center of U_k. This is the polynomial algebra generated by the following elements

$$c_{ks} = \sum_{(i_1,\dots,i_s)\in\{1,\dots,k\}^s} e_{i_1 i_2} e_{i_2 i_3} \dots e_{i_s i_1}, \tag{1}$$

$s = 1, \dots, k$.

Let Γ be the subalgebra of $U(\mathfrak{gl}_n)$ generated by the centers Z_k, $k = 1, \dots, n$, the *Gelfand-Tsetlin subalgebra* Drozd, Ovsienko, and Futorny [1991]. The generators c_{ks}, $k = 1, \dots, n$, $s = 1, \dots, k$ are algebraically independent Želobenko [1973].

Let Λ be the polynomial algebra in the variables $\{\lambda_{ij} \mid 1 \leqslant j \leqslant i \leqslant n\}$. Consider the embedding $\pi : \Gamma \longrightarrow \Lambda$ such that

$$c_{ks} \mapsto \sum_{i=1}^{k} (\lambda_{ki} + k - 1)^s \prod_{j \neq i} \left(1 - \frac{1}{\lambda_{ki} - \lambda_{kj}}\right).$$

One can easily check that $\pi(c_{ks})$ is a symmetric polynomial in Λ of degree s in variables $\lambda_{k1}, \ldots, \lambda_{kk}$. Let $G = \prod_{i=1}^{n} S_i$ be the product of symmetric groups. Then G acts naturally on Λ where S_k permutes the variables $\lambda_{k1}, \ldots, \lambda_{kk}$, $k = 1, \ldots, n$. The image of Γ, $\pi(\Gamma)$, coincides with the subalgebra of G-invariant polynomials in Λ which we identify with Γ.

Consider the Harish-Chandra category $H(U, \Gamma)$. We will call the modules of $H(U, \Gamma)$ *Gelfand-Tsetlin modules*. If $M \in H(U, \Gamma)$ then

$$M = \bigoplus_{\mathsf{m} \in \operatorname{Specm} \Gamma} M(\mathbf{m}),$$

where $M(\mathsf{m}) = \{v \in M | \mathbf{m}^k v = 0 \text{ for some } k \geq 0\}$. Clearly, any simple Gelfand-Tsetlin module over $\mathfrak{gl}(n)$ is a weight module with respect to the Cartan subalgebra spanned by e_{ii}, $i = 1, \ldots, n$. Moreover, for $n = 2$ any simple weight module is a Gelfand-Tsetlin module. For $n > 2$ this is not true in general, but holds for modules with finite weight multiplicities. For a Gelfand-Tsetlin module $M(\mathbf{m}) \in H(U, \Gamma)$ and $\mathbf{m} \in \operatorname{Specm} \Gamma$ we call the dimension of $M(\mathbf{m})$ *the Gelfand-Tsetlin multiplicity* of $\mathbf{m}$.

4.1 Finite dimensional modules over $\mathfrak{gl}_n$. We recall a classical result of Gelfand and Cetlin [1950] which gives an explicit basis for all simple finite dimensional $\mathfrak{gl}_n$-modules.

For convenience we consider the elements of the space $\mathbb{C}^k$ as k-tuples whose entries are labeled as follows $(v_{k1,\ldots,v_{kk}})$. We also identify $\mathbb{C}^{\frac{n(n+1)}{2}}$ with $T_n(\mathbb{C}) = \mathbb{C}^n \times \mathbb{C}^{n-1} \times \ldots \times \mathbb{C}$. Then every vector v in $\mathbb{C}^{\frac{n(n+1)}{2}}$ can be written in the following form:

$$v = (v_{n1}, \ldots, v_{nn} | v_{n-1,1}, \ldots, v_{n-1,n-1} | \cdots | v_{21}, v_{22} | v_{11})$$

to which we associate the following array $T(v)$

$$\begin{array}{ccccccc}
v_{n1} & v_{n2} & & \cdots & & v_{n,n-1} & v_{nn} \\
& v_{n-1,1} & & \cdots & & v_{n-1,n-1} & \\
& & \cdots & \cdots & \cdots & & \\
& & v_{21} & & v_{22} & &
\end{array}$$

v_{11}

Such an array will be called a *Gelfand-Tsetlin tableau* of height n.

For a fixed element $v = (v_{ij})_{j\leq i=1}^{n} \in T_n(\mathbb{C})$ consider the set

$$v + T_{n-1}(\mathbb{Z}) = \{v + w \mid w = (w_{ij})_{j\leq i=1}^{n}, w_{ij} \in \mathbb{Z}, w_{nk} = 0\,, k = 1, \ldots, n\}.$$

Denote by $V(T(v))$ the complex vector space spanned by the set $v + T_{n-1}(\mathbb{Z})$ as a basis. Clearly, the spaces $V(T(v))$ and $T_n(\mathbb{C})$ are not isomorphic as $T(v+w) \neq T(v) + T(w)$ in $V(T(v))$.

A Gelfand-Tsetlin tableau $T(v)$ of height n is called *standard* if $v_{ki} - v_{k-1,i} \in \mathbb{Z}_{\geq 0}$ and $v_{k-1,i} - v_{k,i+1} \in \mathbb{Z}_{>0}$ for all $1 \leq i \leq k \leq n-1$.

Theorem 4.1 (Gelfand and Cetlin [1950]). *Let $L(\lambda)$ be the simple finite dimensional $\mathfrak{gl}_n$-module of highest weight $\lambda = (\lambda_1, \ldots, \lambda_n)$. Then the set of all standard tableaux $T(v)$ with fixed top row $v_{ni} = \lambda_i - i + 1$, $i = 1, \ldots, n$ forms a basis of $L(\lambda)$. Moreover, the action of the generators of $\mathfrak{gl}(n)$ on $L(\lambda)$ is given by the* Gelfand-Tsetlin formulas*:*

$$e_{k,k+1}(T(v)) = -\sum_{i=1}^{k} \left(\frac{\prod_{j=1}^{k+1}(v_{ki} - v_{k+1,j})}{\prod_{j\neq i}^{k}(v_{ki} - v_{kj})} \right) T(v + \delta^{ki}),$$

$$e_{k+1,k}(T(v)) = \sum_{i=1}^{k} \left(\frac{\prod_{j=1}^{k-1}(v_{ki} - v_{k-1,j})}{\prod_{j\neq i}^{k}(v_{ki} - v_{kj})} \right) T(v - \delta^{ki}),$$

$$e_{kk}(T(v)) = \left(k - 1 + \sum_{i=1}^{k} v_{ki} - \sum_{i=1}^{k-1} v_{k-1,i} \right) T(v).$$

If $e_{k,k+1}(T(v))$ or $e_{k+1,k}(T(v))$ contains a summand with a non-standard $T(v \pm \delta^{ki})$, then the summand is assumed to be zero.

These formulas define a Gelfand-Tsetlin modules where the action of the generators of Γ is given by:

$$c_{mk}(T(v)) = \gamma_{mk}(v) T(v),$$

where

$$\gamma_{mk}(v) := \sum_{i=1}^{m} (v_{mi} + m - 1)^k \prod_{j\neq i} \left(1 - \frac{1}{v_{mi} - v_{mj}} \right). \tag{2}$$

To every $w \in v + T_{n-1}(\mathbb{Z})$ we associate the maximal ideal of Λ generated by $\lambda_{ij} - w_{ij}$ and the maximal ideal $\mathbf{m}_w$ of Γ generated by $c_{ij} - \gamma_{ij}(w)$, where $\gamma_{ij}(w)$ are symmetric polynomials defined in (2). Again, the correspondence $w \mapsto \mathbf{m}_w$ is not one-to-one, a given $\mathbf{m} \in \operatorname{Specm}\Gamma$ defines the finite fiber of maximal ideals of Λ corresponding to the set $\widehat{\mathbf{m}}$ of $w \in v + T_{n-1}(\mathbb{Z})$ with $\mathbf{m}_w = \mathbf{m}$.

The basis of tableaux defined in Theorem 4.1 is called the *Gelfand-Tsetlin basis*. Discovery of Gelfand-Tsetlin bases are among the most remarkable results of the representation theory of classical Lie algebras. It provides a convenient realization of every simple finite dimensional representation of the Lie algebra $\mathfrak{gl}_n$. For other types of simple finite dimensional Lie algebras we refer to Molev [2006].

4.2 $U(\mathfrak{gl}_n)$ **is a Galois order over** Γ**.** We identify $T_{n-1}(\mathbb{Z})$ with the free abelian group $\mathcal{M} \simeq \mathbb{Z}^{\frac{n(n-1)}{2}}$ generated by δ^{ij}, $1 \leqslant j \leqslant i \leqslant n-1$, where $(\delta^{ij})_{ij} = 1$ and all other $(\delta^{ij})_{k\ell}$ are zero, $1 \leq j \leq i \leq n-1$. The group $\mathcal{M}$ acts naturally on $T_n(\mathbb{C})$ by translations. We also have the action of $G = S_n \times S_{n-1} \times \cdots \times S_1$ on $T_n(\mathbb{C})$ as follows:

$$\sigma(v) := (v_{n,\sigma^{-1}[n](1)}, \ldots, v_{n,\sigma^{-1}[n](n)} | \ldots | v_{1,\sigma^{-1}[1](1)}).$$

where $v \in T_n(\mathbb{C})$, $\sigma \in G$ and $\sigma[k] \in S_k$. This leads to the action of the semidirect product $G \ltimes T_{n-1}(\mathbb{Z})$ on $T_n(\mathbb{C})$.

Denote by K the field of fractions of Γ and by L the field of fractions of Λ. We have $L^G = K$, $\Lambda^G = \Gamma$ and $G = G(L/K)$ is the Galois group of the field extension $K \subset L$. The group $\mathcal{M}$ acts naturally on L and U is a subalgebra of $(L * \mathcal{M})^G$. Following Futorny and Ovsienko [2014], define a linear map $\tau : U \longmapsto (L * \mathcal{M})^G$ where

$$\tau(e_{mm}) = e_{mm} * e,\ \tau(e_{m\,m+1}) = \sum_{i=1}^{m} a_{mi}^{+} \delta^{mi},\ \tau(e_{m+1\,m}) = \sum_{i=1}^{m} a_{mi}^{-} (\delta^{mi})^{-1},$$

where

$$a_{mi}^{\pm} = \mp \frac{\prod_j (\lambda_{m\pm 1,j} - \lambda_{mi})}{\prod_{j \neq i} (\lambda_{mj} - \lambda_{mi})},$$

and e is the identity element of the group $\mathcal{M}$.

In fact, the map τ is algebra homomorphism since the defining relations of $\mathfrak{gl}_n$ are given by some rational functions which agree on finite dimensional modules, thus relations are satisfied.

Moreover, we have

Theorem 4.2 (Futorny and Ovsienko [2010], Proposition 7.2)**.** *τ is an embedding and U is a Galois order over Γ.*

Applying Theorem 3.2 we obtain that the number of isomorphism classes of simple Gelfand-Tsetlin U-modules with a given maximal ideal of Γ in the support is bounded by $\prod_{i=1}^{n-1} i!$. Another consequence of Theorem 4.2 is the following. If M is a Gelfand-Tsetlin U-module and $\mathbf{m} = \mathbf{m}_v \in \operatorname{Specm}\Gamma$ for some $v \in T_n(\mathbb{C})$ then

$$e_{k,k\pm 1} M(\mathbf{m}) \subset \sum_{i=1}^{k} M(\mathbf{m}_{v\pm\delta^{ki}}).$$

From here and Theorem 3.1 one easily obtains

Corollary 4.1. *(i)* Γ *is a Harish-Chandra subalgebra of* U.

(ii) Γ *is maximal commutative in* U.

4.3 Tableaux modules. The explicit nature of the Gelfand-Tsetlin formulas in Theorem 4.1 and the fact that the coefficients in the formulas are rational functions on the entries of the tableaux, naturally raises the question whether this construction can be extended for more general tableaux.

If V is a Gelfand-Tsetlin modules which has a basis parametrized by the tableaux and the action of Γ is determined by the entries of tableaux as in (2) then such V will be called *tableau module*. The problem of constructing of tableaux modules was studied by Gelfand and Graev in Gelfand and Graev [1965] and by Lemire and Patera (for $n = 3$) in Lemire and Patera [1979], Lemire and Patera [1985]. Tableux relalization for Generalzied Verma modules was considered in Mazorchuk [1998].

If the action of the generators of $\mathfrak{gl}_n$ on a tableau Gelfand-Tsetlin module V is given by the classical Gelfand-Tsetlin formulas as in Theorem 4.1 then V will be called *standard tableau module*. Modules considered in Gelfand and Graev [1965], Lemire and Patera [1979], Lemire and Patera [1985] are standard tableau modules.

We call $T(v)$ a *generic tableau* and v a *generic vector* if $v_{rs} - v_{rt} \notin \mathbb{Z}$ for any $r < n$ and all possible $s \neq t$. For a generic tableau all denominators in the Gelfand-Tsetlin formulas are nonintegers and one can use the same formulas to define *generic* standard tableau Gelfand-Tsetlin module $V(T(v))$ (Drozd, Futorny, and Ovsienko [1994], Section 2.3). All Gelfand-Tsetlin multiplicities of maximal ideals of $V(T(v))$ are 1.

Definition 4.1. *For each generic vector w and any $1 \leq r, s \leq n$ define*

$$d_{rs}(w) := \begin{cases} -\frac{\prod_{j=1}^{s}(w_{s-1,1}-w_{s,j})}{\prod_{j=2}^{s-1}(w_{s-1,1}-w_{s-1,j})} \prod_{j=r}^{s-2} \left(\frac{\prod_{t=2}^{j+1}(w_{j1} - w_{j+1,t})}{\prod_{t=2}^{j}(w_{j1} - w_{jt})} \right), & \text{if } r < s, \\ \frac{\prod_{j=1}^{s-1}(w_{s1}-w_{s-1,j})}{\prod_{j=2}^{s}(w_{s1}-w_{sj})} \prod_{j=s+2}^{r} \left(\frac{\prod_{t=2}^{j-2}(w_{j-1,1} - w_{j-2,t})}{\prod_{t=2}^{j-1}(w_{j-1,1} - w_{j-1,t})} \right), & \text{if } r > s, \\ r - 1 + \sum_{i=1}^{r} w_{ri} - \sum_{i=1}^{r-1} w_{r-1,i}, & \text{if } r = s, \end{cases}$$

Let $1 \leq r < s \leq n-1$. Set $\varepsilon_{rs} := \delta^{r,1} + \delta^{r+1,1} + \ldots + \delta^{s-1,1} \in T_n(\mathbb{Z})$, $\varepsilon_{rr} = 0$ and $\varepsilon_{sr} = -\varepsilon_{rs}$.

Let $\widetilde{S}_k$ be the subset of S_n consisting of the transpositions $(1, i)$, $i = 1, \ldots, k$. For $s < \ell$, set $\Phi_{s\ell} = \widetilde{S}_{\ell-1} \times \cdots \times \widetilde{S}_s$. For $s > \ell$ we set $\Phi_{s\ell} = \Phi_{\ell s}$. Finally we let $\Phi_{\ell\ell} = \{\mathrm{Id}\}$. Every σ in $\Phi_{s\ell}$ will be written as a $|s - \ell|$-tuple of transpositions $\sigma[k]$ (where $\sigma[k]$ is the k-th component of σ).

Proposition 4.1 (Futorny, Grantcharov, and Ramirez [2015]). *Let $v \in T_n(\mathbb{C})$ be generic. Then the $\mathfrak{gl}_n$-module structure on $V(T(v))$ is defined by the formulas:*

$$e_{k\ell}(T(v+z)) = \sum_{\sigma \in \Phi_{k\ell}} d_{k\ell}(\sigma(v+z)) T(v+z+\sigma(\varepsilon_{k\ell})), \tag{3}$$

for $z \in T_{n-1}(\mathbb{Z})$ and $1 \leq k, \ \ell \leq n$. Moreover, $V(T(v))$ is a Gelfand-Tsetlin module with action of Γ given by the formulas (2).

Note that if $v - v' \in T_{n-1}(\mathbb{Z})$ then $V(T(v))$ and $V(T(v'))$ are isomorphic as vectors spaces but not necessarily as the $\mathfrak{gl}_n$-modules. Simple generic Gelfand-Tsetlin modules were described in Futorny, Grantcharov, and Ramirez [ibid.].

The main difficulty in the defining of a tableau Gelfand-Tsetlin module structure on $V(T(v))$ is the existence of entries in one row of $T(v)$ that have integer difference. Let $v \in \mathbb{C}^{\frac{n(n+1)}{2}}$. A pair of entries (v_{ki_j}, v_{ki_s}) such that $k > 1$ and $v_{ki_j} - v_{ki_s} \in \mathbb{Z}$ is called a *singular pair*. We say that v (and $T(v)$) is *singuar* if v has singular pairs. First examples of infinite dimensional tableau Gelfand-Tsetlin modules with singular tableaux were considered in Gelfand and Graev [1965], Lemire and Patera [1979], Lemire and Patera [1985]. A new effective method of constructing standard tableau simple Gelfand - Tsetlin modules was proposed in Futorny, Ramirez, and Zhang [2016]. It allowed to obtain a large family of simple modules that have a basis consisting of Gelfand-Tsetlin tableaux and the action of the generators of $\mathfrak{gl}_n$ is given by the classical Gelfand-Tsetlin formulas. All examples obtained in Gelfand and Graev [1965], Lemire and Patera [1979], Lemire and Patera [1985] are particular cases of this construction. But the class of modules defined in

Futorny, Ramirez, and Zhang [2016] is more general. They build out of a tableau satisfying certain *FRZ-condition*.

A tableau $T(v)$ is *critical* if it has equal entries in one or more rows different from the top row. Otherwise, tableau is *noncritical*.

Theorem 4.3 (Futorny, Ramirez, and Zhang [ibid.], Theorem II)**.** *Let $T(w)$ be a tableau satisfying the FRZ-condition. There exists a unique simple Gelfand-Tsetlin $\mathfrak{gl}_n$-module V_w having the following properties:*

(i) $V_w(\mathbf{m}_w) \neq 0$*;*

(ii) V_m *has a basis consisting of noncritical tableaux and the action of the generators of* $\mathfrak{gl}_n$ *is given by the classical Gelfand-Tsetlin formulas (4.1).*

(iii) All Gelfand-Tsetlin multiplicities of maximal ideals of Γ *in the support of* V_w *equal* 1.

Theorem 4.3 provides a combinatorial way to explicitly construct a large class of infinite dimensional simple Gelfand-Tsetlin modules.

Conjecture 1. If V is a simple Gelfand-Tsetlin $\mathfrak{gl}_n$-module which has a basis consisting of noncritical tableaux with classical action of the generators of $\mathfrak{gl}_n$ then $V \simeq V_w$ for some w satisfying the FRZ-condition.

The conjecture holds for $n \leq 4$.

A systematic study of singular modules was initiated in Futorny, Grantcharov, and Ramirez [2015] where the case of a singular tableau $T(v)$ with a unique singular pair was considered (*1-singular* case). A significant difference from all previous cases is the existence of *derivative* tableaux in the basis of $V(T(v))$ which reflects the fact that the exact bound for the Gelfand-Tsetlin multiplicities of $V(T(v))$ is 2. Alternative interpretation of a tableau Gelfand-Tsetlin module structure on $V(T(v))$ in 1-singular case was given independently in Vishnyakova [2018] and Zadunaisky [2017]. Simple subquotients of $V(T(v))$ were described in Gomes and Ramirez [2016].

We say that v is *singular of index* $m \geq 2$ if:

(i) there exists a row k, $1 < k < n$, and m entries $v_{ki_1}, \ldots, v_{ki_m}$ on this row such that $v_{ki_j} - v_{ki_s} \in \mathbb{Z}$ for all $j, s \in \{1, \ldots, m\}$;

(ii) m is maximal with the property (i).

The case of arbitrary singularity of index $m = 2$ was solved in Futorny, Grantcharov, and Ramirez [2016a]. In this case any number of singular pairs (but not singular triples) and multiple singular pairs in the same row were allowed. Finally, the general case of an arbitrary singularity was solved in Vishnyakova [2017] (for p-singularity) and Ramírez and Zadunaisky [2017] (for arbitrary singularity). We provide the construction from Ramírez and Zadunaisky [ibid.] whose spirit is closer to our original approach.

Recall that L is the field of rational functions in λ_{ij}, $i = 1, \dots, n$, $j = 1, \dots, i$, and $a^{\pm}_{mi} \in L$ for all $1 \leq i \leq k < n$. Consider a set of all tableau with integral entries whose top row consists of zeros. We set $V_{\mathbb{C}}$ to be the $\mathbb{C}$-vector space with this basis, and $V_L = L \otimes_{\mathbb{C}} V_{\mathbb{C}}$. Since τ (4.2) is a homomorphism, V_L is a U-module, with the action of $\mathfrak{gl}_n$ given by the Gelfand-Tsetlin formulas.

The group G acts acts on V_L by the diagonal action, while $\mathcal{M}$ acts on Λ and L by translations: $\delta^{k,i} \cdot \lambda_{l,j} = \lambda_{l,j} + \delta_{k,l}\delta_{i,j}$.

Denote by A the algebra of regular functions over generic tableaux, that is those elements in L which can be evaluated in any generic tableau, and let V_A to be the A-submodule of V_L generated by all integral tableaux. Given a generic tableau $T(v)$, we can recover the corresponding generic module $V(T(v))$ by specializing V_A at v. If $T(v)$ is a singular tableau then we replace A with an algebra $B \subset L$ such that there exists a B-submodule $V_B \subset V_L$ which is also a U-submodule and any element of V_B can be evaluated at v. Specialization at v finally defines $V(T(v))$.

Each point $v \in \mathbb{C}^{\frac{n(n+1)}{2}}$ defines the following refinement $\eta(v)$ of v, which measures of how far is v from being generic Ramírez and Zadunaisky [ibid.]. Fix $1 \leq k \leq n-1$. Construct a graph with vertices $i = 1, \dots, k$, put an edge between i and j if and only if $v_{k,i} - v_{k,j}$ is integer. The graph is the disjoint union of connected components, we set $\eta^{(k)}$ to be a sequence of their cardinalities arranged in descending order. The entries $v_{k,i}$ that form one connected component are called an *η-block* of v. If v is generic then $\eta^{(k)} = (1^k)$, a sequence consisting of n ones. We set $\eta = (\eta^{(1)}, \dots, \eta^{(n-1)}, 1^n)$ to be the *η-type* of v and $\eta(v)$ to be the element in $\mathbb{C}^{\frac{n(n+1)}{2}}$ obtained from v by rearranging of it components to match the η-blocks.

Let B be the localization of Λ by the multiplicative subset of Λ generated by the elements

$$\lambda_{k,i} - \lambda_{k,j} - z,\ 1 \leq i < j \leq k < n, z \in \mathbb{Z} \setminus \{0\}.$$

Following Ramírez and Zadunaisky [ibid.], we say that v is in an *η-normal form* if $v_{k,i} - v_{k,j} \in \mathbb{Z}_{\geq 0}$ implies that $v_{k,i}$ and $v_{k,j}$ belong to the same η-block of v and $i < j$. Clearly, the orbit $G \cdot v$ has at least one (but not necessarily unique) element in normal form. We also say that v is an *η-critical* if it is in η-normal form and $v_{k,i} - v_{k,j} \in \mathbb{Z}$ implies $v_{k,i} = v_{k,j}$.

Consider a subgroup $G_\eta \subset G$ consisting of those elements of G which preserve the block structure of $\eta(v)$.

Fix η and an η-critical v. Set B_η to be the localization of B by the multiplicative set generated by all $\lambda_{k,i} - \lambda_{k,j}$ such that $v_{k,i} \neq v_{k,j}$.

Now we consider divided difference operators that play a key role in the construction of $V(T(v))$. Denote by $s_i^{(k)}$ the simple transposition in G_η which interchanges $\lambda_{k,i}$ and $\lambda_{k,i+1}$ and fixes all other elements. The *divided difference* associated to $s_i^{(k)}$ is

$$\partial_i^{(k)} = \frac{1}{\lambda_{k,i} - \lambda_{k,i+1}}(id - s_i^{(k)}).$$

It can be viewed as an element of the smash product $L\#G_\eta$, where $(f \otimes \sigma)\cdot(g \otimes \sigma') = f\sigma(g) \otimes \sigma\sigma'$ for $f, g \in L$ and all $\sigma, \sigma' \in G_\eta$.

Let $G_{\eta,k} \subset G_\eta$ be the corresponding component of S_k, $k = 1, \dots, n$. If $\sigma = s_{i_1}^{(k)} s_{i_2}^{(k)} \cdots s_{i_l}^{(k)}$ is a reduced decomposition for $\sigma \in G_{\eta,k}$ then set $\partial_\sigma = \partial_{i_1}^{(k)} \cdot \partial_{i_2}^{(k)} \cdots \partial_{i_l}^{(k)}$ which does not depend of the chosen reduced decomposition. This naturally extends to the whole group G_η.

For each $\sigma \in G_\eta$ we define the *symmetrized divided difference operator*

$$D_\sigma^\eta = \mathrm{sym}_\eta \cdot \partial_\sigma,$$

where $\mathrm{sym}_\eta = \frac{1}{|G_\eta|} \sum_{\sigma \in G_\eta} \sigma$.

Since B_η is closed under the action of G_η, we have $D_\sigma^\eta(f) \in B_\eta$ for all $f \in B_\eta$. Denote by $V_\eta \subset V_L$ the B_η-span of $\{D_\sigma^\eta T(z) \mid \sigma \in G_\eta, z \in T_{n-1}(\mathbb{Z})\}$. Then V_η is a U-submodule of V_L. Denote $\mathfrak{N}_\eta = \{z \in T_{n-1}(\mathbb{Z}) \mid v + z \text{ is in normal form}\}$. If $z \in \mathfrak{N}_\eta$ then the stabilizer subgroup of z in G_η is $G_{\epsilon(z)}$ where $\epsilon(z)$ is some refinement of η. Fix $z \in \mathfrak{N}$. We say that $\sigma \in G_\eta$ is a $\epsilon(z)$-shuffle if it is increasing in each $\epsilon(z)$-block. We denote the set of all $\epsilon(z)$-shuffles in G_η by $\mathrm{Shuffle}_{\epsilon(z)}^\eta$. Write $\bar{D}_\sigma^\eta(v+z) = 1 \otimes D_\sigma^\eta(z)$ for $z \in \mathfrak{N}$ and $\sigma \in \mathrm{Shuffle}_{\epsilon(z)}^\eta$.

Combining Theorems 5.3 and 5.6 of Ramírez and Zadunaisky [2017] we obtain

Theorem 4.4. *Let $V(T(v)) = \mathbb{C} \otimes_{B_\eta} V_\eta$, where $\mathbb{C}$ is a right B_η-module such that $1\dot{f} = f(v)$. Then $V(T(v))$ is a Gelfand-Tsetlin module with a basis $\{\bar{D}_\sigma^\eta(v+z) \mid z \in \mathfrak{N}_\eta, \sigma \in \mathrm{Shuffle}_{\epsilon(z)}^\eta\}$ and $\mathbf{m}_v$ belongs to the support of $V(T(v))$.*

Conjecture 2. Any simple Gelfand-Tsetlin module V with $V(\mathbf{m}_v) \neq 0$ is isomorphic to a subquotient of $V(T(v))$ for any singular v.

The conjecture was stated for any singular v of index 2 in Futorny, Grantcharov, and Ramirez [2016a]. It is known to be true for $n = 2$ and $n = 3$, and for the 1-singular v Futorny, Grantcharov, and Ramirez [2017]. In particular, it gives a complete classification of all simple Gelfand-Tsetlin $\mathfrak{gl}(3)$-modules, Futorny, Grantcharov, and Ramirez [2014].

A VIEW ON INVARIANT RANDOM SUBGROUPS AND LATTICES

Tsachik Gelander

Abstract

For more than half a century lattices in Lie groups played an important role in geometry, number theory and group theory. Recently the notion of Invariant Random Subgroups (IRS) emerged as a natural generalization of lattices. It is thus intriguing to extend results from the theory of lattices to the context of IRS, and to study lattices by analyzing the compact space of all IRS of a given group. This article focuses on the interplay between lattices and IRS, mainly in the classical case of semisimple analytic groups over local fields.

Let G be a locally compact group. We denote by $\mathrm{Sub}(G)$ the space of closed subgroups of G equipped with the Chabauty topology. The compact space $\mathrm{Sub}(G)$ is usually too complicated to work with directly. However, considering a random point in $\mathrm{Sub}(G)$ is often much more effective. Note that G acts on $\mathrm{Sub}(G)$ by conjugation. An invariant random subgroup (or shortly IRS) is a G-invariant probability measure on $\mathrm{Sub}(G)$. We denote by $\mathrm{IRS}(G)$ the space of all IRSs of G equipped with the w^*-topology. By Riesz' representation theorem and Alaoglu's theorem, $\mathrm{IRS}(G)$ is compact.

The Dirac measures in $\mathrm{IRS}(G)$ correspond to normal subgroups. Any lattice Γ in G induces an IRS μ_Γ which is defined as the push forward of the G-invariant probability measure from G/Γ to $\mathrm{Sub}(G)$ via the map $g\Gamma \mapsto g\Gamma g^{-1}$.

More generally consider a probability measure preserving action $G \curvearrowright (X, m)$. By a result of Varadarajan, the stabilizer of almost every point in X is closed in G. Moreover, the stabilizer map $X \to \mathrm{Sub}_G,\ x \mapsto G_x$ is measurable, and hence one can push the measure m to an IRS on G. In other words the random subgroup is the stabilizer of a random point in X. In a sense, the study of pmp G-spaces can be divided to the study of stabilizers (i.e. IRSs), the study of orbit spaces and the interplay between the two. Vice versa, every IRS arises (non-uniquely) in this way (see Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2017a, Theorem 2.6]).

MSC2010: primary 22D05; secondary 22E40, 22B99, 20G15, 37A05, 53C35.

Since its rebirth in the beginning of the current decade (see Section 10 for a short summery of the history of IRS), the topic of IRS played an important role in various parts of group theory, geometry and dynamics, and attracted the attention of many mathematicians for various different reasons. Not aiming to give an overview, I will try to highlight here several aspects of the evolving theory.

1 IRS and Lattices

IRSs can be considered as a generalisation of lattices, and one is tempted to extend results from the theory of lattices to IRS. In the other direction, as often happens in mathematics where one considers random objects to prove result about deterministic ones, the notion of IRS turns out to yield an extremely powerful tool to study lattices. In this section I will try to give a taste of the interplay between IRSs and Lattices focusing mainly on the second point of view. Attempting to expose the phenomenon in a rather clear way, avoiding technicality, I will assume throughout most of this section that G is a noncompact simple Lie group, although most of the results can be formulated in the much wider setup of semisimple analytic groups over arbitrary local fields, see Section 1.5.

1.1 Borel Density. Let $\mathrm{PSub}(G)$ denote the space of proper closed subgroups. Since G is an isolated point in $\mathrm{Sub}(G)$ (see Toyama [1949] and Kuranishi [1951]) we deduce that $\mathrm{PSub}(G)$ is compact. Letting $\mathrm{PIRS}(G)$ denote the subspace of $\mathrm{IRS}(G)$ consisting of the measures supported on $\mathrm{PSub}(G)$, we deduce:

Lemma 1.1. *The space of proper IRSs, $PIRS(G)$ is compact.*

Let us say that that an IRS μ is discrete if a random subgroup is μ almost surely discrete, and denote by $\mathrm{DIRS}(G)$ the subspace of $\mathrm{IRS}(G)$ consisting of discrete IRSs. The following is a generalization of the classical Borel Density Theorem:

Theorem 1.2. *(Borel Density Theorem for IRS, Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2017a, Theorem 2.9]) Every proper IRS in G is discrete, i.e. $PIRS(G) = DIRS(G)$. Moreover, for every $\mu \in DIRS(G)$, μ-almost every subgroup is either trivial or Zariski dense.*

In order to prove Theorem 1.2 one first observes that there are only countably many conjugacy classes of non-trivial finite subgroups in G, hence the measure of their union is zero with respect to any non-atomic IRS. Then one can apply the same idea as in Furstenberg's proof of the classical Borel density theorem Furstenberg [1976]. Indeed, taking the Lie algebra of $H \in \mathrm{Sub}(G)$ as well as of its Zariski closure induce measurable maps (see

Gelander and Levit [2017, §4])

$$H \mapsto \mathrm{Lie}(H),\ H \mapsto \mathrm{Lie}(\overline{H}^Z).$$

As G is noncompact, Furstenberg's argument implies that the Grassman variety of non-trivial subspaces of $\mathrm{Lie}(G)$ does not carry an $\mathrm{Ad}(G)$-invariant measure. It follows that $\mathrm{Lie}(H) = 0$ and $\mathrm{Lie}(\overline{H}^Z) \in \{\mathrm{Lie}(G), 0\}$ almost surely, and the two statements of the theorem follow.

1.2 Weak Uniform Discreteness.

Let U be an identity neighbourhood in G. A family of subgroups $\mathfrak{F} \subset \mathrm{Sub}(G)$ is called *U-uniformly discrete* if $\Gamma \cap U = \{1\}$ for all $\Gamma \in \mathfrak{F}$.

Definition 1.3. A family $\mathfrak{F} \subset \mathrm{DIRS}(G)$ of invariant random subgroups is said to be *weakly uniformly discrete* if for every $\epsilon > 0$ there is an identity neighbourhood $U_\epsilon \subset G$ such that

$$\mu(\{\Gamma \in \mathrm{Sub}_G : \Gamma \cap U_\epsilon \neq \{1\}\}) < \epsilon$$

for every $\mu \in \mathfrak{F}$.

A justification for this definition is given by the following result which is proved by an elementary argument and yet provides a valuable information:

Theorem 1.4. *Let G be a connected non-compact simple Lie group. Then DIRS(G) is weakly uniformly discrete.*

Let $U_n, n \in \mathbb{N}$ be a descending sequence of compact sets in G which form a base of identity neighbourhoods, and set

$$K_n = \{\Gamma \in \mathrm{Sub}_G : \Gamma \cap U_n = \{1\}\}.$$

Since G has NSS (no small subgroups), i.e. there is an identity neighbourhood which contains no non-trivial subgroups, we have:

Lemma 1.5. *The sets K_n are open in* $\mathrm{Sub}(G)$.

Proof. Fix n and let $V \subset U_n$ be an open identity neighbourhood which contains no non-trivial subgroups, such that $V^2 \subset U_n$. It follows that a subgroup Γ intersects U_n non-trivially iff it intersects $U_n \setminus V$. Since $U_n \setminus V$ is compact, the lemma is proved. □

In addition, observe that the ascending union $\bigcup_n K_n$ exhausts $\mathrm{Sub}_d(G)$, the set of all discrete subgroups of G. Therefore we have:

Claim 1.6. For every $\mu \in \mathrm{DIRS}(G)$ and $\epsilon > 0$ we have $\mu(K_n) > 1 - \epsilon$ for some n. □

Let

$$\mathcal{K}_{n,\epsilon} := \{\mu \in \mathrm{DIRS}(G) : \mu(K_n) > 1 - \epsilon\}.$$

Since $\mathrm{Sub}(G)$ is metrizable, it follows from Lemma 1.5 that $\mathcal{K}_{n,\epsilon}$ is open. By Claim 1.6, for any given $\epsilon > 0$, the sets $\mathcal{K}_{n,\epsilon}$, $n \in \mathbb{N}$ form an ascending cover of $\mathrm{DIRS}(G)$. Since the latter is compact, we have $\mathrm{DIRS}(G) \subset \mathcal{K}_{m,\epsilon}$ for some $m = m(\epsilon)$. It follows that

$$\mu\big(\{\Gamma \in \mathrm{Sub}(G) : \Gamma \text{ intersects } U_m \text{ trivially}\}\big) > 1 - \epsilon,$$

for every $\mu \in \mathrm{DIRS}(G)$. Thus Theorem 1.4 is proved. □

Picking $\epsilon < 1$ and applying the theorem for the IRS μ_Γ where $\Gamma \le G$ is an arbitrary lattice, one deduces the Kazhdan–Margulis theorem Každan and Margulis [1968], and in particular that there is a positive lower bound on the volume of locally G/K-orbifolds:

Corollary 1.7 (Kazhdan–Margulis theorem)**.** *There is an identity neighbourhood $\Omega \subset G$ such that for every lattice $\Gamma \le G$ there is $g \in G$ such that $g\Gamma g^{-1} \cap \Omega = \{1\}$.*

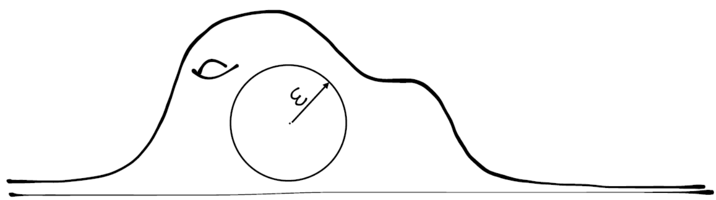

Figure 1: Every X-manifold has a thick part.

A famous conjecture of Margulis Margulis [1991, page 322] asserts that the set of all torsion-free anisotropic arithmetic lattices in G is U-uniformly discrete for some identity neighbourhood $U \subset G$. Theorem 1.4 can be regarded as a probabilistic variant of this conjecture as it implies that all lattices in G are jointly weakly uniformly discrete.

In the language of pmp actions Theorem 1.4 can be reformulated as follows:

Theorem 1.8 (p.m.p. actions are uniformly weakly locally free)**.** *For every $\epsilon > 0$ there is an identity neighbourhood $U_\epsilon \subset G$ such that the stabilizers of $1 - \epsilon$ of the points, in any non-atomic probability measure preserving G-space (X, m) are U_ϵ-uniformly discrete. I.e., there is a subset $Y \subset X$ with $m(Y) > 1 - \epsilon$ such that $U_\epsilon \cap G_y = \{1\}$, $\forall y \in Y$.*

1.3 Local Rigidity.

Observe that local rigidity implies Chabauty locally rigid:

Proposition 1.9. *Let G be a connected Lie group and $\Gamma \le G$ a locally rigid lattice. Then Γ is Chabauty locally rigid, i.e. the conjugacy class of Γ is Chabauty open.*

Proof. Let $\Gamma \le G$ a locally rigid lattice. Let U be a compact identity neighborhood in G satisfying:

- $U \cap \Gamma = \{1\}$,
- U contains no nontrivial groups,

and let V be an open symmetric identity neighborhood with $V^2 \subset U$. By the choice of V we for a subgroup $H \le G$, that $H \cap U \ne \{1\}$ iff H meets the compact set $U \setminus V$.

Recall that Γ, being a lattice in a Lie group, is finitely presented and let $\langle \Sigma | R \rangle$ be a finite presentation of Γ. Denote $S = \{s_1, \dots, s_k\}$. We can pick a sufficiently small identity neighborhood Ω so that for every choice of $g_i \in s_i\Omega$, $i = 1, \dots, k$ and every $w \in R$ we have $w(g_1, \dots, g_n) \in U$.

Now if $H \in \mathrm{Sub}(G)$ is sufficiently close to Γ in the Chabauty topology then $H \cap s_i\Omega \ne \emptyset$, $i = 1, \dots, k$ and $H \cap (U \setminus V) = \emptyset$, i.e. $H \cap U = \{1\}$. Picking $h_i \in H \cap s_i\Omega$, $i = 1, \dots, k$ one sees that the assignment $s_i \mapsto h_i$ induces a homomorphism from Γ into H. Since Γ is locally rigid it follows that if H is sufficiently close to Γ then it contains a conjugate of Γ. However there are only finitely many subgroups containing Γ and intersecting U trivially, hence if H is sufficiently close to Γ then it is a conjugate of Γ. □

Denote by $\mathrm{EIRS}(G)$ the space ergodic IRSs of G, i.e. the set of extreme points of $\mathrm{IRS}(G)$.

Corollary 1.10. *Let G be a connected Lie group and $\Gamma \le G$ a locally rigid lattice. Then the IRS μ_Λ is isolated in EIRS(G).*

Proof. Let Γ be as above. If μ is an IRS of G sufficiently close to μ_Γ then with positive μ-probability a random subgroup is a conjugate of Γ. Thus if μ is ergodic then it must be μ_Γ. □

1.4 Farber property.

Definition 1.11. A sequence μ_n of invariant random subgroups of G is called *Farber*[1] if μ_n converge to the trivial IRS, $\delta_{\{1\}}$.

[1] Various authors use various variants of this notion.

One of the key results of Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2017a] is the following theorem:

Theorem 1.12. *Let G be a simple Lie group of real rank at least 2. Let Γ_n be a sequence of pairwise non-conjugate lattices, then μ_{Γ_n} is Farber.*

The proof relies on the following variant of Stuck–Zimmer theorem (see Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [ibid.]):

Theorem 1.13. *Assuming $\mathrm{rank}(G) \geq 2$, a proper non-trivial ergodic IRS of G is μ_Γ for some lattice Γ, i.e.*

$$EIRS(G) = \{\delta_G, \delta_{\{1\}}, \mu_\Gamma,\ \Gamma \text{ a lattice in } G\}.$$

Proof of Theorem 1.12. Since G is of rank ≥ 2 it has Kazhdan's property (T), Každan [1967]. By E. Glasner and Weiss [1997], $\mathrm{EIRS}(G)$ is compact. Since δ_G and δ_{μ_Γ} where Γ is a lattice in G are isolated points, it follows that $\delta_{\{1\}}$ is the unique accumulation point of $\mathrm{EIRS}(G)$. In particular $\mu_{\Gamma_n} \to \delta_{\{1\}}$. □

1.5 Semisimple analytic groups. Above we have carried out the arguments under the assumption that G is a simple Lie group. In this section we state the results in the more general setup of analytic groups over local fields.

Definition 1. Let k be a local field and $\mathbb{G}$ a connected k-isotropic k-simple linear k-algebraic group.

- A *simple analytic group* is a group of the form $\mathbb{G}(k)$.
- A *semisimple analytic group* is an almost direct product of finitely many simple analytic groups, possibly over different local fields.

Note that if k is a local field and $\mathbb{G}$ is a connected semisimple linear k-algebraic group without k-anisotropic factors then $\mathbb{G}(k)$ is a semisimple analytic group. Such a group is indeed *analytic* in the sense of e.g. Serre [2006]. Associated to a semisimple analytic group G are its universal covering group $\widetilde{G}$ and adjoint group $\overline{G}$. There are central k-isogenies $\widetilde{G} \overset{\widetilde{p}}{\to} G \overset{\overline{p}}{\to} \overline{G}$ and this data is unique up to a k-isomorphism Margulis [1991, p. I.4.11]. For a semisimple analytic group G, denote by G^+ the subgroup of G generated by its unipotent elements Margulis [ibid., pp. I.1.5, I.2.3]. If G is simply connected then $G = G^+$. If G is Archimedean then G^+ is the connected component G_0 at the identity. In general G/G^+ is a compact abelian group. The group G^+ admits no proper finite index subgroups.

Definition 2. A simple analytic group G is *happy* if $\mathrm{char}(k)$ does not the divide $|Z|$ where Z is the kernel of the map $\widetilde{G} \to G$. A semisimple analytic group is *happy* if all of its almost direct factors are.

Note that a simply connected or a zero characteristic semisimple analytic group is automatically happy. From the work of Barnea and Larsen [2004] one obtains that a semisimple analytic group G is happy, iff G/G^+ is a finite abelian group, iff some (equivalently every) compact open subgroup in the non-Archimedean factor of G is finitely generated.

Self Chabauty isolation.

Definition 3. A l.c.s.c. group G is *self-Chabauty-isolated if the point G is isolated in* $\mathrm{Sub}(G)$ *with the Chabauty topology.*

Note that G is self-Chabauty-isolated if and only if there is a finite collection of open subsets $U_1, \ldots, U_n \subset G$ so that the only closed subgroup intersecting every U_i non-trivially is G itself. The following result is proved in Gelander and Levit [2017, §6].

Theorem 4. Let G be a happy semisimple analytic group. Then G^+ is self-Chabauty-isolated.

As an immediate consequence we deduce the analog of Lemma 1.1, namely that the space $\mathrm{PSub}(G^+)$ is compact for every G as in Theorem 4.

Borel Density. The following generalization of Theorem 1.2 was obtained in Gelander and Levit [ibid., Theorem 1.9]:

Theorem 5 (Borel density theorem for IRS)**.** Let k be a local field and G a happy semisimple analytic group over k. Assume that G has no almost k-simple factors of type B_n, C_n or F_4 if $\mathrm{char}(k) = 2$ and of type G_2 if $\mathrm{char}(k) = 3$.

Let μ be an ergodic invariant random subgroup of G. Then there is a pair of normal subgroups $N, M \lhd G$ so that

$$N \leq H \leq M, \quad H/N \text{ is discrete in } G/N \quad \text{and} \quad \overline{H}^{Z} = M$$

for μ-almost every closed subgroup H in G. Here $\overline{H}^{Z}$ is the Zariski closure of H.

Weak Uniform Discreteness. As shown in Gelander [2018, Theorem 2.1] the analog of Theorem 1.4 holds for general semisimple Lie groups:

Theorem 1.14. *Let G be a connected center-free semisimple Lie group with no compact factors. Then $\mathrm{DIRS}(G)$ is weakly uniformly discrete.*

Consider now a general locally compact σ-compact group G. Since $\mathrm{Sub}_d(G) \subset \mathrm{Sub}(G)$ is a measurable subset, by restricting attention to it, one may replace Property NSS by the weaker Property NDSS (no discrete small subgroups), which means that there is an identity neighbourhood which contains no non-trivial discrete subgroups. In that generality, the analog of Lemma 1.5 would say that K_n are relatively open in $\mathrm{Sub}_d(G)$. Thus, the ingredients required for the argument above are:

1. $\mathrm{DIRS}(G)$ is compact,

2. G has NDSS.

In particular we have:

Theorem 1.15. *Let G be a locally compact σ-compact group which satisfies (1) and (2). Then DIRS(G) is weakly uniformly discrete.*

If G possesses the Borel density theorem and G is self-Chabauty-isolated then (1) holds. By the previous paragraphs happy semisimple analytic groups enjoy these two properties, and hence (1).

***p*-adic groups.** Note that a p-adic analytic group G has NDSS, and hence $\mathrm{DIRS}(G)$ is uniformly discrete (in the obvious sense). Moreover, if $G \leq \mathrm{GL}_n(\mathbb{Q}_p)$ is a rational algebraic subgroup, then the first principal congruence subgroup $G(p\mathbb{Z}_p)$ is a torsion-free open compact subgroup. In particular the space $\mathrm{DIRS}(G)$ is $G(p\mathbb{Z}_p)$-uniformly discrete. Supposing further that G is simple, then in view of the Borel density theorem we have:

Let (X, μ) be a probability G-space essentially with no global fixed points. Then the action of the congruence subgroup $G(p\mathbb{Z}_p)$ on X is essentially free.

Positive characteristic. Algebraic groups over local fields of positive characteristic do not posses property NDSS, and the above argument does not apply to them.

Conjecture 1.16. *Let k be a local field of positive characteristic, let $\mathbb{G}$ be simply connected absolutely almost simple k-group with positive k-rank and let $G = \mathbb{G}(k)$ be the group of k-rational points. Then DIRS(G) weakly uniformly discrete.*

The analog of Corollary 1.7 in positive characteristic was proved in Salehi Golsefidy [2013] and Raghunathan [1972]. A. Levit proved Conjecture 1.16 for k-rank one groups Levit [n.d.].

Local Rigidity. Combining Theorem 7.2 and Proposition 7.9 of Gelander and Levit [2017] we obtain the following extension of Proposition 1.9:

Theorem 6. (Chabauty local rigidity Gelander and Levit [ibid.]) Let G be a semisimple analytic group and Γ an irreducible lattice in G. If Γ is locally rigid then it is also Chabauty locally rigid.

Let us also mention the following generalization of the classical Weil local rigidity theorem:

Theorem 7. (Gelander and Levit [2016, Theorem 1.2] Let X be a proper geodesically complete CAT(0) space without Euclidean factors and with Isom$X$ acting cocompactly. Let Γ be a uniform lattice in Isom$X$. Assume that for every de Rham factor Y of X isometric to the hyperbolic plane the projection of Γ to Isom$Y$ is non-discrete. Then Γ is locally rigid.

Farber Property. The proof presented above for Theorem 1.12 follows the lines developed at Gelander and Levit [2017] and is simpler and applies to a more general setup than the original proof from Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2017a]. In particular, the following general version of Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [ibid., Theorem 4.4] is proved in Gelander and Levit [2017]:

Theorem 8. Gelander and Levit [ibid., Theorem 1.1] Let G be a semisimple analytic group. Assume that G is happy, has property (T) and rank$(G) \geq 2$. Let Γ_n be a sequence of pairwise non-conjugate irreducible lattices in G. Then Γ_n is Farber.

Farber property for congruence subgroups. Relying on intricate estimates involving the trace formula, Raimbault [2013] and Fraczyk [2016] were able to establish Benjamini–Schramm convergence for every sequence of congruence lattices in the rank one groups $\mathrm{SL}_2(\mathbb{R})$ and $\mathrm{SL}_2(\mathbb{C})$.

Using property (τ) as a replacement for property (T), Levit [2017a] established Benjamini–Schramm convergence for every sequence of congruence lattices in any higher-rank semisimple group G over local fields. Whenever lattices in G are known to satisfy the congruence subgroup property this applies to all irreducible lattices in G.

1.6 The IRS compactification of moduli spaces. One may also use IRS(G) in order to obtain new compactifications of certain natural spaces.

Example 1.17. Let Σ be a closed surface of genus ≥ 2. Every hyperbolic structure on Σ corresponds to an IRS in $\mathrm{PSL}_2(\mathbb{R})$. Indeed one take a random point and a random tangent vector w.r.t the normalized Riemannian measure on the unit tangent bundle and consider the associated embedding of the fundamental $\pi_1(\Sigma)$ in $\mathrm{PSL}_2(\mathbb{R})$ via deck transformations.

Taking the closure in $\mathrm{IRS}(G)$ of the set of hyperbolic structures on Γ, one obtains an interesting compactification of the moduli space of Σ.

Problem 1.18. Analyse the IRS compactification of $\mathrm{Mod}(\Sigma)$.

Note that the resulting compactification is similar to (but is not exactly) the Deligne–Munford compactification.

2 The Stuck–Zimmer theorem

One of the most remarkable manifestations of rigidity for invariant random subgroups is the following celebrated result due to Stuck and Zimmer [1994].

Theorem 9. Let k be a local field and G be connected, simply connected semi-simple linear algebraic k-group. Assume that G has no k-anisotropic factors, has Kazhdan's property (T) and $\mathrm{rank}_k(G) \geq 2$. Then every properly ergodic and irreducible probability measure preserving Borel action of G is essentially free.

We recall that a probability measure preserving action is properly ergodic if it is ergodic and not essentially transitive, and is irreducible if every non-central normal subgroup is acting ergodically.

In the work of Stuck and Zimmer G is assumed to be a Lie group. The modifications necessary to deal with arbitrary local fields were carried on in Levit [2017b]. Much more generally, Bader and Shalom obtained a variant of the Stuck–Zimmer theorem for products of locally compact groups with property (T) in Bader and Shalom [2006].

The connection between invariant random subgroups and stabilizer structure for probability measure preserving actions allows one to derive the following:

Theorem 10. Let G be as in Theorem 9. Then any irreducible invariant random subgroup of G is either $\delta_{\{e\}}, \delta_G$ or μ_Γ for some irreducible lattice Γ in G.

We would like to point out that the Stuck–Zimmer theorem is a generalization of the following normal subgroup theorem of Margulis.

Theorem 11. Let G be as in Theorem 9 and Γ an irreducible lattice in G. Then any non-trivial normal subgroup $N \lhd \Gamma$ is either central or has finite index in Γ.

The Stuck–Zimmer theorem implies the normal subgroup theorem — indeed the ideas that go into its proof build upon the ideas of Margulis. One key ingredient is the intermediate factor theorem of Nevo and Zimmer, which in turn generalizes the factor theorem of Margulis. We point out that this aspect of the proof is entirely independent of property (T).

Question 2.1. Do Theorems 9 and 10 hold for all higher rank semisimple linear groups, regardless of property (T)?

Observe that the role played by Kazhdan's property (T) in the proof of Theorem 9 is in establishing the following fact.

Proposition 2.2. *Let G be a second countable locally compact group with Kazhdan's property (T). Then every properly ergodic probability measure preserving Borel action of G is not weakly amenable in the sense of Zimmer.*

The Nevo–Zimmer intermediate factor theorem is then used to show that a non-weakly amenable action is essentially free. On the other hand, the contrapositive of weak amenability follows quite readily from the fact that there are no non-trivial cocycles into amenable groups associated to probability measure preserving Borel actions of G.

To summarize, it is currently unknown if groups like $\mathrm{SL}_(\mathbb{R}) \times \mathrm{SL}_2(\mathbb{R})$ or $\mathrm{SL}_2(\mathbb{Q}_p) \times \mathrm{SL}_2(\mathbb{Q}_p)$ admit any non-trivial irreducible invariant random subgroups not coming from lattices.

We would like to point out that rank one semisimple linear groups, discrete hyperbolic or relatively hyperbolic groups as well as mapping class groups and $\mathrm{Out}(F_n)$ have a large supply of exotic invariant random subgroups Bowen [2015b], Dahmani, Guirardel, and Osin [2017], and Bowen, Grigorchuk, and Kravchenko [2015].

3 The Benjamini–Schramm topology

Let $\mathfrak{M}$ be the space of all (isometry classes of) pointed proper metric spaces equipped with the Gromov–Hausdorff topology. This is a huge space and for many applications it is enough to consider compact subspaces of it obtained by bounding the geometry. That is, let $f(\epsilon, r)$ be an integer valued function defined on $(0,1) \times \mathbb{R}^{>0}$, and let $\mathfrak{M}_f$ consist of those spaces for which $\forall \epsilon, r$, the ϵ-entropy of the r-ball $B_X(r,p)$ around the special point is bounded by $f(\epsilon, r)$, i.e. no $f(\epsilon, r)+1$ points in $B_X(r,p)$ form an ϵ-discrete set. Then $\mathfrak{M}_f$ is a compact subspace of $\mathfrak{M}$.

In many situations one prefers to consider some variants of $\mathfrak{M}$ which carry more information about the spaces. For instance when considering graphs, it may be useful to add colors and orientations to the edges. The Gromov–Hausdorff distance defined on these objects should take into account the coloring and orientation. Another example is smooth Riemannian manifolds, in which case it is better to consider framed manifolds, i.e. manifold with a chosen point and a chosen frame at the tangent space at that point. In that case, one replace the Gromov–Hausdorff topology by the ones determined by (ϵ, r) relations (see Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2017a, Section 3] for details), which remembers also the directions from the special point.

We define the *Benjamini–Schramm* space $\mathcal{BS} = \mathrm{Prob}(\mathfrak{M})$ to be the space of all Borel probability measures on $\mathfrak{M}$ equipped with the weak-$*$ topology. Given f as above, we set $\mathcal{BS}_f := \mathrm{Prob}(\mathfrak{M}_f)$. Note that $\mathcal{BS}_f$ is compact.

The name of the space is chosen to hint that this is the same topology induced by 'local convergence', considered by Benjamini and Schramm in Benjamini and Schramm [2001], when restricting to measures on rooted graphs. Recall that a sequence of random rooted bounded degree graphs converges to a limiting distribution iff for every n the statistics of the n ball around the root (i.e. the probability vector corresponding to the finitely many possibilities for n-balls) converges to the limit.

The case of general proper metric spaces can be described similarly. A sequence $\mu_n \in \mathcal{BS}_f$ converges to a limit μ iff for any compact pointed 'test-space' $M \in \mathfrak{M}$, any r and some arbitrarily small[2] $\epsilon > 0$, the μ_n probability that the r ball around the special point is 'ϵ-close' to M tends to the μ-probability of the same event.

Example 3.1. An example of a point in $\mathcal{BS}$ is a measured metric space, i.e. a metric space with a Borel probability measure. A particular case is a finite volume Riemannian manifold — in which case we scale the Riemannian measure to be one, and then randomly choose a point and a frame.

Thus a finite volume locally symmetric space $M = \Gamma\backslash G/K$ produces both a point in the Benjamini–Schramm space and an IRS in G. This is a special case of a general analogy that I'll now describe. Given a symmetric space X, let us denote by $\mathfrak{M}(X)$ the space of all pointed (or framed) complete Riemannian orbifolds whose universal cover is X, and by $\mathcal{BS}(X) = \mathrm{Prob}(\mathfrak{M}(X))$ the corresponding subspace of the Benjamini–Schramm space.

Let G be a non-compact simple Lie group with maximal compact subgroup $K \leq G$ and an associated Riemannian symmetric space $X = G/K$. There is a natural map

$$\{\text{discrete subgroups of } G\} \to \mathfrak{M}(X),\ \Gamma \mapsto \Gamma\backslash X.$$

It can be shown that this map is continuous, hence inducing a continuous map

$$\mathrm{DIRS}(G) \to \mathcal{BS}(X).$$

[2] This doesn't mean that it happens for all ϵ.

It can be shown that the later map is one to one, and since $\mathrm{DIRS}(G)$ is compact, it is a homeomorphism to its image (see Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2017a, Corollary 3.4]). [3]

Remark 3.2 (Invariance under the geodesic flow)**.** Given a tangent vector $\overline{v}$ at the origin (the point corresponding to K) of $X = G/K$, define a map $\mathfrak{F}_{\overline{v}}$ from $\mathfrak{M}(X)$ to itself by moving the special point using the exponent of $\overline{v}$ and applying parallel transport to the frame. This induces a homeomorphism of $\mathfrak{BS}(X)$. The image of $\mathrm{DIRS}(G)$ under the map above is exactly the set of $\mu \in \mathfrak{BS}(X)$ which are invariant under $\mathfrak{F}_{\overline{v}}$ for all $\overline{v} \in T_K(G/K)$.

Thus we can view geodesic-flow invariant probability measures on framed locally X-manifolds as IRS on G and vice versa, and the Benjamini–Schramm topology on the first coincides with the IRS-topology on the second.

Remark 3.3. The analogy above can be generalised, to some extent, to the context of general locally compact groups. Given a locally compact group G, fixing a right invariant metric on G, we obtain a map $\mathrm{Sub}_G \to \mathfrak{M}$, $H \mapsto G/H$, where the metric on G/H is the induced one. Moreover, this map is continuous hence defines a continuous map $\mathrm{IRS}(G) \to \mathfrak{BS}$.

For the sake of simplicity let us forget 'the frame' and consider pointed X-manifolds, and $\mathfrak{BS}(X)$ as probability measures on such. We note that while for general Riemannian manifolds there is a benefit for working with framed manifolds, for locally symmetric spaces of non-compact type, pointed manifolds, and measures on such, behave nicely enough.

In order to examine convergence in $\mathfrak{BS}(X)$ it is enough to use as 'test-space' balls in locally X-manifolds. Moreover, since X is non-positively curved, a ball in an X-manifold is isometric to a ball in X iff it is contractible.

Note that since X is a homogeneous space, all choices of a probability measure on X correspond to the same point in $\mathfrak{BS}(X)$. Abusing notations, we shall denote this point by X.

Definition 3.4. Let us say that a sequence in $\mathfrak{BS}(X)$ is *Farber* if it converges to X.

For an X-manifold M and $r > 0$, we denote by $M_{\geq r}$ the r-thick part in M:

$$M_{\geq r} := \{x \in M : \mathrm{InjRad}_M(x) \geq r\},$$

where $\mathrm{InjRad}_M(x) = \sup\{\epsilon : B_M(x,\epsilon) \text{ is contractible}\}$.

[3] It was Miklos Abert who pointed out to me, about eight years ago, the analogy between Benjamini–Schramm convergence (at that time 'local convergence') and convergence of Invariant Random Subgroups, which later played an important rule in the work Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2017a] and earlier in the work of Abért, Y. Glasner, and Virág [2016, 2014].

Proposition 3.5. *Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2017a, Corollary 3.8] A sequence M_n of finite volume X-manifolds is Farber iff*

$$\frac{\mathrm{vol}((M_n)_{\geq r})}{\mathrm{vol}(M_n)} \to 1,$$

for every $r > 0$.

Theorem 1.12 can be reformulated as:

Theorem 3.6. *Let X be an irreducible Riemannian symmetric space of non compact type of rank at least 2. For any r and ϵ there is V such that if M is an X-manifold of volume $v \geq V$ then $\frac{\mathrm{vol}(M_{\geq r})}{v} \geq 1 - \epsilon$ (see Figure 2).*

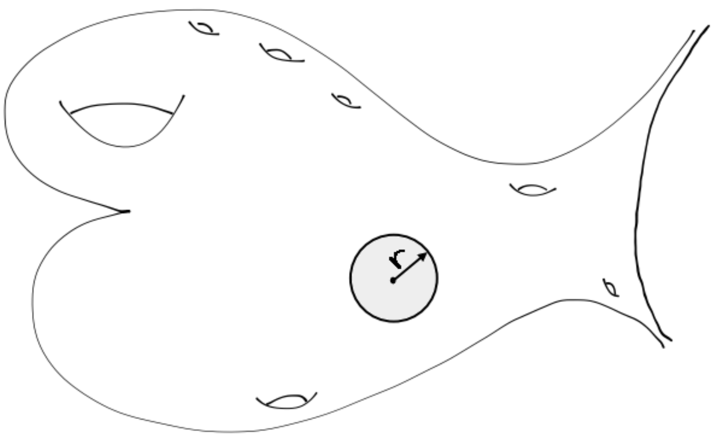

Figure 2: A large volume manifold is almost everywhere fat.

4 Applications to L_2-invariants

Let Γ be a uniform lattice in G. The right quasi-regular representation ρ_Γ of G in $L^2(\Gamma\backslash G, \mu_G)$ decomposes as a direct sum of irreducible representations. Every irreducible unitary representation π of G appears in ρ_Γ with finite multiplicity $m(\pi, \Gamma)$.

Definition 12. The *normalized relative Plancherel measure* of G with respect to Γ is an atomic measure on the unitary dual $\widehat{G}$ given by

$$\nu_\Gamma = \frac{1}{\mathrm{vol}(\Gamma\backslash G)} \sum_{\pi\in\widehat{G}} m(\pi,\Gamma)\delta_\pi .$$

The following result, extending earlier works of de George and Wallach [1978], Delorme [1986] and many others, was proved in Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2017a] for real Lie groups and then generalized to non-archimedean groups in Gelander and Levit [2017]:

Theorem 13. Let G be a semisimple analytic group in zero characteristic. Fix a Haar measure on G and let ν_G be the associated Plancherel measure on $\widehat{G}$. Let Γ_n be a uniformly discrete sequence of lattices in G with μ_{Γ_n} being weak-$*$ convergent to $\delta_{\{e\}}$. Then

$$\nu_{\Gamma_n}(E) \xrightarrow{n\to\infty} \nu_G(E)$$

for every relatively quasi-compact ν^G-regular subset $E \subset \widehat{G}$.

One of the consequence of Theorem 13 is the convergence of normalized Betti numbers (cf. Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2011]). Recently we were able to get rid of the co-compactness and the uniform discreteness assumptions and proved the following general version, making use of the Bowen–Elek Bowen [2015a, §4] simplicial approximation technique:

Theorem 4.1. *Abert, Bergeron, Biringer, and Gelander [n.d.] Let X be a symmetric space of non compact type of $dim(X) \neq 3$ and (M_n) is a weakly convergent sequence of finite volume X-manifolds. Then for all k, the normalized Betti numbers $b_k(M_n)/\mathrm{vol}(M_n)$ converge.*

Here, the only three-dimensional irreducible symmetric spaces of noncompact type are scales of $\mathbb{H}^3$. In fact, the conclusion of Theorem 4.1 is false when $X = \mathbb{H}^3$. As an example, let $K \subset S^3$ be a knot such that the complement $M = S^3 \setminus K$ admits a hyperbolic metric, e.g. the figure-8 knot. Using meridian–longitude coordinates, let M_n be obtained by Dehn filling M with slope $(1,n)$; then each M_n is a homology 3-sphere. The manifolds $M_n \to M$ geometrically, see Benedetti and Petronio [1992, Ch E.6], so the measures μ_{M_n} weakly converge to μ_M (c.f. Bader, Gelander, and Sauer [2016, Lemma 6.4]) and the volumes $\mathrm{vol}(M_n) \to \mathrm{vol}(M)$. However, $0 = b_1(M_n) \not\to b_1(M) = 1$, so the normalized Betti numbers of the sequence $M_1, M, M_2, M, \ldots$ do not converge.

Corollary 14. Suppose that (M_n) is a Farber sequence of finite volume X-manifolds. Then for all $k \in \mathbb{N}$, we have $b_k(M_n)/\mathrm{vol}(M_n) \to \beta_k^{(2)}(X)$.

In the thin case, we were able to push our analytic methods far enough to give a proof for $X = \mathbb{H}^d$, see Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2017a, Theorem 1.8]. Hence, there is no problem in allowing $X = \mathbb{H}^3$ in Corollary 14. The analog of Corollary 14 for p-adic Bruhat Tits buildings is proved in Gelander and Levit [2017].

5 Measures on the space of Riemannian manifolds

When $X = G/K$ is a symmetric space of noncompact type, say, the quotient of a discrete, torsion-free IRS Γ of G is a random X-manifold M. Fixing a base point p in X, the projection of p to $\Gamma\backslash X$ is a natural base point for the quotient. So, we can regard the quotient of an IRS as a random pointed X-manifold. In fact, the conjugation invariance of Γ directly corresponds to a property called *unimodularity* of the random pointed X-manifold, just as IRSs of discrete groups correspond to unimodular random Schreier graphs.

In Biringer and Abert [2016], the Abert and Biringer study unimodular probability measures on the more general space $\mathfrak{M}^d$ of all pointed Riemannian d-manifolds, equipped with the smooth topology. One can construct such unimodular measures from finite volume d-manifolds, or from IRSs of continuous groups as above (see Biringer and Abert [ibid., Proposition 1.9]). Under certain geometric assumptions like pinched negative curvature or local symmetry, they show that sequences of unimodular probability measures are precompact, in parallel with the compactness of the space of IRSs of a Lie group, see Biringer and Abert [ibid., Theorems 1.10 and 1.11]. They also show that unimodular measures on $\mathfrak{M}^d$ are just those that are 'compatible' with its foliated structure. Namely, $\mathfrak{M}^d$ is almost a foliated space, where a leaf is obtained by fixing a manifold M and varying the basepoint. While this foliation may be highly singular, they show in Biringer and Abert [ibid., Theorem 1.6] that after passing to an (actually) foliated desingularization, unimodular measures are just those that are created by integrating the Riemannian measures on the leaves against some invariant transverse measure. This is a precise analogue of the hard-to-formalize statement that a unimodular random graph is a random pointed graph in which the vertices are 'distributed uniformly' across each fixed graph.

6 Soficity of IRS

Definition 15. An IRS μ is *co-sofic* if it is a weak-$*$ limit in $\mathrm{IRS}(G)$ of ones supported on lattices.

The following result justify the name (cf. Abert, Gelander, and Nikolov [2017, Lemma 16]):

Proposition 6.1. *Let F_n be the free group of rank n. A Dirac mass δ_N, $N \lhd F_n$ is co-sofic iff the corresponding group $G = F_n/N$ is sofic.*

Given a group G it is natural to ask:

Question 6.2. Is every IRS in G co-sofic?

In particular for $G = F_n$ this is equivalent to the Aldous–Lyons conjecture that every unimodular network (supported on rank n Schreier graphs) is a limit of ones corresponding to finite Schreier graphs Aldous and Lyons [2007].

Therefore it is particularly intriguing to study Question 6.2 for G, a locally compact group admitting F_n as a lattice. This is the case for $G = SL_2(\mathbf{R}), SL_2(\mathbf{Q}_p)$ and $\mathrm{Aut}(T)$.

7 Exotic IRS

In the lack of Margulis' normal subgroup theorem there are IRS supported on non-lattices. Indeed, from a lattice $\Gamma \leq G$ and a normal subgroup of infinite index $N \lhd \Gamma$ one can cook an IRS in G supported on the closure of the conjugacy class N^G.

A more interesting example in $\mathrm{SO}(n,1)$ (from Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [2016]) is obtained by choosing two compact hyperbolic manifolds A, B with totally geodesic boundary, each with two components, and all four components are pairwise isometric and then glue random copies of A, B along an imaginary line to obtain a random hyperbolic manifold whose fundamental group is an IRS in $\mathrm{SO}(n,1)$. If A, B are chosen wisely, the random subgroup obtained is not contained in a lattice. However, all IRSs obtained that way are co-sofic. Other constructions of exotic IRS in $\mathrm{SO}(3,1)$ are given in Abert, Bergeron, Biringer, Gelander, Nikolov, Raimbault, and Samet [ibid.].

8 Existence

There are many well known examples of discrete groups without nontrivial IRS, for instance $\mathrm{PSL}_n(\mathbb{Q})$, and also the Tarski Monsters. In Gelander [2015, §8] I asked for non-discrete examples, and in particular weather the Neretin group (of almost adthomorphisms of a regular tree) admits non-trivial IRS. Recently Boudec and Bon [2017] constructed an example of a non-discrete locally compact group with no non-trivial IRS. (Note however that it is not compactly generated.)

9 Character Rigidity

Definition 16. Let Γ be a discrete group. A *character* on Γ is an irreducible positive definite complex-valued class function $\varphi : \Gamma \to \mathbb{C}$ satisfying $\varphi(e) = 1$.

The irreducibility of φ simply means that it cannot be written as a convex combination of two distinct characters. This notion was introduced by Thoma in Thoma [1964a,b]. In the abelian case Definition 16 reduces to the classical notion.

We will say that Γ has *Character rigidity* if only the obvious candidates occur as characters of Γ. The following theorem of Bekka [2007] is an outstanding example of such a result.

Theorem 17. Let φ be a character of the group $\Gamma = \mathrm{SL}_n(\mathbb{Z})$ for $n \geq 3$. Then either φ factors through an irreducible representation of some finite congruence quotient $\mathrm{SL}_n(\mathbb{Z}/N\mathbb{Z})$ or φ vanishes outside the center of Γ.

The connection between invariant random subgroups and characters arises from the following construction. Let (X, μ) be a Borel probability space with an action of Γ preserving μ. Consider the following real-valued function $\varphi : \Gamma \to \mathbf{R}$ that is associated to the action of Γ. The function g is given by

$$\varphi(\gamma) = \mu(\mathrm{Fix}(\gamma))$$

for every $\gamma \in \Gamma$, where

$$\mathrm{Fix}(\gamma) = \{x \in X \ : \ \gamma x = x\}.$$

For instance $\varphi(\gamma) = 1$ if γ lies in the kernel of the action and $\varphi(\gamma) = 0$ if μ-almost every point of X is not fixed by γ. It turns out that φ is a positive define class function satisfying $\varphi(e) = 1$.

Let Γ be an irreducible lattice in a higher rank semisimple linear group G with property (T). It can be shown by means of induced actions that Theorem 10 holds for the lattice Γ as well, namely any properly ergodic action of Γ has central stabilizers.

We see that Theorem 17 in fact implies Theorem 9 in the special case of the particular arithmetic group $\Gamma = \mathrm{SL}_n(\mathbb{Z}), n \geq 3$, which in turn implies the normal subgroup theorem of Margulis[4]. A character rigidity result is in general much stronger than invariant random subgroups rigidity — indeed, not all characters arise in the above manner from probability measure preserving actions.

Recently Peterson [2014] has been able to vastly generalize Bekka's result, as follows.

[4]The normal subgroup theorem for $\mathrm{SL}_n(\mathbb{Z})$ with $n \geq 3$ is in fact a much older theorem, dating back to Mennicke's work on the congruence subgroup problem Mennicke [1965].

Theorem 18. Character rigidity in the sense of Theorem 17 holds for any irreducible lattice in a higher rank semisimple Lie group without compact factors and with property (T).

Let us survey a few other well-known classification results for characters of discrete groups. In his original papers Thoma studied characters of the infinite symmetric group Thoma [1964a]. Dudko and Medynets studied characters of the Higman—Thompson and related groups Dudko and Medynets [2014]. Peterson and Thom establish character rigidity for linear groups over infinite fields or localizations of orders in number fields Peterson and Thom [2016b], generalizing several previous results Kirillov [1965] and Ovčinnikov [1971].

10 History

The interplay between a group theoretic and geometric viewpoints characterises the theory of IRS from its beginning. Two groundbreaking papers, Stuck and Zimmer [1994] and Aldous and Lyons [2007] represent these two points of view. Zimmer's work, throughout, was deeply influenced by Mackey's virtual group philosophy which draws an analogy between the subgroups of G and its ergodic actions. When G is a center free, higher rank simple Lie group, it is proved in Stuck and Zimmer [1994] that every non-essentially-free ergodic action is in fact a transitive action on the cosets of a lattice subgroup. These results can be viewed as yet another implementation of higher rank rigidity, but they also show that Mackey's analogy becomes much tighter when one considers non-essentially-free actions.

The Aldous–Lyons paper is influenced by the geometric notion of *Benjamini–Schramm* convergence in graphs, sometimes also referred to as *weak convergence* or as *convergence in local statistics*, developed in Aldous and Steele [2004],Benjamini and Schramm [2001],Benjamini, Lyons, Peres, and Schramm [1999]. Any finite graph[5] gives rise to a random rooted graph, upon choosing the root uniformly at random. Thus the collection of finite graphs, embeds as a discrete set, into the space of Borel probability measures on the (compact) space of rooted graphs. Random rooted graph in the w^*-closure of this set are subject to the *mass transport principal* introduced by Benjamini and Schramm [2001]: For every integrable function on the space of bi-rooted graphs

$$\int \sum_{x \in V(G)} f(G, o, x) d\mu([G, o]) = \int \sum_{x \in V(G)} f(G, x, o) d\mu([G, o]).$$

[5] or more generally an infinite graph whose automorphism group contains a lattice.

Aldous and Lyons define random unimodular graphs to be random rooted graphs subject to the mass transport principal. In Aldous and Lyons [2007, Question 10.1] they ask whether every random unimodular graph is in the w^*-closure of the set of finite graphs. When one specialises this theory to Schreier graphs of a given finitely generated group Γ (more generally to the quotients of the Cayley-Abels graph of a given compactly generated group G) one obtains the theory of IRS in Γ or in G. For probability measures on the Chabauty space of subgroups Sub_Γ — the mass transport principal is equivalent to invariance under the adjoint action of the group. When $\Gamma = F_d$ is the free group and $N \lhd \Gamma$ is a normal subgroup the group Γ/N is *sofic* in the sense of Gromov and Weiss if and only if the IRS δ_N is a w^*-limit of IRS supported on finite index subgroups. Thus the Aldous-Lyons question in the setting of Schreier graphs of F_d specializes to Gromov's question whether every group is sofic.

In a pair of papers Abért, Y. Glasner, and Virág [2016, 2014], Abért, Glasner and Virág introduced the notion of IRS and used it to answer a long standing question in graph theory. A sequence $\{X_n\}$ of finite, distinct d-regular Ramanujan graphs Benjamini–Schramm converges to the universal covering tree T_d. They provided a quantitative estimate for this result, for a Ramanujan graph X,

$$\Pr\{x \in X \mid \mathrm{inj}_X(x) \leq \beta \log\log(|X|)\} = O\left(\log(|X|)^{-\beta}\right),$$

where $\beta = (30\log(d-1))^{-1}$, $\mathrm{Inj}_X(x) = \max\{R \in \mathbf{N} \mid B_X(x,R) \text{ is contractible}\}$ and the probability is the uniform over the vertices of X. The proof combines the geometric and group theoretic viewpoints in an essential way: They start with a sequence of Ramanujan (Schreier) graphs $\{X_n\}$. Passing if necessary to a subsequence they assume that $X_n \to \Delta \backslash F_{d/2}$, where Δ is an IRS in $F_{d/2}$. Now the main technical result of their paper shows that the Schreier graph of an IRS has to satisfy Kesten's spectral gap theorem $\rho(\mathrm{Cay}(\Gamma/\Delta, S)) \geq \rho(\mathrm{Cay}(\Gamma, S))$ with equality if and only if $\Delta = \langle e \rangle$ a.s. Thus the limiting object is indeed the tree.

More generally they develop the theory of Benjamini–Shcramm limits of unimodular random graphs, as well as for Γ-Schreier graphs for arbitrary finitely generated group Γ. In this case the IRS version of Kesten's theorem reads $\rho(\mathrm{Cay}(\Gamma/\Delta, S)) \geq \rho(\mathrm{Cay}(\Gamma, S))$, with an (a.s.) equality, iff Δ is (a.s.) amenable. In hope of reproducing this same beautiful picture for general finitely generated groups, Abért, Glasner and Virág phrased a fundamental question that was quickly answered by Bader, Duchesne, and Lécureux [2016] giving rise to the following theorem: Every amenable IRS in a group Γ is supported on the subgroups of the amenable radical of Γ.

Independently of all of the above, Lewis Bowen in Bowen [2014], introduced the notion of an IRS, and of the *Poisson boundary relative to an IRS*. He used these notions to solve a long standing question in dynamics — proving that the Furstenberg entropy spectrum of the free group is a closed interval. Let (G, μ) be a locally compact group with a Borel probability measure on it, and (X, ν) a (G, μ) space. This means that $G \curvearrowright X$ acts on X measurably and ν is a μ-stationary probability measure in the sense that $\nu = \mu * \nu$. The Furstenberg entropy of this space is

$$h_\mu(X, \nu) = \int \int -\log \frac{d\eta \circ g}{d\eta}(x) d\eta(x) d\mu(g).$$

$\mathrm{Spec}(G, \mu) := \{h_\mu(X, \nu) \mid (X, \nu) \text{ an ergodic}(G, \mu)\text{-space}\}$ is called *the Furstenberg entropy spectrum* and it is bounded in the interval $[0, h_{max}(\mu)]$. The value 0 is obtained when the action is measure preserving, and the maximal value is always attained by the Poisson boundary $B(G, \mu)$. The study of the entropy spectrum is tightly related to the study of factors of the Poisson boundary. Nevo and Zimmer, Nevo and Zimmer [2000], consider a restricted spectrum, that comes only form actions subject to certain mixing properties and show that this restricted spectrum $\mathrm{Spec}'(G)$ is finite for a centre free, higher rank semisimple Lie group G. This result was then used in their proof of the intermediate factor theorem, which in retrospect also validated the proof of the Stuck-Zimmer theorem Nevo and Zimmer [1999, 2002b,a]. Bowen's work on IRS filled in a gap in the other direction — providing as it did many examples of stationary actions.

Let $K \in \mathrm{Sub}(G)$. The Poisson boundary $B(K \backslash G, \mu)$ is the (Borel) quotient of the space of all μ-random walks on $K \backslash G$ under the shift $\sigma(Kg_0, Kg_1, Kg_2, \ldots) = (Kg_1, Kg_2, \ldots)$. If $\Delta = N$ happens to be normal then one retains the Kaimanovich–Vershik description of the Poisson boundary on G/N and clearly G acts on this space from the left giving it the structure of a (G, μ)-space. In the more general setting introduced by Bowen, G still acts on the natural bundle over $\mathrm{Sub}(G)$, where the fibre over $K \in \mathrm{Sub}(G)$ is $B(K \backslash G, \mu)$. The natural action of G on the space of all walks on all these coset spaces, given by $g(Kg_1, Kg_2, \ldots) = (gKg^{-1}gg_1, gKg^{-1}gg_2, \ldots)$ clearly commutes with the shift and gives rise to a well defined action of (G, μ) on this bundle. Any choice of an IRS $\theta \in \mathrm{IRS}(G)$ gives rise to a (G, μ)-stationary measure on this bundle. Now for $F_d = \langle s_1, \ldots, s_d \rangle$, $\mu = \frac{1}{2d}\left(\sum_{i=1}^d s_i + s_i^{-1}\right)$ the proof that $\mathrm{Spec}(F_d, \mu) = [0, h_{\max}(\mu)]$ is completed by finding a certain path $\alpha : I :\to \mathrm{IRS}(F_d)$ in the space of IRSs with the following properties: (i) the path starts at the trivial IRS (corresponding to the action on the Poisson boundary), (ii) it ends at an IRS giving rise to arbitrarily small entropy values and (iii) the entropy function is continuous on this path. Continuity of the entropy function is very special and so are the IRS that are chosen in order to allow for this continuity. The existence of paths on the other hand is actually general, in Bowen [2015b] Bowen proves that the collection of ergodic IRS on F_d that are not supported on finite index subgroups is path connected.

Vershik [2012, 2010], also indpendently, arrived at IRS from his study of the representation theory and especially the characters of S_f^∞ — the group of finitely supported permutations of a countable set. To an IRS $\mu \in \mathrm{IRS}(\Gamma)$ in a countable group define its *Vershik character* as follows

$$\phi_\mu : \Gamma \to \mathbf{R}_{\geq 0}, \qquad \phi_\mu(\gamma) = \mu\left(\{\Delta \in \mathrm{Sub}(\Gamma) \mid \gamma \in \Delta\}\right).$$

If the IRS is realized as the stabilizer Γ_x of a random point in a p.m.p. action $\Gamma \curvearrowright (X, \nu)$ (by Abért, Y. Glasner, and Virág [2014], every IRS can be realized in this fashion), the same IRS is given by $\phi_\nu(\gamma) = \nu(Fix(\gamma))$. Vershik also describes the GNS constuctions associated with this character. Let $R = \{(x, y) \in X \times X | y \in \Gamma x\}$ and let η be the infinite measure on R given by $\int f(x, y)\eta(x, y) = \int \sum_{y \in \Gamma x} f(x, y) d\mu(x)$. Γ acts on R via its action on the first coordinate $\gamma(x, y) = (\gamma x, y)$ and hence it acts on the Hilbert space $L_2(R, \eta)$. Let $\chi(x, y) = 1_{x=y} \in L_2(R, \eta)$ be the characteristic function of the diagonal. It is easy to verify that $phi_\mu(\gamma) = \langle \gamma\chi, \chi \rangle$. The defintion of the Vershik character clarified the deep connection between character rigidity in the snese of Connes and and the Stuck–Zimmer theorem.

Acknowledgments. Several people helped me in writing up parts of this paper: Ian Biringer with Section 5, Arie Levit with Section 9 and Section 2 and Yair Glasner with Section 10.

SOME RESULTS ON AFFINE DELIGNE–LUSZTIG VARIETIES

Xuhua He (何旭华)

Abstract

The study of affine Deligne-Lusztig varieties originally arose from arithmetic geometry, but many problems on affine Deligne-Lusztig varieties are purely Lie-theoretic in nature. This survey deals with recent progress on several important problems on affine Deligne-Lusztig varieties. The emphasis is on the Lie-theoretic aspect, while some connections and applications to arithmetic geometry will also be mentioned.

1 Introduction

1.1 Bruhat decomposition and conjugacy classes. Let $\mathbb{G}$ be a connected reductive group over a field $\mathbf{k}$ and $G = \mathbb{G}(\mathbf{k})$. In this subsection, we assume that $\mathbf{k}$ is algebraically closed. Let B be a Borel subgroup of G and W be the finite Weyl group of G. The Bruhat decomposition $G = \sqcup_{w \in W} BwB$ plays a fundamental role in Lie theory. This is explained by Lusztig [2010] in the memorial conference of Bruhat:

"By allowing one to reduce many questions about G to questions about the Weyl group W, Bruhat decomposition is indispensable for the understanding of both the structure and representations of G."

Below we mention two examples of the interaction between the Bruhat decomposition and the (ordinary and twisted) conjugation action of G.

1. Assume that $\mathbf{k} = \overline{\mathbb{F}}_q$ and σ is the Frobenius of $\mathbf{k}$ over $\mathbb{F}_q$. We assume that $\mathbb{G}$ is defined over $\mathbb{F}_q$ and we denote by σ the corresponding Frobenius morphism on G. The (classical) Deligne-Lusztig varieties was introduced by Deligne and Lusztig in their seminal work Deligne and Lusztig [1976]. For any element $w \in W$, the corresponding Deligne-Lusztig variety X_w is a subvariety of the flag variety G/B defined by

$$X_w = \{gB \in G/B; g^{-1}\sigma(g) \in BwB\}.$$

X. H. was partially supported by NSF DMS-1463852.
MSC2010: primary 14L05; secondary 20G25.
Keywords: Affine Deligne-Lusztig varieties, loop groups, affine Weyl groups.

By Lang's theorem, the variety X_w is always nonempty. It is a locally closed, smooth variety of dimension $\ell(w)$. The finite reductive group $\mathbb{G}(\mathbb{F}_q)$ acts naturally on X_w and on the cohomology of X_w. The Deligne-Lusztig variety X_w plays a crucial role in the representation theory of finite reductive groups, see Deligne and Lusztig [1976] and Lusztig [1984]. The structure of X_w has also found important applications in number theory, e.g., in the work of Rapoport, Terstiege, and W. Zhang [2013], and in the work of Li and Y. Zhu [2017] on the proof of special cases of the "arithmetic fundamental lemma" of W. Zhang [2012].

2. Let $\mathbf{k}$ be any algebraically closed field. In a series of papers Lusztig [2012], Lusztig discovered a deep relation between the unipotent conjugacy classes of G and the conjugacy classes of W, via the study of the intersection of the unipotent conjugacy classes with the Bruhat cells of G.

1.2 Affine Deligne-Lusztig varieties. The main objects of this survey are affine Deligne-Lusztig varieties, analogous of classical Deligne-Lusztig varieties for loop groups.

Unless otherwise stated, in the rest of this survey we assume that $\mathbf{k} = \overline{\mathbb{F}}_q((\epsilon))$. Let σ be the Frobenius morphism of $\mathbf{k}$ over $\mathbb{F}_q((\epsilon))$. We assume that $\mathbb{G}$ is defined over $\mathbb{F}_q((\epsilon))$ and we denote by σ the corresponding Frobenius morphism on the loop group $G = \mathbb{G}(\mathbf{k})$. We choose a σ-stable Iwahori subgroup I of G. If G is unramified, then we also choose a σ-stable hyperspecial parahoric subgroup $K \supset I$. The affine flag variety $Fl = G/I$ and the affine Grassmannian $Gr = G/K$ (if G is unramified) have natural scheme structures.[1]

Let S be a maximal $\mathbf{k}$-split torus of G defined over $\mathbb{F}_q((\epsilon))$ and let T be its centralizer, a maximal torus of G. The Iwahori-Weyl group associated to S is

$$\tilde{W} = N(\mathbf{k})/T(\mathbf{k})_1,$$

where N is the normalizer of S in G and $T(\mathbf{k})_1$ is the maximal open compact subgroup of $T(\mathbf{k})$. The group $\tilde{W}$ is also a split extension of the relative (finite) Weyl group W_0 by the normal subgroup $X_*(T)_{\Gamma_0}$, where $X_*(T)$ is the coweight lattice of T and Γ_0 is the Galois group of $\overline{\mathbf{k}}$ over $\mathbf{k}$ (cf. Pappas and Rapoport [2008, Appendix]). The group $\tilde{W}$ has a natural quasi-Coxeter structure. We denote by ℓ and $\leqslant$ the length function and the Bruhat order on $\tilde{W}$. We have the following generalization of the Bruhat decomposition

$$G = \sqcup_{w \in \tilde{W}} IwI,$$

[1] One may replace $\overline{\mathbb{F}}_q((\epsilon))$ by the fraction field of the Witt ring. In that case, the affine Grassmannian Gr and the affine flag variety Fl have the structure of perfect schemes, thanks to the recent breakthrough of X. Zhu [2017], and of Bhatt and Scholze [2017]. Many of the results we discuss in this survey hold for the fraction field of the Witt ring as well.

due to Iwahori and Matsumoto [1965] in the split case, and to Bruhat and Tits [1972] in the general case. If G is unramified, then we also have

$$G = \sqcup_{\lambda \text{ is a dominant coweight}} K\epsilon^{\lambda} K.$$

Affine Deligne-Lusztig varieties were introduced by Rapoport in Rapoport [2005]. Compared to the classical Deligne-Lusztig varieties, we need two parameters here: an element w in the Iwahori-Weyl group W and an element b in the loop group G. The corresponding affine Deligne-Lusztig variety (in the affine flag variety) is defined as

$$X_w(b) = \{gI \in G/I; g^{-1} b\sigma(g) \in IwI\} \subset Fl.$$

If G is unramified, one may use a dominant coweight λ instead of an element in $\tilde{W}$ and define the affine Deligne-Lusztig variety (in the affine Grassmannian) by

$$X_\lambda(b) = \{gK \in G/K; g^{-1} b\sigma(g) \in K\epsilon^{\lambda} K\} \subset Gr.$$

Affine Deligne-Lusztig varieties are schemes locally of finite type over $\overline{\mathbb{F}}_q$. Also the varieties are isomorphic if the element b is replaced by another element b' in the same σ-conjugacy class.

A major difference between affine Deligne-Lusztig varieties and classical Deligne-Lusztig varieties is that affine Deligne-Lusztig varieties have the second parameter: the element b, or the σ-conjugacy class $[b]$ in the loop group G; while in the classical case considered in Section 1.1, by Lang's theorem there is only one σ-conjugacy class in $\mathbb{G}(\overline{\mathbb{F}}_q)$ and thus adding a parameter $b \in \mathbb{G}(\overline{\mathbb{F}}_q)$ does not give any new variety.

The second parameter $[b]$ in the affine Deligne-Lusztig varieties makes them rather challenging to study, both from the Lie-theoretic point of view, and from the arithmetic-geometric point of view. Below we list some major problems on the affine Deligne-Lusztig varieties:

- When is an affine Deligne-Lusztig variety nonempty?
- If it is nonempty, what is its dimension?
- What are the connected components?
- Is there a simple geometric structure for certain affine Deligne-Lusztig varieties?

We may also consider the affine Deligne-Lusztig varieties associated to arbitrary parahoric subgroups, besides hyperspecial subgroups and Iwahori subgroups. This will be discussed in Section 7.

1.3 A short overview of $X(\mu, b)$. The above questions may also be asked for a certain union $X(\mu, b)$ of affine Deligne-Lusztig varieties in the affine flag variety.

Let μ be a dominant coweight of G with respect to a given Borel subgroup of G over **k** (in applications to number theory, μ usually comes from a Shimura datum). The admissible set $\mathrm{Adm}(\mu)$ was introduced by Kottwitz and Rapoport in R. Kottwitz and Rapoport [2000]. It is defined by

$$\mathrm{Adm}(\mu) = \{w \in \tilde{W}; w \leqslant t^{x(\mu)} \text{ for some } x \in W_0\}.$$

We may explain it in a more Lie-theoretic language. Let $Gr_{\mathcal{G}}$ be the deformation from the affine Grassmannian to the affine flag variety Gaitsgory [2001]. The coherence conjecture of Pappas and Rapoport [2008] implies that the special fiber of the global Schubert variety $\overline{Gr}_{\mathcal{G},\mu}$ associated to the coweight μ (cf. X. Zhu [2014, Definition 3.1]) is $\cup_{w \in \mathrm{Adm}(\mu)} IwI/I$. This conjecture was proved by Zhu in X. Zhu [ibid.]. Now we set

$$X(\mu, b) = \cup_{w \in \mathrm{Adm}(\mu)} X_w(b) \subset Fl.$$

This is a closed subscheme of Fl and serves as the group-theoretic model for the Newton stratum corresponding to $[b]$ in the special fiber of a Shimura variety giving rise to the datum (G, μ).

It is also worth mentioning that, although the admissible set $\mathrm{Adm}(\mu)$ has a rather simple definition, it is a very complicated combinatorial object. We refer to the work of Haines and Ngô Haines and Châu [2002], and the recent joint work of the author with Haines and He [2017] for some properties of $\mathrm{Adm}(\mu)$.

1.4 Current status. Affine Deligne-Lusztig varieties in the affine Grassmannian are relatively more accessible than the ones in the affine flag variety, mainly due to the following two reasons:

- The set of dominant coweights is easier to understand than the Iwahori-Weyl group;
- For $X_\lambda(b)$ the group G is unramified while for $X_w(b)$, we need to deal with ramified, or even non quasi-split reductive groups.

For an unramified group G, we also have the fibration $\cup_{w \in W_0 t^\lambda W_0} X_w(b) \to X_\lambda(b)$, with fibers isomorphic to the flag variety of $\mathbb{G}(\overline{\mathbb{F}}_q)$. Thus much information on $X_\lambda(b)$ can be deduced from $X_w(b)$.

Nevertheless, the study of the affine Deligne-Lusztig varieties in affine Grassmannian is a very challenging task and has attracted the attention of experts in arithmetic geometry in the past two decades. It is a major achievement in arithmetic geometry to obtain a fairly good understanding on these varieties.

As to the affine Deligne-Lusztig varieties in the affine flag varieties, the situation is even more intriguing. We have made significant progress in the past 10 years in this direction, yet many aspects of $X_w(b)$ remain rather mysterious. I hope that by combining various Lie-theoretic methods together with arithmetic-geometric methods, our knowledge on affine Deligne-Lusztig varieties will be considerably advanced.

In the rest of the survey, we will report on some recent progress on the affine Deligne-Lusztig varieties.

Acknowledgments. We thank Ulrich Görtz, Urs Hartl, George Lusztig, Michael Rapoport, Sian Nie and Rong Zhou for useful comments.

2 Some relation with affine Hecke algebras

2.1 The set $B(G)$ and Kottwitz's classification. Let $B(G)$ be the set of σ-conjugacy classes of G. R. E. Kottwitz [1985] and R. E. Kottwitz [1997] gave a classification of the set $B(G)$, generalizing the Dieudonné-Manin classification of isocrystals by their Newton polygons. Any σ-conjugacy class $[b]$ is determined by two invariants:

- The element $\kappa([b]) \in \pi_1(G)_\Gamma$, where Γ is the Galois group of $\bar{\mathbf{k}}$ over $\mathbb{F}_q((\epsilon))$;
- The Newton point ν_b in the dominant chamber of $X_*(T)_{\Gamma_0} \otimes \mathbb{Q}$.

A different point of view, which is quite useful in this survey, is the relation between the set $B(G)$ with the set $B(\tilde{W}, \sigma)$ of σ-conjugacy classes of $\tilde{W}$. Recall that $\tilde{W} = N(\mathbf{k})/T(\mathbf{k})_1$. The natural embedding $N(\mathbf{k}) \to G$ induces a natural map $\Psi : B(\tilde{W}, \sigma) \to B(G)$. By Görtz, Haines, R. E. Kottwitz, and Reuman [2010] and He [2014], the map Ψ is surjective. The map Ψ is not injective. However, there exists an important family $B(\tilde{W}, \sigma)_{str}$ of straight σ-conjugacy classes of $\tilde{W}$. By definition, a σ-conjugacy class $\mathcal{O}$ of $\tilde{W}$ is *straight* if it contains an element $w \in \mathcal{O}$ such that $\ell(w\sigma(w) \cdots \sigma^{n-1}(w)) = n\ell(w)$ for all $n \in \mathbb{N}$. The following result is discovered in He [ibid., Theorem 3.7].

Theorem 2.1. *The map $\Psi : B(\tilde{W}, \sigma) \to B(G)$ induces a bijection*

$$B(\tilde{W}, \sigma)_{str} \longleftrightarrow B(G).$$

This result gives the parametrization of the σ-conjugacy classes of G in terms of the set of straight σ-conjugacy classes of its Iwahori-Weyl group $\tilde{W}$. In particular, the two parameters occurring in the definition of the affine Deligne-Lusztig variety $X_w(b)$ are all from $\tilde{W}$.

Note that the affine Deligne-Lusztig variety $X_w(b)$ is closely related to the intersection $IwI \cap [b]$. This intersection is very complicated in general. However, it is discovered in He [2014] that for certain elements $w \in \tilde{W}$, the intersection $IwI \cap [b]$ equals IwI. More precisely, we denote by $\tilde{W}_{\sigma-\min}$ the set of elements in $\tilde{W}$ that are of minimal length in their σ-conjugacy classes. Then

$$\text{For } w \in \tilde{W}_{\sigma-\min},\ IwI \subset [b] \text{ if } [b] = \Psi(w).$$

This serves as the starting point of the reduction method for affine Deligne-Lusztig varieties $X_w(b)$ for arbitrary w.

2.2 "Dimension=Degree" theorem. Deligne and Lusztig introduced in Deligne and Lusztig [1976] a reduction method to study the classical Deligne-Lusztig varieties. Their method works for the affine Deligne-Lusztig varieties as well. Some combinatorial properties of affine Weyl groups established in joint work with Nie 2014 allow us to reduce the study of $X_w(b)$ for any w, via the reduction method à la Deligne and Lusztig, to the study of $X_w(b)$ for $w \in \tilde{W}_{\sigma-\min}$.

The explicit reduction procedure, however, is rather difficult to keep track of. In He [2014], we discovered that the same reduction procedure appears in a totally different context as follows.

Let H be the affine Hecke algebra (over $\mathbb{Z}[v^{\pm 1}]$) associated to $\tilde{W}$. Let $[\tilde{H}, \tilde{H}]_\sigma$ be the σ-twisted commutator, i.e. the $\mathbb{Z}[v^{\pm 1}]$-submodule of H generated by $[h, h']_\sigma = hh' - h'\sigma(h)$. By He and Nie [2014], the σ-twisted cocenter $\overline{H} = H/[H, H]_\sigma$ has a standard basis given by $\{T_{\mathcal{O}}\}$, where $\mathcal{O}$ runs over all the σ-conjugacy classes of $\tilde{W}$. Thus for any $w \in \tilde{W}$, we have

$$T_w \equiv \sum_{\mathcal{O}} f_{w,\mathcal{O}} T_{\mathcal{O}} \mod [H, H]_\sigma.$$

The coefficients $f_{w,\mathcal{O}} \in \mathbb{N}[v - v^{-1}]$, which we call the class polynomials (over $v - v^{-1}$). We have the following "dimension=degree" theorem established in He [2014].

Theorem 2.2. *Let $b \in G$ and $w \in \tilde{W}$. Then*

$$\dim(X_w(b)) = \max_{\mathcal{O}; \Psi(\mathcal{O}) = [b]} \frac{1}{2}\big(\ell(w) + \ell(\mathcal{O}) + \deg(f_{w,\mathcal{O}})\big) - \langle \nu_b, 2\rho \rangle.$$

Here $\ell(\mathcal{O})$ is the length of any minimal length element in $\mathcal{O}$ and ρ is the half sum of positive roots in G. Here we use the convention that the dimension of an empty variety and the degree of a zero polynomial are both $-\infty$. Thus the above theorem reduces the nonemptiness question and the dimension formula of $X_w(b)$ to some questions on the class polynomials $f_{w,\mathcal{O}}$ for $\Psi(\mathcal{O}) = [b]$.

The explicit computation of the class polynomials is very difficult at present. Note that there is a close relation between the cocenter and representations of affine Hecke algebras

Ciubotaru and He [2017]. One may hope that some progress in the representation theory of affine Hecke algebras would also advance our knowledge on affine Deligne-Lusztig varieties. At present, we combine the "dimension=degree" theorem together with some Lie-theoretic techniques, and the results on $X_\lambda(b)$ in the affine Grassmannian established previously by arithmetic-geometric method, to obtain some explicit answers to certain questions on $X_w(b)$ and on $X(\mu, b)$.

3 Nonemptiness pattern

3.1 Mazur's inequality. In this subsection, we discuss the non-emptiness patterns of affine Deligne-Lusztig varieties. Here Mazur's inequality plays a crucial role.

In Mazur [1973], Mazur proved that the Hodge slope of any F-crystal is always larger than or equal to the Newton slope of associated isocrystal. The converse was obtained by Kottwitz and Rapoport in R. Kottwitz and Rapoport [2003]. Here we regard the Newton slope and Hodge slope as elements in $\mathbb{Q}_+^n = \{a_1, \cdots, a_n; a_1 \geqslant \cdots \geqslant a_n\}$ and the partial order in $\mathbb{Q}_+^n$ is the dominance order, i.e. $(a_1, \cdots, a_n) \preceq (b_1, \cdots, b_n)$ if and only if $a_1 \leqslant b_1, a_1+a_2 \leqslant b_1+b_2, \cdots, a_1+\cdots+a_{n-1} \leqslant b_1+\cdots+b_{n-1}, a_1+\cdots+a_n = b_1+\cdots+b_n$.

Note that $\mathbb{Q}_+^n$ is the set of rational dominant coweights for GL_n. The dominant order can be defined for the set of rational dominant coweights for any reductive group. This is what we use to describe the nonemptiness pattern of some affine Deligne-Lusztig varieties.

3.2 In the affine Grassmannian. For $X_\lambda(b)$ in the affine Grassmannian, we have a complete answer to the nonemptiness question.

Theorem 3.1. *Let λ be a dominant coweight and $b \in G$. Then $X_\lambda(b) \neq \varnothing$ if and only if $\kappa([b]) = \kappa(\lambda)$ and $\nu_b \preceq \lambda$.*

The "only if" part was proved by Rapoport and Richartz in Rapoport and Richartz [1996], and by Kottwitz in R. E. Kottwitz [2003]. The "if" part was proved by Gashi [2010]. The result also holds if the hyperspecial subgroup of an unramified group is replaced by a maximal special parahoric subgroup of an arbitrary reductive group. This was obtained in He [2014] using the "dimension=degree" Theorem 2.2.

3.3 In the affine flag. Now we consider the variety $X_w(b)$ in the affine flag variety.

(i) We first discuss the case where $[b]$ is basic, i.e., the corresponding Newton point ν_b is central in G (and thus Mazur's inequality is automatically satisfied).

Theorem 3.2. *Let G be a quasi-split group. Let $[b] \in B(G)$ be basic and $w \in \tilde{W}$. Then $X_w(b) \neq \varnothing$ if and only if there is no "Levi obstruction".*

The "Levi obstruction" is defined in terms of the P-alcove elements, introduced by Görtz, Haines, Kottwitz, and Reuman in Görtz, Haines, R. E. Kottwitz, and Reuman [2010]. The explicit definition is technical and we omit it here. This result was conjectured by Görtz, Haines, R. E. Kottwitz, and Reuman [ibid.] for split groups and was established in joint work with Görtz and Nie 2015 for any quasi-split group. Note that the "quasi-split" assumption here is not essential as one may relate $X_w(b)$ for any reductive group G to another affine Deligne-Lusztig variety for the quasi-split inner form of G. We refer to He [2016a, Theorem 2.27] for the explicit statement in the general setting.

(ii) For any nonbasic σ-conjugacy class $[b]$, one may ask for analogues of "Mazur's inequality" and/or the "Levi obstruction" in order to describe the nonemptiness pattern of $X_w(b)$. This is one of the major open problems in this area. We refer to Görtz, Haines, R. E. Kottwitz, and Reuman [2010, Remark 12.1.3] for some discussion in this direction. As a first step, one may consider the conjecture of Görtz-Haines-Kottwitz-Reumann Görtz, Haines, R. E. Kottwitz, and Reuman [ibid., Conjecture 9.5.1 (b)] on the asymptotic behavior of $X_w(b)$ for nonbasic $[b]$. Some affirmative answer to this conjecturewas given in He [2016a, Theorem 2.28] in the case where $[b] = [\epsilon^\lambda]$ for some dominant coweight λ.

3.4 Kottwitz-Rapoport conjecture. To describe the nonemptiness pattern on the union $X(\mu, b)$ of affine Deligne-Lusztig varieties in the affine flag variety, we recall the definition of neutrally acceptable σ-conjugacy classes introduced by Kottwitz in R. E. Kottwitz [1997],

$$B(G, \mu) = \{[b] \in B(G); \kappa([b]) = \kappa(\mu), \nu_b \leqslant \mu^\diamond\},$$

where $\mu^\diamond$ is the Galois average of μ.

By Theorem 3.1, $X_\mu(b) \neq \varnothing$ if and only if $[b] \in B(G, \mu)$. We have a similar result for the union $X(\mu, b)$ of affine Deligne-Lusztig varieties in the affine flag variety.

Theorem 3.3. *Let $[b] \in B(G)$. Then $X(\mu, b) \neq \varnothing$ if and only if $[b] \in B(G, \mu)$.*

This result was conjectured by Kottwitz and Rapoport in R. Kottwitz and Rapoport [2003] and Rapoport [2005]. The "only if" part is a group-theoretic version of Mazur's inequality and was proved by Rapoport and Richartz for unramified groups in Rapoport and Richartz [1996, Theorem 4.2]. The "if" part is the "converse to Mazur's inequality" and was proved by Wintenberger in Wintenberger [2005] for quasi-split groups. The general case in both directions was established in He [2016b] by a different approach, via a detailed analysis of the map $\Psi : B(\tilde{W}) \to B(G)$, of the partial orders on $B(G)$ (an analogy of Grothendieck's conjecture for the loop groups) and of the maximal elements in $B(G, \mu)$ He and Nie [2018].

As we mentioned in Section 3.3, for a single affine Deligne-Lusztig variety $X_w(b)$, one may reduce the case of a general group to the quasi-split case. However, for the union of affine Deligne-Lusztig varieties, the situation is different. There is no relation between the admissible set $\mathrm{Adm}(\mu)$ (and hence $X(\mu, b)$) for an arbitrary reductive group and its quasi-split inner form. This adds essential difficulties in the study of $X(\mu, b)$ for non quasi-split groups.

Rad and Hartl in Rad and Hartl [2016] established the analogue of the Langlands-Rapoport conjecture Langlands and Rapoport [1987] for the rational points in the moduli stacks of global G-shtukas, for arbitrary connected reductive groups and arbitrary parahoric level structure. They described the rational points as a disjoint union over isogeny classes of global G-Shtukas, and then used Theorem 3.3 to determine which isogeny classes are nonempty.

4 Dimension formula

4.1 In the affine Grassmannian. For $X_\lambda(b)$ in the affine Grassmannian, we have an explicit dimension formula.

Theorem 4.1. *Let λ be a dominant coweight and $b \in G$. If $X_\lambda(b) \neq \varnothing$, then*

$$\dim X_\lambda(b) = \langle \lambda - \nu_b, \rho \rangle - \frac{1}{2} \mathit{def}_G(b),$$

where $\mathit{def}_G(b)$ is the defect of b.

The dimension formula of $X_\lambda(b)$ was conjectured by Rapoport in Rapoport [2005], inspired by Chai's work Chai [2000]. The current reformulation is due to R. E. Kottwitz [2006]. For split groups, the conjectural formula was obtained by Görtz, Haines, R. E. Kottwitz, and Reuman [2006] and Viehmann [2006]. The conjectural formula for general quasi-split unramified groups was obtained independently by X. Zhu [2017] and Hamacher [2015a].

4.2 In the affine flag variety. Now we consider $X_w(b)$ in the affine flag variety.

Theorem 4.2. *Let $[b] \in B(G)$ be basic and $w \in \tilde{W}$ be an element in the shrunken Weyl chamber (i.e., the lowest two-sided cell of $\tilde{W}$). If $X_w(b) \neq \varnothing$, then*

$$\dim X_w(b) = \frac{1}{2}(\ell(w) + \ell(\eta_\sigma(w)) - \mathit{def}_G(b)).$$

Here $\eta_\sigma : \tilde{W} \to W_0$ is defined in Görtz, Haines, R. E. Kottwitz, and Reuman [2010].

This dimension formula was conjectured by Görtz, Haines, Kottwitz, and Reuman in Görtz, Haines, R. E. Kottwitz, and Reuman [ibid.] for split groups and was established for residually split groups in He [2014]. The proof in He [ibid.] is based on the "dimension=degree" Theorem 2.2, some results on the σ-twisted cocenter $\overline{H}$ of affine Hecke algebra H, together with the dimension formula of $X_\lambda(b)$ (which was only known for split groups at that time). The dimension formula for arbitrary reductive groups (under the same assumption on b and w) is obtained by the same argument in He [ibid.], once the dimension formula of $X_\lambda(b)$ for quasi-split unramified groups became available, cf. Theorem 4.1.

Note that the assumption that w is contained in the lowest two-sided cell is an essential assumption here. A major open problem is to understand the dimension of $X_w(b)$ for $[b]$ basic, when w is in the critical stripes (i.e., outside the lowest two-sided cell). So far, no conjectural dimension formula has been formulated. However, the "dimension=degree" Theorem 2.2 and the explicit computation in low rank cases Görtz, Haines, R. E. Kottwitz, and Reuman [2010] indicate that this problem might be closely related to the theory of Kazhdan-Lusztig cells. I expect that further progress on the affine cellularity of affine Hecke algebras, which is a big open problem in representation theory, might shed new light on the study of $\dim X_w(b)$.

I also would like to point out that affine Deligne-Lusztig varieties in affine Grassmannians are equi-dimensional, while in general affine Deligne-Lusztig varieties in the affine flag varieties are not equi-dimensional.

4.3 Certain unions. We will see in Section 8 that for certain pairs (G, μ), $X(\mu, b)$ admits some simple geometric structure. In these cases, one may write down an explicit dimension formula for $X(\mu, b)$. Outide these case, very little is known for $\dim X(\mu, b)$.

Here we mention one difficult case: the Siegel modular variety case. Here $G = Sp_{2g}$ and μ is the minuscule coweight. It was studied by Görtz and Yu in Görtz and Yu [2010], in which they showed that for basic $[b]$, $\dim X(\mu, b) = \frac{g^2}{2}$ if g is even and $\frac{g(g-1)}{2} \leqslant \dim X(\mu, b) \leqslant [\frac{g^2}{2}]$ if g is odd. It would be interesting to determine the exact dimension when g is odd.

5 Hodge–Newton decomposition

To study the set-theoretic and geometric properties of affine Deligne-Lusztig varieties, a very useful tool is to reduce the study of affine Deligne-Lusztig varieties of a connected reductive group to certain affine Deligne-Lusztig varieties of its Levi subgroups. Such reduction is achieved by the Hodge-Newton decomposition, which originated in Katz's work Katz [1979] on F-crystals with additional structures. In this section, we discuss its variation for affine Deligne-Lusztig varieties in affine Grassmannians, and further development on affine Deligne-Lusztig varieties in affine flag varieties, and on the union of affine Deligne-Lusztig varieties.

5.1 In the affine Grassmannian. For affine Deligne-Lusztig varieties in the affine Grassmannian, Kottwitz in R. E. Kottwitz [2003] (see also Viehmann [2008]) established the following Hodge-Newton decomposition, which is the group-theoretic generalization of Katz's result. Here the pair (λ, b) is called Hodge-Newton decomposable with respect to a proper Levi subgroup M if $b \in M$ and λ and b have the same image under the Kottwitz's map κ_M for M.

Theorem 5.1. *Let M be a Levi subgroup of G and (λ, b) be Hodge-Newton decomposable with respect to M. Then the natural map $X^M_\lambda(b) \to X^G_\lambda(b)$ is an isomorphism.*

5.2 In the affine flag variety. For affine Deligne-Lusztig varieties in affine flag varieties, the situation is more complicated, as the Hodge-Newton decomposability condition on the pairs (w, b) is rather difficult. As pointed out in Görtz, Haines, R. E. Kottwitz, and Reuman [2010], "It is striking that the notion of P-alcove, discovered in the attempt to understand the entire emptiness pattern for the $X_x(b)$ when b is basic, is also precisely the notion needed for our Hodge-Newton decomposition."

The Hodge-Newton decomposition for $X_w(b)$ was established by Görtz, Haines, Kottwitz and Reuman in Görtz, Haines, R. E. Kottwitz, and Reuman [ibid.].

Theorem 5.2. *Suppose that $P = MN$ is a semistandard Levi subgroup of G and $w \in \tilde{W}$ is a P-alcove element in the sense of Görtz, Haines, R. E. Kottwitz, and Reuman [ibid.]. Let $b \in M$. Then the natural map $X^M_w(b) \to X^G_w(b)$ induces a bijection*

$$J^M_b \backslash X^M_w(b) \cong J^G_b \backslash X^G_w(b).$$

5.3 Certain unions. For $X(\mu, b)$, the Hodge-Newton decomposability condition is still defined on the pair (μ, b). However, the precise condition is more complicated than in Section 5.1 as we consider arbitrary connected reductive groups, not only the unramified ones. We refer to Goertz, He, and Nie [2016, Definition 2.1] for the precise definition. The following Hodge-Newton decomposition for $X(\mu, b)$ was established in a joint work with Görtz and Nie 2016.

Theorem 5.3. *Suppose that (μ, b) is Hodge-Newton decomposable with respect to some proper Levi subgroup. Then*

$$X(\mu, b) \cong \bigsqcup_{P'=M'N'} X^{M'}(\mu_{P'}, b_{P'}),$$

where P' runs through a certain finite set of semistandard parabolic subgroups. The subsets in the union are open and closed.

We refer to Goertz, He, and Nie [2016, Theorem 3.16] for the precise statement. Note that an essential new feature is that unlike the Hodge-Newton decomposition of a single affine Deligne-Lusztig variety (e.g. $X_\lambda(b)$ or $X_w(b)$) where only one Levi subgroup is involved, in the Hodge-Newton decomposition of $X(\mu, b)$ several Levi subgroups are involved.

Thus, the statement here is more complicated than the Hodge-Newton decomposition of $X_\lambda(b)$ and $X_w(b)$. But this is consistent with the fact that the Newton strata in the special fiber of Shimura varieties with Iwahori level structure are more complicated than those with hyperspecial level structure. I believe that the Hodge-Newton decomposition here would help us to overcome some of the difficulties occurring in the study of Shimura varieties with Iwahori level structure (as well as arbitrary parahoric level structures). We will see some results in this direction in Section 6 and in Section 8.

6 Connected components

In this subsection, we discuss the set of connected components of some closed affine Deligne-Lusztig varieties, e.g.

$$X_{\preceq\lambda}(b) := \cup_{\lambda' \preceq \lambda} X_{\lambda'}(b) \text{ and } X(\mu, b) = \cup_{w \in \text{Adm}(\mu)} X_w(b).$$

The explicit description of the set of connected components has some important applications in number theory, which we will mention later.

Note that affine Grassmannians and affine flag varieties are not connected in general, and their connected components are indexed by $\pi_1(G)_{\Gamma_0}$. This gives the first obstruction to the connectedness. The second obstruction comes from the Hodge-Newton decomposition, which we discussed in Section 5. One may expect that these are the only obstructions. We have the following results.

Theorem 6.1. *Assume that G is an unramified simple group and that (λ, b) is Hodge-Newton indecomposable. Then*

$$\pi_0(X_{\preceq\lambda}(b)) \cong \pi_1(G)^{\sigma}_{\Gamma_0}.$$

This was first proved by Viehmann for split groups, and then by M. Chen, Kisin, and Viehmann [2015] for quasi-split unramified groups and for λ minuscule. The description of $\pi_0(X_{\preceq\lambda}(b))$ for G quasi-split unramified, and λ non-minuscule, was conjectured in M. Chen, Kisin, and Viehmann [ibid.] and was established by Nie [2015].

Note that the minuscule coweight case is especially important for applications in number theory. Kisin [2017] proved the Langlands-Rapoport conjecture for mod-p points on Shimura varieties of *abelian type* with *hyperspecial level structure*. Compared to the function field analogous of Langlands-Rapoport conjecture Rad and Hartl [2016], there are extra complication coming from algebraic geometry and the explicit description of the connected components of $X(\mu, b)$ in M. Chen, Kisin, and Viehmann [2015] is used in an essential way to overcome the complication.

Theorem 6.2. *Let μ be a dominant coweight and $b \in G$. Assume that $[b] \in B(G, \mu)$ and that (μ, b) is Hodge-Newton indecomposable. Then*

(1) If $[b]$ is basic, then $\pi_0(X(\mu, b)) \cong \pi_1(G)^{\sigma}_{\Gamma_0}$.

(2) If G is split, then $\pi_0(X(\mu, b)) \cong \pi_1(G)$.

Here part (1) was obtained in joint work with Zhou 2016. As an application, we verified the Axioms in He and Rapoport [2017] for certain PEL type Shimura varieties. In He and Zhou [2016], the set of connected components of $X(\mu, b)$ was also studied for nonbasic b. We proved the in a residually split group, the set of connected components is "controlled" by the set of straight elements, together with the obstruction from the corresponding Levi subgroup. Combined with the work of Zhou [2017], we verified in the residually split case, the description of the mod-p isogeny classes on Shimura varieties conjectured by Langlands and Rapoport [1987]. Part (2) is recent work of L. Chen and Nie [2017].

We would like to point out that in the statement, the following two conditions are essential:

- The σ-conjugacy class $[b]$ is neutrally acceptable, i.e. $[b] \in B(G, \mu)$. This condition comes from the Kottwitz-Rapoport conjecture (see Theorem 3.3).
- The pair (μ, b) is Hodge-Newton indecomposable. In the general case, we need to apply the Hodge-Newton decomposition (see Theorem 5.3). As a consequence, several $\pi_1(M)$ are involved in the description of $\pi_0(X(\mu, b))$ in general.

7 Arbitrary parahoric level structure

7.1 Parahoric level versus Iwahori level. Let $K' \supset I$ be a standard parahoric subgroup of G and $W_{K'}$ be the finite Weyl group of K'. We define

$$X(\mu, b)_{K'} = \{gK' \in G/K'; g^{-1} b \sigma(g) \in K' \operatorname{Adm}(\mu) K'\}.$$

If $K' = I$, then $X(\mu, b)_{K'} = X(\mu, b)$. If G is unramified, μ is minuscule and $K' = K$ is a hyperspecial parahoric subgroup, then $X(\mu, b)_{K'} = X_\mu(b)$. As we have mentioned, the varieties $X_\mu(b)$ (resp. $X(\mu, b)$) serve as group-theoretic models for the Newton strata in the special fiber of Shimura varieties with hyperspecial (resp. Iwahori) level structure. The variety $X(\mu, b)_{K'}$ plays the same role in the study of Shimura varieties with arbitrary parahoric level structure.

The following result relates $X(\mu, b)_{K'}$ for an arbitrary parahoric subgroup K' with $X(\mu, b)$ (for the Iwahori subgroup I).

Theorem 7.1. *The projection map $G/I \to G/K'$ induces a surjection*

$$X(\mu, b) \twoheadrightarrow X(\mu, b)_{K'}.$$

This was conjectured by Kottwitz and Rapoport in Kudla and Rapoport [2011] and Rapoport [2005] and was proved in He [2016b]. This fact allows one to reduce many questions (e.g. nonemptiness pattern, connected components, etc.) of $X(\mu, b)_{K'}$ for arbitrary K' to the same questions for $X(\mu, b)$. In fact, the statements in Theorem 3.3 and Theorem 6.2 hold if $X(\mu, b)$ is replaced by $X(\mu, b)_{K'}$ for an arbitrary parahoric subgroup K'.

7.2 Lusztig's G-stable pieces. I would like to draw attention to some crucial ingredient in the proof, which has important applications in arithmetic geometry.

Note that $I \operatorname{Adm}(\mu) I \subsetneq K' \operatorname{Adm}(\mu) K'$ if $I \subsetneq K'$. In order to show that $X(\mu, b) \to X(\mu, b)_{K'}$ is surjective, one needs to have some decomposition of $K' \operatorname{Adm}(\mu) K'$, finer than the decomposition into K' double cosets. The idea of the sought-after decomposition is essentially due to Lusztig. In 2004, Lusztig introduced G-stable pieces for reductive groups over algebraically closed fields. The closure relation between G-stable pieces was determined in He [2007b] and a more systematic approach using the " partial conjugation action" technique was given later in He [2007a]. The notion and the closure relation of G-stable pieces also found application in arithmetic geometry, e.g. in the work of Pink, Wedhorn and Ziegler on algebraic zip data Pink, Wedhorn, and Ziegler [2011].

7.3 Ekedahl-Kottwitz-Oort-Rapoport stratification. Lusztig's idea was also adapted to loop groups, first with a hyperspecial parahoric subgroup, independently by the author 2011, and by Viehmann [2014]. It was used it to define the Ekedahl-Oort stratification of a general Shimura variety.

The desired decomposition of $K' \operatorname{Adm}(\mu) K'$ for an arbitrary parahoric subgroup K' was given in He [2016b] as

$$K' \operatorname{Adm}(\mu) K' = \sqcup_{w \in {}^{K'}\tilde{W} \cap \operatorname{Adm}(\mu)} K' \cdot_\sigma IwI,$$

where ${}^{K'}\tilde{W}$ is the set of minimal length elements in $W_{K'} \backslash \tilde{W}$ and $\cdot_\sigma$ means the σ-conjugation action. This decomposition is used in joint work with Rapoport 2017 to define the Ekedahl-Kottwitz-Oort-Rapoport stratification of Shimura varieties with arbitrary parahoric level structure. This stratification interpolates between the Kottwitz-Rapoport stratification in the case of the Iwahori level structure and the Ekedahl-Oort stratification Viehmann [2014] in the case of hyperspecial level structure.

8 Affine Deligne-Lusztig varieties with simple geometric structure

8.1 Simple geometric structure for some $X(\mu, b_0)_{K'}$. The geometric structure of $X(\mu, b_0)_{K'}$ for basic b_0 is rather complicated in general. However, in certain cases, $X(\mu, b_0)_{K'}$ admit a simple description. The first nontrivial example is due to Vollaard and Wedhorn in Vollaard and Wedhorn [2011]. They showed that $X_\mu(b_0)$ for an unramified unitary group of signature $(1, n-1)$ and $\mu = (1, 0, \cdots, 0)$ (and for hyperspecial parahoric level structure), is a union of classical Deligne-Lusztig varieties, and the index set and the closure relations between the strata are encoded in a Bruhat-Tits building. Since then, this question has attracted significant attention. We mention the work of Rapoport, Terstiege, and Wilson [2014] on ramified unitary groups, of Howard and Pappas [2014], Howard and Pappas [2017] on orthogonal groups, of Tian and Xiao [2016] in the Hilbert-Blumenthal case. In all these works, the parahoric subgroups involved are hyperspecial parahoric subgroups or certain maximal parahoric subgroups. The analogous group-theoretic question for maximal parahoric subgroups was studied in joint work with Görtz Görtz and He [2015].

Note that these simple descriptions of closed affine Deligne-Lusztig varieties (and the corresponding basic locus of Shimura varieties) have been used, with great success, towards applications in number theory: to compute intersection numbers of special cycles, as in the Kudla-Rapoport program Kudla and Rapoport [2011] or in work Rapoport, Terstiege, and W. Zhang [2013], Li and Y. Zhu [2017] towards Zhang's Arithmetic Fundamental Lemma W. Zhang [2012]; and to prove the Tate conjecture for certain Shimura varieties Tian and Xiao [2014], Helm, Tian, and Xiao [2017].

The work of Vollaard and Wedhorn [2011], Rapoport, Terstiege, and Wilson [2014], Howard and Pappas [2014], Howard and Pappas [2017], Tian and Xiao [2016] focused on specific Shimura varieties with certain maximal parahoric level structure. The work Görtz and He [2015] studied the analogous group-theoretic question for arbitrary reductive groups. The conceptual interpretation on the occurrence of classical Deligne-Lusztig varieties was given; however, a large part of the work in Görtz and He [ibid.] was still obtained by brute force.

8.2 Some equivalent conditions. From the Lie-theoretic point of view, one would like to consider not only the maximal parahoric subgroups, but all parahoric subgroups; and one would like to have a conceptual understanding on the following question:

When and why is $X(\mu, b_0)_{K'}$ naturally a union of classical Deligne-Lusztig varieties? This was finally achieved in joint work with Görtz and Nie 2015 as follows

Theorem 8.1. *Assume that G is simple, μ is a dominant coweight of G and K' is a parahoric subgroup. Then the following conditions are equivalent:*

- *For basic $[b_0] \in B(G, \mu)$, $X(\mu, b_0)_{K'}$ is naturally a union of classical Deligne-Lusztig varieties;*
- *For any nonbasic $[b] \in B(G, \mu)$, $\dim X(\mu, b)_{K'} = 0$;*
- *The pair (μ, b) is Hodge-Newton decomposable for any nonbasic $[b] \in B(G, \mu)$;*
- *The coweight μ is minute for G.*

Here the minute condition is an explicit combinatorial condition on the coweight μ. For quasi-split groups, it means that for any σ-orbit $\mathcal{O}$ on the set of simple roots, we have $\sum_{i \in \mathcal{O}} \langle \mu, \omega_i \rangle \leqslant 1$. For non quasi-split groups, the condition is more involved and we refer to Goertz, He, and Nie [2016, Definition 2.2] for the precise definition. It is also worth mentioning that it is not very difficult to classify the pairs (G, μ) with the minute condition. In Goertz, He, and Nie [ibid., Theorem 2.5], a complete list of the cases is obtained, where $X(\mu, b_0)_{K'}$ is naturally a union of classical Deligne-Lusztig varieties.

Fargues and Rapoport conjectured that for p-adic period domains, the weakly admissible locus coincides with the admissible locus if and only if the pair (μ, b) is Hodge-Newton decomposable for any nonbasic $[b] \in B(G, \mu)$ (cf. Goertz, He, and Nie [ibid., Conjecture 0.1]). This conjectured is established in a very recent preprint M. Chen, Fargues, and Shen [2017] by Chen, Fargues and Shen.

8.3 Further remarks. From the Lie-theoretic point of view, there are some quite striking new features in Theorem 8.1:

1. The relations between the variety $X(\mu, b)_{K'}$ for the basic σ-conjugacy class and for nonbasic σ-conjugacy classes;
2. The relation between the condition that $X(\mu, b_0)_{K'}$ has a simple description and the Hodge-Newton decomposability condition;
3. The existence of a simple description of $X(\mu, b_0)_{K'}$ is independent of the parahoric subgroup K'.

Note that part (1) and part (2) are new even for the specific Shimura varieties with hyperspecial level structure considered in the previous works. Part (3) is the most mysterious one. In Goertz, He, and Nie [2016], we state that "We do not see any reason why this independence of the parahoric could be expected a priori, but it is an interesting parallel with the question when the weakly admissible and admissible loci in the rigid analytic period domain coincide."

For applications to number theory, one needs to consider the fraction field of the Witt ring instead of the formal Laurent series field $\overline{\mathbb{F}}_q((\epsilon))$. In that setting, we have a similar, but weaker result, namely, $X(\mu, b_0)_{K'}$ is naturally a union of classical Deligne-Lusztig varieties as perfect schemes. It is expected that the structural results hold without perfection, as indicated in the special cases established in the papers mentioned in Section 8.1.

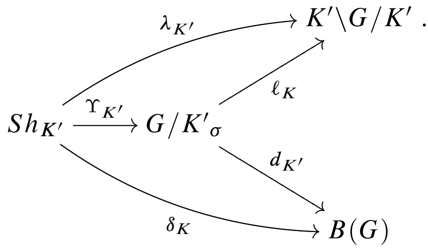
9 Some applications to Shimura varieties

In the last subsection, we give a very brief discussion of some applications to arithmetic geometry.

9.1 Some characteristic subsets. The study of some characteristic subsets in the special fiber of a Shimura variety is a central topic in arithmetic geometry. We mention the *Newton strata*, the *Ekedahl-Oort strata* for the hyperspecial level structure and the *Kottwitz-Rapoport strata* for the Iwahori level structure. Concerning these stratifications, there are many interesting questions one may ask, e.g. which strata are nonempty, what is the relation between these various stratifications, etc.. These questions have been intensively studied in recent years and there is a large body of literature on these questions. Among them, we mention the work of Viehmann and Wedhorn [2013] on the nonemptiness of Newton strata and Ekedahl-Oort strata for PEL type Shimura varieties with hyperspecial level structure, the work of M. Kisin, Madapusi, and Shin [n.d.] on the nonemptiness of the basic Newton stratum, the work of Hamacher [2015b] on the closure relation between Newton strata, and the work of Wedhorn [1999] and Moonen [2004] on the density of the μ-ordinary locus (i.e. the Newton stratum corresponding to ϵ^{μ}). We refer to He and Rapoport [2017, Introduction] and Viehmann [2015] for more references.

9.2 An axiomatic approach. In the works mentioned above, both algebro-geometric and Lie-theoretic methods are involved, and are often mixed together.

In joint work with He and Rapoport [2017], we purposed an axiomatic approach to the study of these characteristic subsets in a general Shimura variety. We formulated five axioms, based on the existence of integral models of Shimura varieties (which have been established in various cases by the work of Rapoport and Zink [1996], Kisin and Pappas [2015]), the existence of the following commutative diagram and some compatibility conditions:



Here K' is a parahoric subgroup, $Sh_{K'}$ is the special fiber of a Shimura variety with K' level structure, and G/K'_σ is the set-theoretic quotient of G by the σ-conjugation action of K'.

As explained in Goertz, He, and Nie [2016, §6.2], affine Deligne-Lusztig varieties are involved in the diagram in an essential way, via the bijection

$$J_b \backslash X(\mu, b)_{K'} \xrightarrow{\sim} d_{K'}^{-1}([b]) \cap \ell_{K'}^{-1}(K' \operatorname{Adm}(\{\mu\})K').$$

9.3 Some applications and current status of the axioms. It is shown in He and Rapoport [2017] that under those axioms, the Newton strata, the Ekedahl-Oort strata, the Kottwitz-Rapoport strata, and the Ekedahl-Kottwitz-Oort-Rapoport strata discussed in Section 7, are all nonempty in their natural range. Furthermore, under those axioms several relations between these various stratifications are also established in He and Rapoport [ibid.].

Following He and Rapoport [ibid.], Shen and C. Zhang [2017] studied the geometry of good reductions of Shimura varieties of abelian type. They established basic properties of these characteristic subsets, including nonemptiness, closure relations and dimension formula and some relations between these stratifications.

In joint work with Nie 2017, based on the framework of He and Rapoport [2017], we studied the density problem of the μ-ordinary locus. Under the axioms of He and Rapoport [ibid.] we gave several explicit criteria on the density of the μ-ordinary locus.

Algebraic geometry is essential in the verification of these axioms. For PEL type Shimura varieties associated to unramified groups of type A and C and to odd ramified unitary groups, the axioms are verified in joint work with Zhou 2016. For Shimura varieties of Hodge type, most of the axioms are verified in recent work of Zhou [2017].

EXT-ANALOGUES OF BRANCHING LAWS

Dipendra Prasad

Abstract

We consider the Ext-analogues of branching laws for representations of a group to its subgroups in the context of p-adic groups.

Contents

1 Introduction

Considering the restriction of representations of a group G to one of its subgroups H, say of $G = \mathrm{SO}_{n+1}(F)$ to $H = \mathrm{SO}_n(F)$ for a non-archimedean local field F has been a very

MSC2010: primary 11F70; secondary 22E55.

fruitful direction of research especially through its connections to questions on period integrals of automorphic representations, cf. Gan, Gross, and Prasad [2012] for the conjectural theory both locally and globally. The question for local fields amounts to understanding $\mathrm{Hom}_{\mathrm{SO}_n(F)}[\pi_1, \pi_2]$ for irreducible admissible representations π_1 of $\mathrm{SO}_{n+1}(F)$, and π_2 of $\mathrm{SO}_n(F)$. The first result proved about this is the multiplicity one property which says that this space is at most one dimensional, cf. Aizenbud, Gourevitch, Rallis, and Schiffmann [2010], Sun and Zhu [2012]. It may be mentioned that before the full multiplicity one theorem was proved, even finite dimensionality of the space was not known. With multiplicity one theorem proved, one then goes on to prove more precise description of the set of irreducible admissible representations π_1 of $\mathrm{SO}_{n+1}(F)$, and π_2 of $\mathrm{SO}_n(F)$ with $\mathrm{Hom}_{\mathrm{SO}_n(F)}[\pi_1, \pi_2] \neq 0$. These have now become available in a series of papers due to Waldspurger, and Moeglin-Waldspurger, cf. J.-L.Waldspurger [2010], J.-L.Waldspurger [2012b], J.-L.Waldspurger [2012a], Moeglin and J.-L.Waldspurger [2012]. There is also a recent series of papers by Beuzart-Plessis on similar questions for unitary groups, cf. Beuzart-Plessis [2016], Beuzart-Plessis [2015], Beuzart-Plessis [2014].

Given the interest in the space $\mathrm{Hom}_{\mathrm{SO}_n(F)}[\pi_1, \pi_2]$, it is natural to consider the related spaces $\mathrm{Ext}^i_{\mathrm{SO}_n(F)}[\pi_1, \pi_2]$, and in fact homological algebra methods suggest that the simplest answers are not for these individual spaces, but for the alternating sum of their dimensions: $\mathrm{EP}[\pi_1, \pi_2] = \sum_{i=0}^{\infty} (-1)^i \dim \mathrm{Ext}^i_{\mathrm{SO}_n(F)}[\pi_1, \pi_2]$; these hopefully more manageable objects –certainly more flexible– when coupled with vanishing of higher Ext's (when available) may give theorems about $\mathrm{Hom}_{\mathrm{SO}_n(F)}[\pi_1, \pi_2]$. We hasten to add that before we can define $\mathrm{EP}[\pi_1, \pi_2]$, $\mathrm{Ext}^i_{\mathrm{SO}_n(F)}[\pi_1, \pi_2]$ needs to be proved to be finite dimensional for π_1 and π_2 finite length admissible representations of $\mathrm{SO}_{n+1}(F)$ and $\mathrm{SO}_n(F)$ respectively, and also proved to be 0 for i large. Vanishing of $\mathrm{Ext}^i_{\mathrm{SO}_n(F)}[\pi_1, \pi_2]$ for large i is a well-known generality to which we will come to later. Towards a proof of finite dimensionality of Ext^i in this case, to be made by an inductive argument on n later in the paper, we note that unlike $\mathrm{Hom}_{\mathrm{SO}_n(F)}[\pi_1, \pi_2]$, where we will have no idea how to prove finite dimensionality if both π_1 and π_2 are cuspidal, exactly this case we can handle apriori, for $i > 0$, as almost by the very definition of cuspidal representations, they are both projective and injective objects in the category of smooth representations. Recently, there is a very general finiteness theorem for $\mathrm{Ext}^i[\pi_1, \pi_2]$ (for spherical varieties) in Aizenbud and Sayag [2017]. However, we have preferred to give our own older approach via Bessel models which intervene when analyzing principal series representations of $\mathrm{SO}_{n+1}(F)$ when restricted to $\mathrm{SO}_n(F)$. As a bonus, this approach gives explicit answers about Euler-Poincaré characteristics.

Thinking about Ext-analogues suggest interchanging the roles of π_1 and π_2 in analogy with the known relationship, $\mathrm{EP}[V_1, V_2^\vee] = \mathrm{EP}[V_2, V_1^\vee]$ when V_1 and V_2 are finite length representations on the same group, and allows one to consider submodules as in $\mathrm{Hom}_{\mathrm{SO}_n(F)}[\pi_2, \pi_1]$, and more generally, $\mathrm{Ext}^i_{\mathrm{SO}_n(F)}[\pi_2, \pi_1]$.

Based on various examples, a clear picture seems to be emerging about $\mathrm{Ext}^i_H[\pi_1, \pi_2]$. For example, we expect that when π_1 and π_2 are tempered, $\mathrm{Ext}^i_H[\pi_1, \pi_2]$ is nonzero only for $i = 0$. On the other hand we expect that $\mathrm{Ext}^i_H[\pi_2, \pi_1]$ is typically zero for $i = 0$ (so no wonder branching is usually not considered as a subrepresentation!), and shows up only for i equals the split rank of the center of the Levi from which π_2 arises through parabolic induction of a supercuspidal representation; in fact $\mathrm{Ext}^i_H[\pi_2, \pi_1]$ is zero beyond the split rank of the center of this Levi by generalities, so $\mathrm{Ext}^i_H[\pi_1, \pi_2]$ is typically nonzero only for $i = 0$, whereas $\mathrm{Ext}^i_H[\pi_2, \pi_1]$ is nonzero only for the largest possible i. We make precise some of these suggestions during the course of the paper, and discuss some examples as evidence for the suggested conjectures made here.

In the process of relating $\mathrm{Ext}^i[\pi_1, \pi_2]$ with $\mathrm{Ext}^i[\pi_2, \pi_1]$, we were led to a duality theorem for a general reductive group which turned out to be a consequence of the work in P.Schneider and U.Stuhler [1997]. It is the subject matter of Section 8. As an example, calculation of $\dim_{\mathbb{C}} \mathrm{Hom}_{\mathrm{PGL}_2(F)}[\pi_1 \otimes \pi_2, \pi_3]$ which was part of author's work in Prasad [1990], and simple calculations about $\mathrm{EP}_{\mathrm{PGL}_2(F)}[\pi_1 \otimes \pi_2, \pi_3]$ allow the calculation of $\mathrm{Ext}^1_{\mathrm{PGL}_2(F)}[\pi_1 \otimes \pi_2, \pi_3]$, and then by the duality theorem, we are able to analyze $\mathrm{Hom}_{\mathrm{PGL}_2(F)}[\pi_3, \pi_1 \otimes \pi_2]$ (irreducible submodules of the tensor product).

In the archimedean case, several papers of T. Kobayashi, see e.g. Kobayashi [1994], do study the restriction problem for $(\mathfrak{g}, K)$-modules in the sense of sub-modules but the analogous restriction problem in the sense of sub-modules seems to be absent in the p-adic case. Proposition 5.1 and Proposition 5.3 suggest that $\mathrm{Hom}_H[\pi_2, \pi_1] = 0$ whenever π_1 is an irreducible tempered representation of G (assumed to be simple) unless H has compact center, and π_2 is a supercuspidal representation of it.

To summarize the main results of the paper, we might mention Theorem 4.2 giving a complete understanding of $\mathrm{EP}_{\mathrm{GL}_n(F)}[\pi_1, \pi_2]$ for π_1 and π_2 finite length representations of $\mathrm{GL}_{n+1}(F)$ and $\mathrm{GL}_n(F)$ respectively. Theorem 6.1 proves $\mathrm{Ext}^i_{\mathrm{SO}_n(F)}[\pi_1, \pi_2]$ to be finite dimensional for π_1 and π_2 finite length representations of $\mathrm{SO}_{n+1}(F)$ and $\mathrm{SO}_n(F)$ respectively, and as Corollary 6.3 of the proof, gives a good understanding of $\mathrm{EP}_{\mathrm{SO}_n(F)}[\pi_1, \pi_2]$ when π_1 is a principal series. We formulate as Conjecture 5.1 the vanishing of $\mathrm{Ext}^i_{\mathrm{GL}_n(F)}[\pi_1, \pi_2]$ for $i > 0$ for generic representations, and Conjecture 7.1 suggests that the integral formula discovered by Waldspurger in the papers J.-L.Waldspurger [2010] and J.-L.Waldspurger [2012b] are actually for Euler-Poincaré characteristic of general finite length representations in the spirit of Kazhdan orthogonality. In Section 9 we suggest that all nontrivial Ext's have some 'geometric' origin.

Acknowledgments. The author thanks Ann-Marie Aubert, Jeffrey Adams, U.K. Anandavardhanan, Joseph Bernstein, Atsushi Ichino, Raphael Beuzart-Plessis, Peter Schneider, Maarten Solleveld, and Sandeep Varma for useful discussions and correspondence. This paper is an updated version of the paper with the same title in arXiv from 2013!

2 Preliminaries

Given a connected reductive F-group G, we make the usual abuse of notation to also denote by G the locally compact totally disconnected group $G(F)$ of F-rational points of the algebraic group G. We denote by $\mathfrak{R}(G)$ the abelian category of smooth representations of G over $\mathbb{C}$. The abelian category $\mathfrak{R}(G)$ has enough projectives and enough injectives, e.g. for any compact open subgroup K of G, $\mathrm{ind}_K^G(\mathbb{C})$ is a projective object in $\mathfrak{R}(G)$, and $\mathrm{Ind}_K^G(\mathbb{C})$ is an injective object in $\mathfrak{R}(G)$ (we use throughout the paper ind for compactly supported induction and Ind for induction without compact support condition); in fact these projective objects and their direct summands, and their smooth duals as injective objects suffice for all considerations in the paper. Since $\mathfrak{R}(G)$ has enough projectives and enough injectives, it is meaningful to talk about $\mathrm{Ext}^i_G[\pi_1, \pi_2]$ as the derived functors of $\mathrm{Hom}_G[\pi_1, \pi_2]$.

For reductive p-adic groups G considered in this paper, it is known that $\mathrm{Ext}^i_G[\pi, \pi']$ is zero for any two smooth representations π and π' of G when i is greater than the F-split rank of G. This is a standard application of the projective resolution of the trivial representation $\mathbb{C}$ of G provided by the building associated to G. For another proof of this, and for finite dimensionality of $\mathrm{Ext}^i_G[\pi, \pi']$, see Proposition 2.9 below.

For two smooth representations π and π' of G one can consider the Euler-Poincaré pairing $\mathrm{EP}_G[\pi, \pi']$ between π and π' defined by

$$\mathrm{EP}_G[\pi, \pi'] = \sum_i (-1)^i \dim_{\mathbb{C}} \mathrm{Ext}^i_G[\pi, \pi'].$$

For this definition to make sense, we must prove that $\mathrm{Ext}^i_G[\pi, \pi']$ are finite-dimensional vector spaces over $\mathbb{C}$ for all integers i. An obvious remark which will be tacitly used throughout this paper is that if

$$0 \to \pi_1 \to \pi \to \pi_2 \to 0,$$

is an exact sequence of smooth G-modules, and if any two of the $\mathrm{EP}_G[\pi_1, \pi']$, $\mathrm{EP}_G[\pi, \pi']$, $\mathrm{EP}_G[\pi_2, \pi']$, make sense, then so does the third (finite dimensionality of the Ext groups, and zero beyond a stage), and

$$\mathrm{EP}_G[\pi, \pi'] = \mathrm{EP}_G[\pi_1, \pi'] + \mathrm{EP}_G[\pi_2, \pi'].$$

This remark will be used to break up representations π or π' in terms of simpler objects for which EP can be proved to make sense by reducing to smaller groups via some form of Frobenius recoprocity.

The following proposition summarizes some key properties of the Euler-Poincaré pairing, see P.Schneider and U.Stuhler [1997] for the proofs (part 2.1 (4) is known only in characteristic zero).

Proposition 2.1. *Let π and π' be finite-length, smooth representations of a reductive p-adic group G. Then:*

1. $\mathrm{EP}[\pi_1^\vee, \pi_2]$ *is a symmetric, $\mathbb{Z}$-bilinear form on the Grothendieck group of finite-length representations of G.*

2. EP *is locally constant. (A family $\{\pi_\lambda\}$ of representations on a fixed vector space V is said to* vary continuously *if all $\pi_\lambda|_K$ are all equivalent for some compact open subgroup K, and the matrix coefficients $\langle \pi_\lambda v, \tilde{v}\rangle$ vary continuously in λ.)*

3. $\mathrm{EP}_G[\pi, \pi'] = 0$ *if π or π' is induced from any proper parabolic subgroup in G.*

4. $\mathrm{EP}_G[\pi, \pi'] = \int_{C_{ellip}} \Theta(c)\bar{\Theta}'(c)\, dc$, *where Θ and Θ' are the characters of π and π' assumed to have the same unitary central character, and dc is a natural measure on the set C_{ellip} of regular elliptic conjugacy classes in G. (Note that if G has non-compact center, then both sides of this equality are zero; the right hand side being zero as there are no regular elliptic elements in G in that case, and the left hand side being zero by a simple argument.)*

Several assertions about Hom spaces can be converted into assertions about Ext^i. The following generality allows one to do so.

Proposition 2.2. *Let $\mathfrak{A}$ and $\mathfrak{B}$ be two abelian categories, and $\mathfrak{F}$ a functor from $\mathfrak{A}$ to $\mathfrak{B}$, and $\mathfrak{G}$ a functor from $\mathfrak{B}$ and $\mathfrak{A}$. Assume that $\mathfrak{G}$ is a left adjoint of $\mathfrak{F}$, i.e., there is a natural equivalence of functors:*

$$\mathrm{Hom}_{\mathfrak{B}}[X, \mathfrak{F}(Y)] \cong \mathrm{Hom}_{\mathfrak{A}}[\mathfrak{G}(X), Y].$$

Then,

1. *If $\mathfrak{F}$ and $\mathfrak{G}$ are exact functors, then $\mathfrak{F}$ maps injective objects of $\mathfrak{A}$ to injective objects of $\mathfrak{B}$, and $\mathfrak{G}$ maps projective objects of $\mathfrak{B}$ to projective objects of $\mathfrak{A}$.*

2. *If $\mathfrak{F}$ and $\mathfrak{G}$ are exact functors, then* $\mathrm{Ext}^i_{\mathfrak{B}}[X, \mathfrak{F}(Y)] \cong \mathrm{Ext}^i_{\mathfrak{A}}[\mathfrak{G}(X), Y]$.

Proof. Part (1) of the Proposition follows directly from definitions; see Bernstein [1992], Proposition 8. For part (2), it suffices to note that if

$$\cdots P_n \to P_{n-1} \to \cdots \to P_1 \to P_0 \to X \to 0,$$

is a projective resolution of an object X in $\mathfrak{B}$, then by part (1) of the Proposition,

$$\cdots \mathcal{G}(P_n) \to \mathcal{G}(P_{n-1}) \to \cdots \to \mathcal{G}(P_1) \to \mathcal{G}(P_0) \to \mathcal{G}(X) \to 0,$$

is a projective resolution of $\mathcal{G}(X)$. Therefore part (2) of the proposition follows from the adjointness relationship between $\mathcal{F}$ and $\mathcal{G}$. □

The following is a direct consequence of Frobenius reciprocity combined with Proposition 2.2.

Proposition 2.3. *Let H be a closed subgroup of a p-adic Lie group G. Then,*

1. *The restriction of any smooth projective representation of G to H is a projective object in $\mathfrak{R}(H)$, and $\mathrm{Ind}_H^G U$ is an injective representation of G for any injective representation U of H.*
2. *For any smooth representation U of H, and V of G,*

$$\mathrm{Ext}^i_G[V, \mathrm{Ind}_H^G U] \cong \mathrm{Ext}^i_H[V, U].$$

Note that for any two smooth representations U, V of G,

$$\mathrm{Hom}_G[U, V^\vee] \cong \mathrm{Hom}_G[V, U^\vee],$$

where $U^\vee, V^\vee$ are the smooth duals of U, V respectively. Therefore we have adjoint functors as in Proposition 2.2 with $\mathcal{F} = \mathcal{G}$ to be the smooth dual from the category of smooth representations of a p-adic group G to its opposite category. By Proposition 2.2, it follows that the smooth dual of a projective object in $\mathfrak{R}(G)$ is an injective object in $\mathfrak{R}(G)$, and further we have the following proposition.

Proposition 2.4. *For a p-adic Lie group G, let U and V be two smooth representations of G. Then,*

$$\mathrm{Ext}^i_G[U, V^\vee] \cong \mathrm{Ext}^i_G[V, U^\vee].$$

Since the smooth dual of $\mathrm{ind}_H^G(U)$ is $\mathrm{Ind}_H^G(U^\vee)$ (for normalized induction), the previous two propositions combine to give:

Proposition 2.5. *For H a closed subgroup of a p-adic Lie group G, let U be a smooth representation of H, and V a smooth representation of G. Then,*

$$\mathrm{Ext}^i_H[V, U^\vee] \cong \mathrm{Ext}^i_G[V, \mathrm{Ind}_H^G(U^\vee)] \cong \mathrm{Ext}^i_G[\mathrm{ind}_H^G U, V^\vee].$$

For smooth representations U, V, W of G, the canonical isomorphism,

$$\mathrm{Hom}_G[V \otimes U, W^\vee] \cong \mathrm{Hom}_G[U \otimes W, V^\vee],$$

translates into the following proposition by Proposition 2.2.

Proposition 2.6. *For a p-adic Lie group G, and U, V, W smooth representations of G, there are canonical isomorphisms,*

$$\mathrm{Ext}^i_G[V \otimes U, W^\vee] \cong \mathrm{Ext}^i_G[U \otimes W, V^\vee],$$

in particular

$$\mathrm{Ext}^i_G[V \otimes U, \mathbb{C}] \cong \mathrm{Ext}^i_G[V, U^\vee].$$

Proposition 2.2 with the form of Frobenius reciprocity for Jacquet modules, implies the following proposition.

Proposition 2.7. *For P a parabolic subgroup of a reductive p-adic group G with Levi decomposition $P = MN$, the Jacquet functor $V \to V_N$ from $\mathfrak{R}(G)$ to $\mathfrak{R}(M)$ takes projective objects to projective objects, and for $V \in \mathfrak{R}(G)$, $U \in \mathfrak{R}(M)$, we have (using normalized parabolic induction and normalized Jacquet module),*

$$\mathrm{Ext}^i_G[V, \mathrm{Ind}_P^G U] \cong \mathrm{Ext}^i_M[V_N, U].$$

The proof of the following proposition is exactly as the proof of the earlier proposition. This proposition will play an important role in setting-up an inductive context to prove theorems on a group G in terms of similar theorems for subgroups.

Proposition 2.8. *For P a (not necessarily parabolic) subgroup of a reductive p-adic group G with Levi decomposition $P = MN$, let ψ be a character of N normalized by M. Then for any irreducible representation μ of M, one can define a representation of P, denoted by $\mu \cdot \psi$ which when restricted to M is μ, and when restricted to N is ψ. For any smooth representation V of G, let $V_{N,\psi}$ be the twisted Jacquet module of V with respect to the character ψ of N which is a smooth representation of M. Then,*

$$\mathrm{Ext}^i_G[\mathrm{ind}_P^G(\mu \cdot \psi), V^\vee] \cong \mathrm{Ext}^i_M[V_{N,\psi}, \mu^\vee].$$

The following much deeper result than these earlier results follows from the so called *Bernstein's second adjointness theorem.*

Theorem 2.1. *For P a parabolic subgroup of a reductive p-adic group G with Levi decomposition $P = MN$, let U be a smooth representation of M thought of as a representation of P, and V a smooth representation of G. Let $P^- = MN^-$ be the parabolic* *opposite to $P = MN$. Then we have (using normalized parabolic induction and normalized Jacquet module),*

$$\mathrm{Ext}^i_G[\mathrm{Ind}_P^G U, V] \cong \mathrm{Ext}^i_M[U, V_{N^-}].$$

As a sample of arguments with the Ext groups, we give a proof of the following basic proposition.

Proposition 2.9. *Suppose that V is a smooth representation of G of finite length, and that all of its irreducible subquotients are subquotients of representations induced from supercuspidal representations of a Levi factor of the standard parabolic subgroup $P = MU$ of G, defined by a subset Θ of the set of simple roots for a maximal split torus of G. Then if V' is a finite length smooth representation of G, $\mathrm{Ext}^i_G[V, V']$ and $\mathrm{Ext}^i_G[V', V]$ are finite dimensional vector spaces over $\mathbb{C}$. If V' is any smooth representation of G, $\mathrm{Ext}^i_G[V, V'] = \mathrm{Ext}^i_G[V', V] = 0$ for $i > d(M) = d - |\Theta|$ where d is the F-split rank of G. Further, $\mathrm{EP}_G[\pi, \pi'] = 0$ if both π, π' are finite length representations of G, and π or π' is induced from a proper parabolic subgroup of G.*

Proof. This is Corollary III.3.3 in P.Schneider and U.Stuhler [1997]. Since this is elementary enough, we give another proof.

We begin by noting that tensoring V by the resolution of $\mathbb{C}$ by projective modules in $\mathfrak{R}(G)$ afforded by the building associated to G gives a projective resolution of V, but one which is not finitely generated as a G-module even if V is irreducible, and therefore proving finite dimensionality of $\mathrm{Ext}^i_G[V, V']$ requires some work. The resolution given by the building at least proves that these are 0 beyond the split rank of G. Our proof below first proves the assertions on $\mathrm{Ext}^i_G[V, V']$ if V or V' is a full principal series $\mathrm{Ind}_P^G \rho$ where ρ is a cuspidal representation of M, and then handles all subquotients by a standard *dévissage*.

Fix a surjective map $\phi : M \to \mathbb{Z}^{d(M)}$ with kernel M^ϕ which is sometimes called the subgroup of M generated by compact elements.

Let ρ be a cuspidal representation of M. Therefore ρ restricted to M^ϕ, which is $[M, M]$ up to a compact group, is an injective module, and hence $\mathrm{Ext}^i_{M^\phi}[V_N, \rho] = 0$ for $i > 0$. By Frobenius reciprocity, combined with the spectral sequence associated to the normal subgroup M^ϕ of M with quotient $\mathbb{Z}^d$, it follows that:

$$\begin{aligned}\mathrm{Ext}^i_G[V, \mathrm{Ind}_P^G \rho] &\cong \mathrm{Ext}^i_M[V_N, \rho] \\ &\cong H^i(\mathbb{Z}^{d(M)}, \mathrm{Hom}_{M^\phi}[V_N, \rho]).\end{aligned}$$

This proves that $\mathrm{Ext}^i_G[V, \mathrm{Ind}_P^G \rho] = 0$ for $i > d(M)$ for any smooth representation V of G, and that $\mathrm{Ext}^i_G[V, \mathrm{Ind}_P^G \rho]$ are finite dimensional for V of finite length.

Similarly, by the second adjointness theorem, it follows that $\mathrm{Ext}^i_G[\mathrm{Ind}_P^G(\rho), V'] = 0$ for $i > d(M)$, and that $\mathrm{Ext}^i_G[\mathrm{Ind}_P^G(\rho), V']$ are finite dimensional for V' a finite length representation in $\mathfrak{R}(G)$.

Having proved properties of $\mathrm{Ext}^i_G[V, \mathrm{Ind}_P^G \rho]$ and $\mathrm{Ext}^i_G[\mathrm{Ind}_P^G(\rho), V']$, the rest of the proposition about $\mathrm{Ext}^i_G[V, V']$ follows by *dévissage* by writing an irreducible representation V of G as a quotient of a principal series $Ps = \mathrm{Ind}_P^G \rho$, and using conclusions on the principal series to make conclusions on V. This part of the argument is very similar to what we give in Lemma 6.1, so we omit it here. □

3 Kunneth Theorem

In this section, we prove a form of the Kunneth theorem which we will have several occasions to use. A version of Kunneth's theorem is there in Raghuram [2007] assuming, however, finite length conditions on both E_1 and E_2 which is not adequate for our applications.

During the course of the proof of the Kunneth Theorem, we will need to use the following most primitive form of Frobenius reciprocity.

Lemma 3.1. *Let K be an open subgroup of a p-adic group G. Let E be a smooth representation of K, and F a smooth representation of G. Then,*

$$\mathrm{Hom}_G[\mathrm{ind}_K^G E, F] \cong \mathrm{Hom}_K[E, F].$$

Theorem 3.1. *Let G_1 and G_2 be two p-adic groups. Let E_1, F_1 be any two smooth representations of G_1, and E_2, F_2 be any two smooth representations of G_2. Then assuming that G_1 is a reductive p-adic group, and E_1 has finite length, we have*

$$\mathrm{Ext}^i_{G_1 \times G_2}[E_1 \boxtimes E_2, F_1 \boxtimes F_2] \cong \bigoplus_{i=j+k} \mathrm{Ext}^j_{G_1}[E_1, F_1] \otimes \mathrm{Ext}^k_{G_2}[E_2, F_2].$$

Proof. If P_1 is a projective module for G_1, and P_2 a projective module for G_2, then $P_1 \boxtimes P_2$ is a projective module for $G_1 \times G_2$.

Let

$$\cdots \to P_1 \to P_0 \to E_1 \to 0,$$

$$\cdots \to Q_1 \to Q_0 \to E_2 \to 0,$$

be a projective resolution for E_1 as a G_1-module, and a projective resolution for E_2 as a G_2-module.

It follows that the tensor product of these two exact sequences:

$$\cdots \to P_1 \boxtimes Q_0 + P_0 \boxtimes Q_1 \to P_0 \boxtimes Q_0 \to E_1 \boxtimes E_2 \to 0,$$

is a projective resolution of $E_1 \boxtimes E_2$. Therefore, $\mathrm{Ext}^i_{G_1\times G_2}[E_1 \boxtimes E_2, F_1 \boxtimes F_2]$ can be calculated by taking the cohomology of the chain complex $\mathrm{Hom}_{G_1\times G_2}[\bigoplus_{i+j=k} P_i \boxtimes Q_j, F_1 \boxtimes F_2]$.

It is possible to choose a projective resolution of E_1 by $P_i = \mathrm{ind}_{K_i}^{G_1} W_i$ for finite dimensional representations W_i of compact open subgroups K_i of G_1. The existence of such a projective resolution is made possible through the construction of an equivariant sheaf on the Bruhat-Tits building of G_1 associated to the representation E_1, cf. P.Schneider and U.Stuhler [1997]. this is the step which needs G_1 to be reductive, and also requires the admissibility of E_1.

Since W_i are finite dimensional, we have the isomorphism

$$\mathrm{Hom}_{K\times G_2}[W_i \boxtimes Q_j, F_1 \boxtimes F_2] \cong \mathrm{Hom}_K[W_i, F_1] \otimes \mathrm{Hom}_{G_2}[Q_j, F_2],$$

therefore,

$$\begin{aligned}\mathrm{Hom}_{G_1\times G_2}[P_i \boxtimes Q_j, F_1 \boxtimes F_2] &= \mathrm{Hom}_{G_1\times G_2}[\mathrm{ind}_K^{G_1}(W_i) \boxtimes Q_j, F_1 \boxtimes F_2] \\ &\cong \mathrm{Hom}_{K\times G_2}[W_i \boxtimes Q_j, F_1 \boxtimes F_2] \\ &\cong \mathrm{Hom}_K[W_i, F_1] \otimes \mathrm{Hom}_{G_2}[Q_j, F_2] \\ &\cong \mathrm{Hom}_{G_1}[P_i, F_1] \otimes \mathrm{Hom}_{G_2}[Q_j, F_2].\end{aligned}$$

Thus we are able to identify the chain complex $\mathrm{Hom}_{G_1\times G_2}[\bigoplus_{i+j=k} P_i \boxtimes Q_j, F_1 \boxtimes F_2]$ as the tensor product of the chain complexes $\mathrm{Hom}_{G_1}[P_i, F_1]$ and $\mathrm{Hom}_{G_2}[Q_j, F_2]$. Now the abstract Kunneth theorem which calculates the cohomology of the tensor product of two chain complexes in terms of the cohomology of the individual chain complexes completes the proof of the theorem. □

4 Branching laws from $\mathrm{GL}_{n+1}(F)$ to $\mathrm{GL}_n(F)$

We begin by recalling the following basic result in this context, cf. Prasad [1993].

Theorem 4.1. *Given an irreducible generic representation π_1 of $\mathrm{GL}_{n+1}(F)$, and an irreducible generic representation π_2 of $\mathrm{GL}_n(F)$,*

$$\mathrm{Hom}_{\mathrm{GL}_n(F)}[\pi_1, \pi_2] = \mathbb{C}.$$

The aim of this section is to prove the following theorem which can be considered as the Euler-Poincaré version of Theorem 4.1.

Theorem 4.2. *Let π_1 be an admissible representation of $\mathrm{GL}_{n+1}(F)$ of finite length, and π_2 an admissible representation of $\mathrm{GL}_n(F)$ of finite length. Then, $\mathrm{Ext}^i_{\mathrm{GL}_n(F)}[\pi_1, \pi_2]$ are* *finite dimensional vector spaces over* $\mathbb{C}$, *and*

$$\mathrm{EP}_{\mathrm{GL}_n(F)}[\pi_1,\pi_2] = \dim \mathrm{Wh}(\pi_1)\cdot \dim \mathrm{Wh}(\pi_2),$$

where $\mathrm{Wh}(\pi_1)$, *resp.* $\mathrm{Wh}(\pi_2)$, *denotes the space of Whittaker models for* π_1, *resp.* π_2, *with respect to fixed non-degenerate characters on the maximal unipotent subgroups in* $\mathrm{GL}_{n+1}(F)$ *and* $\mathrm{GL}_n(F)$.

The proof of this theorem will be accomplished using some results of Bernstein and Zelevinsky regarding the structure of representations of $\mathrm{GL}_{n+1}(F)$ restricted to the mirabolic subgroup.

Denote by E_n the mirabolic subgroup of $\mathrm{GL}_{n+1}(F)$ consisting of matrices whose last row is equal to $(0,0,\cdots,0,1)$ and let N_{n+1} be the group of upper triangular unipotent matrices in $\mathrm{GL}_{n+1}(F)$. We will be using subgroups $\mathrm{GL}_i(F)$ of $\mathrm{GL}_{n+1}(F)$ for $i\le n+1$ always sitting at the upper left corner of $\mathrm{GL}_{n+1}(F)$. We fix a nontrivial character ψ_0 of F and let ψ_{n+1} be the character of N_{n+1} given by

$$\psi_{n+1}(u) = \psi_0(u_{1,2}+u_{2,3}+\cdots+u_{n,n+1}).$$

For a representation π of $\mathrm{GL}_{n+1}(F)$, let

$$\pi^i = \text{ the } i\text{-th derivative of } \pi,$$

which is a representation of $\mathrm{GL}_{n+1-i}(F)$. It will be important for us to note that π^i are representations of finite length of $\mathrm{GL}_{n+1-i}(F)$ if π is of finite length for $\mathrm{GL}_{n+1}(F)$.

To recall the definition of π^i, let $R_{n+1-i} = \mathrm{GL}_{n+1-i}(F)\cdot V_i$ be the subgroup of $\mathrm{GL}_{n+1}(F)$ consisting of matrices

$$\begin{pmatrix} g & v \\ 0 & z \end{pmatrix}$$

with $g\in \mathrm{GL}_{n+1-i}(F)$, $v\in M_{(n+1-i)\times i}$, $z\in N_i$. If the character ψ_i of N_i is extended to V_i by extending it trivially across $M_{(n+1-i)\times i}$, then we have

$$\pi^i = \pi_{V_i,\psi_i},$$

where π_{V_i,ψ_i} is the twisted Jacquet module of π, i.e., the maximal quotient of π on which V_i operates via the character ψ_i.

Here is a generality from Bernstein and Zelevinsky [1976], §3.5.

Proposition 4.1. *Any smooth representation* Σ *of* E_n *has a natural filtration by* $E = E_n$ *modules*

$$0=\Sigma_0\subset\Sigma_1\subset\Sigma_2\subset\cdots\subset\Sigma_{n+1}=\Sigma$$

such that

$$\Sigma_{i+1}/\Sigma_i = \mathrm{ind}_{R_i}^{E_n}(\Sigma^{n+1-i} \otimes \psi_{n+1-i}) \quad \textit{for } i = 0, \cdots, n,$$

where $R_i = \mathrm{GL}_i(F) \cdot V_{n+1-i}$ *is the subgroup of* $\mathrm{GL}_{n+1}(F)$ *consisting of*

$$\begin{pmatrix} g & v \\ 0 & z \end{pmatrix}$$

with $g \in \mathrm{GL}_i(F)$, $v \in M_{i\times(n+1-i)}$, $z \in N_{n+1-i}$, *and the character* ψ_{n+1-i} *on* N_{n+1-i} *is extended to* V_{n+1-i} *by extending it trivially across* $M_{i\times(n+1-i)}$.

The proof of the following proposition is a direct consequence of Proposition 2.8.

Proposition 4.2. *For a smooth representation* π_1 *of* $\mathrm{GL}_{n+1}(F)$, *and* π_2 *of* $\mathrm{GL}_n(F)$,

$$\mathrm{Ext}^j_{\mathrm{GL}_n(F)}[\mathrm{ind}_{R_i}^{\mathrm{GL}_n(F)}(\pi_1^{n-i+1} \otimes \psi_{n-i}), \pi_2^\vee] = \mathrm{Ext}^j_{\mathrm{GL}_i(F)}[\pi_2^{n-i}, (\pi_1^{n-i+1})^\vee].$$

Proof. Since $\mathrm{GL}_n(F) \cdot R_i = E_n$, $\mathrm{GL}_n(F) \cap R_i = \mathrm{GL}_i(F) \cdot V_{n-i}$, the restriction of $\pi_1^{n+1-i} \otimes \psi_{n+1-i}$ from R_i to $\mathrm{GL}_n(F) \cap R_i = \mathrm{GL}_i(F) \cdot V_{n-i}$ is $\pi_1^{n+1-i} \otimes \psi_{n-i}$ for any i, $0 \le i \le n$. Therefore, the proposition follows from Proposition 2.8. □

Lemma 4.1. *For any two smooth representations* V_1, V_2 *of* $\mathrm{GL}_n(F)$, $n \ge 1$, *of finite length,*

$$\mathrm{EP}_{\mathrm{GL}_n(F)}[V_1, V_2] = 0.$$

Proof. It suffices to prove the lemma assuming that both V_1 and V_2 are irreducible representations of $\mathrm{GL}_n(F)$. If the two representations V_1, V_2 were irreducible, and had different central characters, then clearly $\mathrm{Ext}^i_{\mathrm{GL}_n(F)}[V_1, V_2] = 0$ for all integers i. On the other hand, we know by Proposition 2.1(b) that for representations V_1 and V_2 of finite length of $\mathrm{GL}_n(F)$, $\mathrm{EP}_{\mathrm{GL}_n(F)}[V_1, V_2]$ is constant in a connected family, so denoting by ν the character $\nu(g) = |\det g|$ of $\mathrm{GL}_n(F)$, we have $\mathrm{EP}_{\mathrm{GL}_n(F)}[V_1, V_2] = \mathrm{EP}_{\mathrm{GL}_n(F)}[\nu^s \cdot V_1, V_2]$ for all $s \in \mathbb{C}$. Choosing s appropriately, we can change the central character of $\nu^s \cdot V_2$ to be different from V_1, and hence $\mathrm{EP}_{\mathrm{GL}_n(F)}[V_1, V_2] = \mathrm{EP}_{\mathrm{GL}_n(F)}[\nu^s \cdot V_1, V_2] = 0$. □

Proof of Theorem 4.2: Since the Euler-Poincaré characteristic is additive in exact sequences, it suffices to calculate $\mathrm{EP}_{\mathrm{GL}_n(F)}[\mathrm{ind}_{R_i}^{\mathrm{GL}_n(F)}(\pi_1^{n-i} \otimes \psi_{n-i+1}), \pi_2]$ which by Proposition 2.8 is $\mathrm{EP}_{\mathrm{GL}_i(F)}[(\pi_2^{n-i})^\vee, (\pi_1^{n-i+1})^\vee]$, which by Lemma 4.1 above is 0 unless $i = 0$. (Note that in $\mathrm{EP}_{\mathrm{GL}_i(F)}[(\pi_2^{n-i})^\vee, (\pi_1^{n-i+1})^\vee]$, both the representations involved are admissible representations of $\mathrm{GL}_i(F)$.) For $i = 0$, note that we are dealing with $\mathrm{GL}_0(F) = 1$, and the representations involved are $(\pi_1^\vee)^{n+1}$ and $(\pi_2^\vee)^n$, which are nothing but the space of Whittaker models of $\pi_1^\vee$ and $\pi_2^\vee$. Since for representations V_1, V_2 of the group $\mathrm{GL}_0(F) = 1$, $\mathrm{EP}[V_1, V_2] = \dim \mathrm{Hom}[V_1, V_2] = \dim V_1 \cdot \dim V_2$, this completes the proof of the theorem.

Remark 4.1. One knows, cf. Prasad [1993], that there are irreducible generic representations of $\mathrm{GL}_3(F)$ which have the trivial representation of $\mathrm{GL}_2(F)$ as a quotient; similarly, there are irreducible nongeneric representations of $\mathrm{GL}_3(F)$ with irreducible generic representations of $\mathrm{GL}_2(F)$ as a quotient. For such pairs (π_1, π_2) of representations, it follows from Theorem 4.2 that $\mathrm{EP}_{\mathrm{GL}_2(F)}[\pi_1, \pi_2] = 0$, whereas $\mathrm{Hom}_{\mathrm{GL}_2(F)}[\pi_1, \pi_2] \neq 0$. Therefore, for such pairs (π_1, π_2) of irreducible representations, we must have $\mathrm{Ext}^i_{\mathrm{GL}_2(F)}[\pi_1, \pi_2] \neq 0$, for some $i > 0$.

5 Conjectural vanishing of Ext groups for generic representations

The following conjecture seems to be at the root of why the simple and general result of previous section on Euler-Poincaré characteristic translates into a simple result about Hom spaces for generic representations. The author has not managed to prove it in any generality. There is a recent preprint by Chan and Savin, cf. Chan and Savin [2017] dealing with some cases of this conjecture.

Conjecture 5.1. *Let π_1 be an irreducible generic representation of $\mathrm{GL}_{n+1}(F)$, and π_2 an irreducible generic representation of $\mathrm{GL}_n(F)$. Then,*

$$\mathrm{Ext}^i_{\mathrm{GL}_n(F)}[\pi_1, \pi_2] = 0, \quad \text{for all} \quad i > 0.$$

Remark 5.1. By Remark 4.1, one cannot remove the genericity condition for either π_1 or π_2 in the above conjecture. In particular, one cannot expect that a generic representation of $\mathrm{GL}_{n+1}(F)$ when restricted to $\mathrm{GL}_n(F)$ is a projective representation in $\mathcal{R}(\mathrm{GL}_n(F))$ although this is the case for supercuspidal representations of $\mathrm{GL}_{n+1}(F)$. The paper Chan and Savin [ibid.] proves that the part of the Steinberg representation of $\mathrm{GL}_{n+1}(F)$ (denoted St_{n+1}) in the Iwahori component of the Bernstein decomposition for $\mathcal{R}(GL_n(F))$ is a projective module. There is no doubt then that St_{n+1} when restricted to $\mathrm{GL}_n(F)$ is a projective representation in $\mathcal{R}(\mathrm{GL}_n(F))$, therefore

$$\mathrm{Ext}^i_{\mathrm{GL}_n(F)}[\mathrm{St}_{n+1}, \pi_2] = 0 \quad \text{for} \quad i > 0$$

for any irreducible representation π_2 of $\mathrm{GL}_n(F)$. As a consequence, it will follow from the duality theorem of Schneider-Stuhler, cf. Theorem 8.1 below, that St_{n+1} contains no irreducible submodule of $\mathrm{GL}_n(F)$.

Towards checking the validity of this conjecture in some cases, note that by Theorem 4.1 and Theorem 4.2, under the hypothesis of the conjecture,

$$\dim \mathrm{Hom}_{\mathrm{GL}_n(F)}[\pi_1, \pi_2] = 1, \quad \text{and} \quad \mathrm{EP}[\pi_1, \pi_2] = 1.$$

It follows that if we already knew that $\mathrm{Ext}^i_{\mathrm{GL}_n(F)}[\pi_1,\pi_2]=0,\ \ i>1$, then we will also know that, $\mathrm{Ext}^1_{\mathrm{GL}_n(F)}[\pi_1,\pi_2]=0$, and the conjecture will be proved for such representations.

It is easy to see that if π_1 or π_2 is cuspidal, then $\mathrm{Ext}^i_{\mathrm{GL}_n(F)}[\pi_1,\pi_2]=0$ for $i>1$. We do one slightly less obvious case when π_1 arises as a subquotient of a principal series representation induced from a cuspidal representation of a maximal parabolic in $\mathrm{GL}_{n+1}(F)$.

It follows from Corollary III.3.3(i) of P.Schneider and U.Stuhler [1997] that if π_1 arises from a cuspidal representation of a maximal parabolic in $\mathrm{GL}_{n+1}(F)$, it has a projective resolution of length 1 in the category $\mathcal{R}_\chi(G)$ of smooth representations of $G=\mathrm{GL}_{n+1}(F)$ with central character χ. It is easy to see that a projective module in $\mathcal{R}_\chi(\mathrm{GL}_{n+1}(F))$ when considered as a representation of $\mathrm{GL}_n(F)$ is a projective module in $\mathcal{R}(\mathrm{GL}_n(F))$, cf. Proposition 3.2 in M.Nori and Prasad [2017]. This proves vanishing of $\mathrm{Ext}^i_{\mathrm{GL}_n(F)}[\pi_1,\pi_2]=0$ for $i>1$, hence also of $\mathrm{Ext}^1_{\mathrm{GL}_n(F)}[\pi_1,\pi_2]$.

This takes care of $G=\mathrm{GL}_{n+1}(F)$ for $n+1\le 3$, except that for $\mathrm{GL}_3(F)$ if both π_1 and π_2 arise as components of principal series representations induced from their Borel subgroups then there is a possibility of having nontrivial $\mathrm{Ext}^2_{\mathrm{GL}_2(F)}[\pi_1,\pi_2]$. By the duality theorem of Schneider-Stuhler, cf. Theorem 8.1 below, we will have, $\mathrm{Hom}_{\mathrm{GL}_2(F)}[D\pi_2,\pi_1]\neq 0$ (where $D\pi_2$ is the Aubert-Zelevinsky involution of π_2). The following proposition takes care of this.

Proposition 5.1. *Let π_1 be an irreducible generic representation of $\mathrm{GL}_3(F)$, and π_2 any irreducible representation of $\mathrm{GL}_2(F)$ which is not a twist of the Steinberg representation of $\mathrm{GL}_2(F)$. Then*

$$\mathrm{Hom}_{\mathrm{GL}_2(F)}[\pi_2,\pi_1]=0.$$

We will not prove this proposition here but discuss two propositions which deal with all but a few cases of the proposition above. The cases left out by the next two propositions can be handled by the Mackey restriction of an explicit principal series (especially using that different inducing data can give rise to the same principal series).

Proposition 5.2. *Let $H_1\subset H$ be p-adic groups with $Z=F^\times$ contained in the center of H with $Z\cap H_1=\{1\}$. Suppose μ is a smooth representation of H_1, and π_2 an irreducible admissible representation of H. Then $\mathrm{Hom}_H[\pi_2,\mathrm{ind}_{H_1}^H(\mu)]=0$.*

Proof. Note that for each $x\in H/H_1$, restriction of functions from H to $(Z=F^\times)\cdot x$ gives rise to $F^\times$-equivariant maps

$$\mathrm{ind}_{H_1}^H(\mu)\longrightarrow \mathcal{S}(F^\times),$$

which can be assumed to be nonzero for any $f\in\mathrm{ind}_{H_1}^H(\mu)$ by choosing $x\in H/H_1$ appropriately.

Therefore if $\mathrm{Hom}_H[\pi_2, \mathrm{ind}_{H_1}^H(\mu)] \neq 0$ choosing $x \in H/H_1$ appropriately, we get a nonzero map from $\pi_2 \longrightarrow \mathcal{S}(F^\times)$ which is ω-equivariant where ω is the central character of π_2. Since $\mathcal{S}(F^\times)$ has no functions on which $F^\times$ operates by a character, the proof of the proposition is complete. □

This lemma when combined with the Bernstein-Zelevinsky filtration in Proposition 4.1 has the following as an immediate consequence.

Proposition 5.3. *Let π_1 be any smooth representation of $\mathrm{GL}_{n+1}(F)$ of finite length, and π_2 any irreducible representation of $\mathrm{GL}_n(F)$. Then if*

$$\mathrm{Hom}_{\mathrm{GL}_n(F)}[\pi_2, \pi_1] \neq 0,$$

then π_2 appears a submodule of $J_{n,1}(\pi_1)$ where $J_{n,1}$ denotes the un-normalized Jacquet module with respect to the $(n,1)$ parabolic in $\mathrm{GL}_{n+1}(F)$ considered as a module for $\mathrm{GL}_n(F) \subset \mathrm{GL}_n(F) \times \mathrm{GL}_1(F)$; in particular, if $J_{n,1}(\pi_1) = 0$, then there are no nonzero $\mathrm{GL}_n(F)$-submodules in π_1.

Proof. The proof of the proposition is an immediate consequence of the observation that the Bernstein-Zelevinsky filtration in Proposition 4.1 when restricted to $\mathrm{GL}_n(F)$ gives rise to representations of $\mathrm{GL}_n(F)$ induced from subgroups $H_i \subset \mathrm{GL}_n(F)$ with $H_i \cap \{Z(\mathrm{GL}_n(F)) = F^\times\} = \{1\}$ except in the case when $H_i = \mathrm{GL}_n(F)$ which corresponds to the Jacquet module $J_{n,1}(\pi_1)$. □

6 Finite dimensionality of Ext groups

In this section we prove the finite dimensionality of Ext-groups in the case of $\mathrm{SO}_n(F) \subset \mathrm{SO}_{n+1}(F)$. The proof will have an inductive structure, and will involve Bessel models in the inductive step, so we begin by recalling the concept of Bessel models.

Let $V = X + D + W + Y$ be a quadratic space over the non-archimedean local field F with X and Y totally isotropic subspaces of V in duality with each other under the underlying bilinear form, D an anisotropic line in V, and W a quadratic subspace of V. Suppose that the dimension of X is k; fix a complete flag $\langle e_1 \rangle \subset \langle e_1, e_2 \rangle \subset \cdots \subset \langle e_1, e_2, \cdots, e_k \rangle = X$ of isotropic subspaces in X. Let $P = MU$ be the parabolic subgroup in $\mathrm{SO}(V)$ stabilizing this flag, with $M = \mathrm{GL}_1(F)^k \times \mathrm{SO}(D+W)$. For $W \subset V$ a codimension $2k+1$ subspace as above, the subgroup $\mathrm{SO}(W) \cdot U$ which is uniquely defined up to conjugacy by $\mathrm{SO}(V)$ makes frequent appearance in this work, as well as in other works on classical groups. We call this subgroup as the *Bessel subgroup*, and denote it as $\mathrm{Bes}(V, W) = \mathrm{SO}(W) \cdot U$.

Let $P_X = M_X \cdot U_X$ be the maximal parabolic of $\mathrm{SO}(V)$ stabilizing X. We have $M_X \cong \mathrm{GL}(X) \cdot \mathrm{SO}(W + D)$, and U_X sits in the exact sequence,

$$1 \to \Lambda^2 X \to U_X \to X \otimes (D + W) \to 1.$$

Let $\ell : U \to F$ be a linear form such that

1. its restriction to each of the simple root spaces in $\mathrm{GL}(X)$ defined by the flag $\langle e_1 \rangle \subset \langle e_1, e_2 \rangle \subset \cdots \subset \langle e_1, e_2, \cdots, e_k \rangle = X$ of isotropic subspaces in X is non-trivial;
2. its restriction to the unipotent radical of the parabolic $P_X = M_X U_X$ in $\mathrm{SO}(V)$ stabilizing X is trivial on the subgroup of U_X which is $\Lambda^2 X$;
3. and on the quotient of U_X by $\Lambda^2 X$ which can be identified to $(D + W) \otimes X$, ℓ is given by the tensor product of a linear form on $D + W$ which is trivial on W, and a linear form on X which is trivial on the subspace $\langle e_1, e_2, \cdots, e_{k-1} \rangle$.

Composing the linear form $\ell : U \to F$ with a nontrivial character $\psi_0 : F \to \mathbb{C}^\times$, we get a character $\psi : U \to \mathbb{C}^\times$. This character $\psi : U \to \mathbb{C}^\times$ depends only on $W \subset V$ a nondegenerate subspace of V of odd codimension, such that the quadratic space V/W is split, and is independent of all choices made along the way (including that of the character ψ_0). The character ψ of U is invariant under $\mathrm{SO}(W)$. For any representation σ of $\mathrm{SO}(W)$, $\mathrm{Bes}(V, W) = \mathrm{SO}(W) \cdot U$ comes equipped with the representation which is σ on $\mathrm{SO}(W)$, and ψ on U; since ψ is fixed when considering representations of $\mathrm{Bes}(V, W) = \mathrm{SO}(W) \cdot U$, we denote this representation of $\mathrm{Bes}(V, W) = \mathrm{SO}(W) \cdot U$ as σ itself or sometimes as $\sigma \otimes \psi$.

The Bessel models of a smooth representation π of $\mathrm{SO}(V)$ are irreducible admissible representations σ of $\mathrm{SO}(W)$ such that the following isomorphic spaces are nonzero:

$$\begin{aligned}\mathrm{Hom}_{\mathrm{Bes}(V,W)}[\pi, \sigma] &\cong \mathrm{Hom}_{\mathrm{SO}(V)}\left[\pi, \mathrm{Ind}_{\mathrm{Bes}(V,W)}^{\mathrm{SO}(V)}(\sigma)\right] \\ &\cong \mathrm{Hom}_{\mathrm{SO}(V)}\left[\mathrm{ind}_{\mathrm{Bes}(V,W)}^{\mathrm{SO}(V)}(\sigma^\vee), \pi^\vee\right].\end{aligned}$$

When W is a codimension one subspace of V, then $\mathrm{Bes}(V, W) = \mathrm{SO}(W)$, and the notion of a Bessel model is simply that of restriction from $\mathrm{SO}(V)$ to $\mathrm{SO}(W)$, whereas when $\dim(W) = 0, 1$, then the notion of a Bessel model is nothing but that of the Whittaker model (for a particular character of the maximal unipotent subgroup of $\mathrm{SO}(V)$ if $\dim(W) = 1$).

We can define the higher Ext versions of the Bessel models as one of the following isomorphic spaces:

$$\mathrm{Ext}^i_{\mathrm{Bes}(V,W)}[\pi,\sigma] \cong \mathrm{Ext}^i_{\mathrm{SO}(V)}\left[\pi, \mathrm{Ind}^{\mathrm{SO}(V)}_{\mathrm{Bes}(V,W)}(\sigma)\right]$$
$$\cong \mathrm{Ext}^i_{\mathrm{SO}(V)}\left[\mathrm{ind}^{\mathrm{SO}(V)}_{\mathrm{Bes}(V,W)}(\sigma^\vee), \pi^\vee\right].$$

The following proposition whose proof we will omit is analogous to that of Theorem 15.1 of Gan, Gross, and Prasad [2012]. It allows one to prove finite dimensionality of $\mathrm{Ext}^i_{\mathrm{Bes}(V,W_0)}[\pi,\sigma]$ if we know the finite dimensionality of $\mathrm{Ext}^i_{\mathrm{SO}(W)}[\pi,\sigma']$ where W is a codimension one subspace in the quadratic space V, and σ' an irreducible representation of $\mathrm{SO}(W)$.

Proposition 6.1. *Let $W \subset V$ be a nondegenerate quadratic subspace of codimension 1 over a non-archimedean local field F. Suppose that*

$$W = Y_k \oplus W_0 \oplus Y_k^\vee$$

and

$$V = Y_k \oplus V_0 \oplus Y_k^\vee,$$

with Y_k and $Y_k^\vee$ isotropic subspaces and $W_0 \subset V_0$ nondegenerate quadratic spaces with W_0 a subspace of codimension one in V_0. Let $P_W(Y_k)$ be the parabolic in $\mathrm{SO}(W)$ stabilizing Y_k with Levi subgroup

$$M = \mathrm{GL}(Y_k) \times \mathrm{SO}(W_0)$$

For an irreducible supercuspidal representation τ of $\mathrm{GL}(Y_k)$ and an irreducible admissible representation π_0 of $\mathrm{SO}(W_0)$, let

$$\tau \rtimes \pi_0 = \mathrm{Ind}^{\mathrm{SO}(W)}_{P_W(Y_k)}(\tau \boxtimes \pi_0)$$

be the corresponding (un-normalized) principal series representation of $\mathrm{SO}(W)$. Let π be an irreducible admissible representation $\mathrm{SO}(V)$ which does not belong to the Bernstein component associated to $(\mathrm{GL}(Y_k) \times \mathrm{SO}(V_0), \tau \boxtimes \mu)$ for any irreducible representation μ of $\mathrm{SO}(V_0)$. Then

$$\mathrm{Ext}^i_{\mathrm{SO}(W)}[\pi, \tau \rtimes \pi_0] \cong \mathrm{Ext}^i_{\mathrm{Bes}(V,W_0)}[\pi,\pi_0].$$

Corollary 6.1. *With the notation as above, if $\mathrm{Ext}^i_{\mathrm{SO}(W)}[\pi, \tau \rtimes \pi_0]$ are finite dimensional, then so are $\mathrm{Ext}^i_{\mathrm{Bes}(V,W_0)}[\pi,\pi_0]$.*

Proof. It suffices to observe that given π_0, there is a representation π of $\mathrm{SO}(V)$ which does not belong to the Bernstein component associated to $(\mathrm{GL}(Y_k) \times \mathrm{SO}(V_0), \tau \boxtimes \mu)$ for any irreducible representation μ of $\mathrm{SO}(V_0)$. □

We now come to the proof of finite dimensionality of the Ext groups.

Theorem 6.1. *Let $V = X + D + W + Y$ be as at the beginning of the section, a quadratic space over the non-archimedean local field F with W a quadratic subspace of codimension $2k+1$. Then for any irreducible admissible representation π of $\mathrm{SO}(V)$ and irreducible admissible representation σ of $\mathrm{SO}(W)$, $\mathrm{Ext}^i_{\mathrm{Bes}(V,W)}[\pi,\sigma]$ are finite dimensional vector spaces over $\mathbb{C}$ for all $i \geq 0$.*

Proof. The proof of this theorem will be by induction on the dimension of V. We thus assume that for any quadratic spaces $\mathcal{W} \subset \mathcal{V}$ with $\dim(\mathcal{V}) < \dim(V)$ (with $\mathcal{V}/\mathcal{W}$ a split quadratic space of odd dimension), and for any irreducible admissible representation π of $\mathrm{SO}(\mathcal{V})$ and irreducible admissible representation σ of $\mathrm{SO}(\mathcal{W})$,

$$\mathrm{Ext}^i_{\mathrm{Bes}(\mathcal{V},\mathcal{W})}[\pi,\sigma]$$

are finite dimensional vector spaces over $\mathbb{C}$ for all $i \geq 0$.

We begin by proving the theorem for a principal series representation of $\mathrm{SO}(V)$ induced from an irreducible representation of a maximal parabolic subgroup. By the previous proposition, we need only prove the finite dimensionality of $\mathrm{Ext}^i_{\mathrm{SO}(V')}[\pi,\pi']$ where V' is a codimension one subspace of V, and π' is an irreducible, admissible representation of $\mathrm{SO}(V')$.

Much of the proof below closely follows the paper Moeglin and J.-L.Waldspurger [2012], where they have to do much harder work to precisely analyze $\mathrm{Hom}_{\mathrm{SO}(V')}[\pi,\pi']$.

Assume that the dimension of V is $n+1$, and that V' is a subspace of dimension n. Let $V = X + V_0 + Y$ with X and Y totally isotropic subspaces of V of dimension m, and in perfect pairing with each other. Let P be the maximal parabolic subgroup of $\mathrm{SO}(V)$ stabilizing X. Let $M = \mathrm{GL}(X) \times \mathrm{SO}(V_0)$ be a Levi subgroup of P, $\pi_0 \otimes \sigma_0$ an irreducible representation of M realized on the space $E_{\pi_0} \otimes E_{\sigma_0}$, and $\pi = \pi_0 \rtimes \sigma_0$ the corresponding principal series representation of $\mathrm{SO}(V)$. Denote by E_π the space of function on $\mathrm{SO}(V)$ with values in $E_{\pi_0} \otimes E_{\sigma_0}$ verifying the usual conditions under left translation by $P(F)$ for defining the principal series representation $\pi = \pi_0 \rtimes \sigma_0$ of $\mathrm{SO}(V)$.

To understand the restriction of the principal series $\pi = \pi_0 \rtimes \sigma_0$ to $\mathrm{SO}(V')$, we need to analyze the orbits of $\mathrm{SO}(V')$ on $P(F)\backslash \mathrm{SO}(V)$. To every $g \in P(F)\backslash \mathrm{SO}(V)$, one can associate an isotropic subspace $g^{-1}(X)$ of V. Let $\mathcal{U}$ be the set of $g \in P(F)\backslash \mathrm{SO}(V)$ such that $\dim(g^{-1}(X) \cap V') = m-1$, and let $\mathcal{X}$ be the set of $g \in P(F)\backslash \mathrm{SO}(V)$ such that $\dim(g^{-1}(X) \cap V') = m$. Then $\mathcal{U}$ is an open subset of $P(F)\backslash \mathrm{SO}(V)$ which is a single orbit under $\mathrm{SO}(V')$, and $\mathcal{X}$ is a closed subset of $P(F)\backslash \mathrm{SO}(V)$ which is a single orbit under $\mathrm{SO}(V')$ unless n is even, and $n = 2m$ in which case there are two orbits in $\mathcal{X}$ under $\mathrm{SO}(V')$.

Denote by $E_{\pi,\mathcal{U}}$ the subspace of functions in E_π with support in $\mathcal{U}$, and denote by $E_{\pi,\mathcal{X}}$ the space $E_\pi/E_{\pi,\mathcal{U}}$. The spaces $E_{\pi,\mathcal{U}}$ and $E_{\pi,\mathcal{X}}$ are invariant under $\mathrm{SO}(V')$, and we have an exact sequence of $\mathrm{SO}(V')$-modules,

$$0 \to E_{\pi,\mathfrak{U}} \to E_\pi \to E_{\pi,\mathfrak{X}} \to 0.$$

To prove the finite dimensionality of Ext groups $\mathrm{Ext}^i_{\mathrm{SO}(V')}[E_\pi, \pi']$, it suffices to prove similar finite dimensionality theorems for the Ext groups involving the $\mathrm{SO}(V')$-modules $E_{\pi,\mathfrak{U}}$ and $E_{\pi,\mathfrak{X}}$. We analyze the two terms separately.

For analyzing $E_{\pi,\mathfrak{X}}$, we assume (after conjugation by $\mathrm{SO}(V)$) that both X and Y are contained in V'. Thus, $V' = X + V_0' + Y$ with $V_0' = V' \cap V_0$. It can be seen that,

$$E_{\pi,\mathfrak{X}} = \pi_0|.|^{1/2} \times \sigma_0|_{\mathrm{SO}(V_0')}.$$

By Theorem 2.1 (the second adjointness theorem of Bernstein),

$$\mathrm{Ext}^i_{\mathrm{SO}(V')}[E_{\pi,\mathfrak{X}}, \pi'] = \mathrm{Ext}^i_M[\pi_0|.|^{1/2} \boxtimes \sigma_0|_{\mathrm{SO}(V_0')}, \pi'_{N^-}],$$

where $M = \mathrm{GL}(X) \times \mathrm{SO}(V_0')$.

The proof of the finite dimensionality of $\mathrm{Ext}^i_{\mathrm{SO}(V')}[E_{\pi,\mathfrak{X}}, \pi']$ now follows from the induction hypothesis according to which the theorem was supposed to be known for $\mathrm{SO}(V_0') \subset \mathrm{SO}(V_0)$, besides the fact that π'_{N^-}, the Jacquet module with respect to the opposite parabolic $P^- = MN^-$ is an admissible representation of $M = \mathrm{GL}(X) \times \mathrm{SO}(V_0')$, hence has a finite filtration by tensor product of irreducible representations of $\mathrm{GL}(X)$ and $\mathrm{SO}(V_0')$, and then an application of the Kunneth theorem.

We now move on to $E_{\sigma,\mathfrak{U}}$. In this case, after conjugation by $\mathrm{SO}(V)$, we will be in the situation,

$$V' = X' + D' + V_0 + Y',$$

where X' and Y' are totally isotropic subspaces of V' of dimension $(m-1)$, and D', V_0, $X' + Y'$ are non-degenerate quadratic spaces. Let $X' = \{e_1, \cdots, e_{m-1}\}$, and $Y' = \{f_1, \cdots, f_{m-1}\}$. Let $V_k' = X_{k-1}' + D' + V_0 + Y_{k-1}'$, where $X_{k-1}' = \{e_{m-k+1}, \cdots, e_{m-1}\}$, and $Y_{k-1}' = \{f_{m-k+1}, \cdots, f_{m-1}\}$, each of dimension $(k-1)$ for $k = 1, \cdots, m$, and let $G_k' = \mathrm{SO}(V_k')$.

Using the filtration of the representation π_0 of $\mathrm{GL}(X)$ restricted to its mirabolic subgroup given by Proposition 4.1 in terms of the derivatives $\pi_0^k = \Delta^k(\pi_0)$, Moeglin and J.-L.Waldspurger [ibid.] obtain a filtration,

$$0 = \mu_{m+1} \subset \mu_m \subset \mu_{m-1} \cdots \subset \mu_1 = E_{\sigma,\mathfrak{U}},$$

with,

$$\mu_k/\mu_{k+1} \cong \Delta^k(\pi_0) \rtimes \mu_k',$$

as modules for $\mathrm{SO}(V')$; the representation $\Delta^k(\pi_0) \rtimes \mu'_k$ is a principal series representation of $\mathrm{SO}(V')$ induced from a parabolic $P_k = M_k N_k$ with Levi subgroup $M_k = GL_{m-k}(F) \times G'_k$, and where

$$\mu'_k = \mathrm{ind}_{\mathrm{Bes}(V'_k, V_0)}^{G'_k}(\sigma_0),$$

By Theorem 2.1,

$$\mathrm{Ext}^i_{\mathrm{SO}(V')}[\mu_k/\mu_{k+1}, \pi'] = \mathrm{Ext}^i_{\mathrm{SO}(V')}[\Delta^k(\pi_0) \rtimes \mu'_k, \pi'] \cong \mathrm{Ext}^i_{M_k}[\Delta^k(\pi_0) \boxtimes \mu'_k, \pi'_{N_k^-}],$$

with $M_k = GL_{m-k}(F) \times G'_k$, a Levi subgroup in $\mathrm{SO}(V')$. Once again Kunneth theorem implies the finite dimensionality of the Ext groups,

$$\mathrm{Ext}^i_{M_k}[\Delta^k(\pi_0) \boxtimes \mu'_k, \pi'_{N_k^-}].$$

Having proved the theorem for principal series representations of $\mathrm{SO}(V)$ induced from maximal parabolics, the next lemma proves the theorem in general. □

Lemma 6.1. *Let V be a quadratic space over the non-archimedean local field F with W a quadratic subspace of codimension 1. If for any principal series representation Ps of $\mathrm{SO}(V)$ induced from a maximal parabolic and any irreducible admissible representation σ of $\mathrm{SO}(W)$, $\mathrm{Ext}^i_{\mathrm{SO}(W)}[Ps, \sigma]$ are finite dimensional vector spaces over $\mathbb{C}$ for all $i \geq 0$, then for any irreducible representation π of $\mathrm{SO}(V)$ and any irreducible admissible representation σ of $\mathrm{SO}(W)$, $\mathrm{Ext}^i_{\mathrm{SO}(W)}[\pi, \sigma]$ are finite dimensional vector spaces over $\mathbb{C}$ for all $i \geq 0$.*

Proof. By Proposition 2.3, if π is a supercuspidal representation of $\mathrm{SO}(V)$, its restriction to $\mathrm{SO}(W)$ is a projective object in $\mathfrak{R}(SO(W))$. Therefore $\mathrm{Ext}^i_{SO(W)}[\pi, \sigma]$ are zero for $i > 0$, and $\mathrm{Ext}^0_{SO(W)}[\pi, \sigma] = \mathrm{Hom}_{SO(W)}[\pi, \sigma]$ is finite dimensional.

Assume now that π is not a supercuspidal representation, and write π as a quotient of a principal series representation induced from a representation of a maximal parabolic subgroup of $\mathrm{SO}(V)$. We thus have an exact sequence,

$$0 \to \lambda \to Ps \to \pi \to 0.$$

This gives rise to a long exact sequence,

$$0 \to \mathrm{Hom}_{\mathrm{SO}(W)}[\pi, \sigma] \to \mathrm{Hom}_{\mathrm{SO}(W)}[Ps, \sigma] \to \mathrm{Hom}_{\mathrm{SO}(W)}[\lambda, \sigma] \to$$
$$\to \mathrm{Ext}^1_{\mathrm{SO}(W)}[\pi, \sigma] \to \mathrm{Ext}^1_{\mathrm{SO}(W)}[Ps, \sigma] \to \mathrm{Ext}^1_{\mathrm{SO}(W)}[\lambda, \sigma] \to \mathrm{Ext}^2_{\mathrm{SO}(W)}[\pi, \sigma] \to \cdots$$

Since we know that all Hom spaces in the above exact sequence are finite dimensional, and also $\mathrm{Ext}^1_{\mathrm{SO}(W)}[Ps, \sigma]$ is given to be finite dimensional, we get the finite dimensionality of $\mathrm{Ext}^1_{\mathrm{SO}(W)}[\pi, \sigma]$ for any irreducible representation π of $\mathrm{SO}(V)$. This implies finite dimensionality of $\mathrm{Ext}^1_{\mathrm{SO}(W)}[\pi, \sigma]$ for any finite length representation π of $\mathrm{SO}(V)$. Armed with this finite dimensionality of $\mathrm{Ext}^1_{\mathrm{SO}(W)}[\pi, \sigma]$ for any finite length representation π of $\mathrm{SO}(V)$, and with the knowledge that $\mathrm{Ext}^2_{\mathrm{SO}(W)}[Ps, \sigma]$ is given to be finite dimensional, we get the finite dimensionality of $\mathrm{Ext}^2_{\mathrm{SO}(W)}[\pi, \sigma]$ for any irreducible representation π of $\mathrm{SO}(V)$, and similarly we get the finite dimensionality of $\mathrm{Ext}^i_{\mathrm{SO}(W)}[\pi, \sigma]$ for any irreducible representation π of $\mathrm{SO}(V)$, and any $i \geq 0$. □

The proof of Theorem 6.1 uses Theorem 3.1 (Kunneth theorem) for representations of $\mathrm{GL}_m(F) \times G'_k$. Since for any two irreducible representations V, V' of $\mathrm{GL}_m(F)$, $\mathrm{EP}_{\mathrm{GL}_m(F)}[V, V'] = 0$ unless $m = 0$ cf. Lemma 4.1, we obtain the following corollary of the proof of the theorem.

Corollary 6.2. *For a principal series representation $\pi = \pi_0 \rtimes \sigma_0$ of $\mathrm{SO}(V)$ where σ_0 is an admissible representation of $\mathrm{SO}(W)$, and π' is an admissible representation of $\mathrm{SO}(V')$ where $W \subset V' \subset V$ with V' a nondegenerate codimension 1 subspace of the quadratic space V with $\dim(V') - \dim(W) = 2m - 1$,*

$$\mathrm{EP}_{\mathrm{SO}(V')}[\pi, \pi'] = \mathrm{EP}_{\mathrm{Bes}(V', W)}[\pi', \sigma_0] \cdot \dim \mathrm{Wh}(\pi_0).$$

Definition: A finite length representation π of a classical group will be called a *full principal series* if it is irreducible and supercuspidal, or is of the form $\pi = \pi_0 \rtimes \sigma_0$ with both π_0 and σ_0 irreducible, and σ_0 supercuspidal.

The following corollary is a consequence of the previous corollary together with the fact that if σ is a cuspidal representation of $\mathrm{SO}(W)$, then $\sigma \otimes \psi$ is an injective module for $\mathrm{Bes}(V, W)$.

Corollary 6.3. *Let π be a finite length representation of $\mathrm{SO}(V)$, and π' of $\mathrm{SO}(V')$ where $V' \subset V$ is a nondegenerate codimension 1 subspace of the quadratic space V. Assume that π is a full principal series, and π' is an irreducible representation of $\mathrm{SO}(V')$. Then, $\mathrm{EP}_{\mathrm{SO}(V')}[\pi, \pi']$ is either 0 or 1. If $\pi = \pi_0 \rtimes \sigma_0$ of $\mathrm{SO}(V)$ where σ_0 is an admissible representation of $\mathrm{SO}(W)$ with $\dim W \leq 1$, $\mathrm{EP}_{\mathrm{SO}(V')}[\pi, \pi'] = \dim \mathrm{Wh}(\pi) \cdot \dim \mathrm{Wh}(\pi')$ (if $\dim W = 1$, $\mathrm{Wh}(\pi')$ is for a particular character of a maximal unipotent subgroup of $\mathrm{SO}(V')$).*

Remark 6.1. In the previous corollary, we see a large number of cases when the Euler-Poincaré characteristic is 0 or 1. Is there a multiplicity one result for EP, or for Ext^i?

7 An integral formula of Waldspurger, and a conjecture on E-P

In this section we review an integral formula of Waldspurger which we then propose to be the integral formula for the Euler-Poincaré pairing for $\mathrm{EP}_{\mathrm{Bes}(V,W)}[\sigma, \sigma']$ for σ any finite length representation of $\mathrm{SO}(V)$, and σ' any finite length representation of $\mathrm{SO}(W)$, where V and W are quadratic spaces over F with $V = X + D + W + Y$ with W a quadratic subspace of V of codimension $2k + 1$ with X and Y totally isotropic subspaces of V in duality with each other under the underlying bilinear form, and D an anisotropic line in V. Let $Z = X + Y$.

Let $\underline{\mathfrak{T}}$ denote the set of elliptic tori T in $\mathrm{SO}(W)$ such that there exist quadratic subspaces W_T, W_T' of W such that:

1. $W = W_T \oplus W_T'$, and $V = W_T \oplus W_T' \oplus D \oplus Z$.
2. $\dim(W_T)$ is even, and $\mathrm{SO}(W_T')$ and $\mathrm{SO}(W_T' \oplus D \oplus Z)$ are quasi-split.
3. T is a maximal (elliptic) torus in $\mathrm{SO}(W_T)$.

Clearly the group $\mathrm{SO}(W)$ operates on $\underline{\mathfrak{T}}$. Let $\mathfrak{T}$ denote a set of orbits for this action of $\mathrm{SO}(W)$ on $\underline{\mathfrak{T}}$. For our purposes we note the most important elliptic torus $T = \langle e \rangle$ corresponding to $W_T = 0$.

For σ an admissible representation of $\mathrm{SO}(V)$ of finite length, define a function $c_\sigma(t)$ for regular elements of a torus T belonging to $\underline{\mathfrak{T}}$ by the germ expansion of the character $\theta_\sigma(t)$ of σ on the centralizer of t in the Lie algebra of $\mathrm{SO}(V)$, and picking out 'the' leading term. The semi-simple part of the centralizer of t in the Lie algebra of V is the Lie algebra of $\mathrm{SO}(W_T' \oplus D \oplus Z)$ which, if $W_T' \oplus D \oplus Z$ has odd dimension, has a unique conjugacy class of regular nilpotent element, but if $W_T' \oplus D \oplus Z$ has even dimension, then although there are several regular nilpotent conjugacy classes, there is one which is 'relevant', and is what is used to define $c_\sigma(t)$. Similarly, for σ' an admissible representation of $\mathrm{SO}(W)$ of finite length, one defines a function $c_{\sigma'}(t)$ for regular elements of a torus T belonging to $\underline{\mathfrak{T}}$ by the germ expansion of the character $\theta_{\sigma'}(t)$ of σ'.

Define a function Δ_T on an elliptic torus T belonging to $\underline{\mathfrak{T}}$ with $W = W_T \oplus W_T'$, by $\Delta(t) = |\det(1-t)|_{W_T}|_F$, and let D^H denote the discriminant function on $H(F)$. For a torus T in H, define the Weyl group $W(H,T)$ by the usual normalizer divided by the centralizer: $W(H,T) = N_{H(F)}(T)/Z_{H(F)}(T)$.

The following theorem is proved by Waldspurger in J.-L.Waldspurger [2010] and J.-L.Waldspurger [2012b].

Theorem 7.1. *Let $V = X + D + W + Y$ be a quadratic space over the non-archimedean local field F with W a quadratic subspace of codimension $2k+1$ as above. Then for any irreducible admissible representation σ of $\mathrm{SO}(V)$ and irreducible admissible representation σ' of $\mathrm{SO}(W)$,*

$$\sum_{T \in \mathfrak{T}} |W(H,T)|^{-1} \int_{T(F)} c_\sigma(t) c_{\sigma'}(t) D^H(t) \Delta^k(t) dt,$$

is a finite sum of absolutely convergent integrals. (The Haar measure on $T(F)$ is normalized to have volume 1.) If either σ is a supercuspidal representation of $\mathrm{SO}(V)$*, and σ' is arbitrary irreducible admissible representation of* $\mathrm{SO}(W)$*, or both σ and σ' are tempered representations, then*

$$\dim \mathrm{Hom}_{\mathrm{Bes}(V,W)}[\sigma, \sigma'] = \sum_{T \in \mathcal{T}} |W(H,T)|^{-1} \int_{T(F)} c_\sigma(t) c_{\sigma'}(t) D^H(t) \Delta^k(t) dt.$$

Given this theorem of Waldspurger, it is most natural to propose the following conjecture on Euler-Poincaré pairing.

Conjecture 7.1. *Let $V = X + D + W + Y$ be a quadratic space over the non-archimedean local field F with W a quadratic subspace of V of codimension $2k+1$ as before. Then for any irreducible admissible representation σ of* $\mathrm{SO}(V)$ *and irreducible admissible representation σ' of* $\mathrm{SO}(W)$*,*

1.

$$\begin{aligned} \mathrm{EP}_{\mathrm{Bes}(V,W)}[\sigma, \sigma'] &= \sum_i (-1)^i \dim \mathrm{Ext}^i_{\mathrm{Bes}(V,W)}[\sigma, \sigma'] \\ &= \sum_{T \in \mathcal{T}} |W(H,T)|^{-1} \int_{T(F)} c_\sigma(t) c_{\sigma'}(t) D^H(t) \Delta^k(t) dt. \end{aligned}$$

2. *If σ and σ' are irreducible tempered representations, then* $\mathrm{Ext}^i_{\mathrm{Bes}(V,W)}[\sigma, \sigma'] = 0$ *for $i > 0$.*

Remark 7.1. Note that a supercuspidal representation of $\mathrm{SO}(V)$ is a projective object in the category of smooth representations of $\mathrm{SO}(V)$, and hence by Proposition 2.4, it remains a projective object in the category of smooth representations of $\mathrm{SO}(W) \cdot U$. Therefore if σ or σ' is supercuspidal, $\mathrm{Ext}^i_{\mathrm{Bes}(V,W)}[\sigma, \sigma'] = 0$ for $i > 0$. (We note that for a supercuspidal representation σ' of $\mathrm{SO}(W)$, the representation $\sigma' \otimes \psi$ is an injective module in the category of smooth representations of $\mathrm{SO}(W) \cdot U$.) Thus Waldspurger's theorem is equivalent to the conjectural statement on Euler-Poincaré characteristic if σ or σ' is supercuspidal (except that it is not proved if σ' is supercuspidal, but σ is arbitrary). Part 2 of the conjecture is there as the simplest possible explanation of Waldspurger's theorem for tempered representations!

Example 7.1. Assume that either $G = \mathrm{SO}_{n+1}(F)$ is a split group, and σ is induced from a character of a Borel subgroup of G, or $H = \mathrm{SO}_n(F)$ is a split group and σ' is induced from a character of a Borel subgroup of H. Then the conjectural formula on Euler-Poincaré becomes $\mathrm{EP}[\sigma, \sigma'] = 1$ which is a consequence of Corollary 6.3.

Remark 7.2. We consider the Waldspurger integral formula as some kind of Riemann-Roch theorem. Recall that for X a smooth projective variety with Todd class T_X, and for any coherent sheaf $\mathfrak{F}$ on X with Chern class $c(\mathfrak{F})$, one has,

$$EP(X, \mathfrak{F}) = \sum_i (-1)^i \dim H^i(X, \mathfrak{F}) = \sum_i (-1)^i \dim \mathrm{Ext}^i(\mathcal{O}_X, \mathfrak{F}) = \int_X (T_X \cdot c(\mathfrak{F})).$$

In our case, $EP[\pi_1, \pi_2] = \sum_i (-1)^i \dim \mathrm{Ext}^i_H[\pi_1, \pi_2]$ is conjecturally expressed as

$$EP[\pi_1, \pi_2] = \int_X T_X \cdot c(\pi_1, \pi_2),$$

where X is a certain set of elliptic tori in H, T_X is a function on this set of elliptic tori, and $c(\pi_1, \pi_2)$ is a function on these elliptic tori defined in terms of the germ expansion of π_1 and π_2.

8 The Schneider-Stuhler duality theorem

The following theorem is a mild generalization of a duality theorem of Schneider and Stuhler due to M.Nori and Prasad [2017]; it turns questions on $\mathrm{Ext}^i[\pi_1, \pi_2]$ to $\mathrm{Ext}^j[\pi_2, \pi_1]$, and therefore is of central importance to our theme in this paper.

Theorem 8.1. *Let G be a reductive p-adic group, and π an irreducible, admissible representation of G. Let $d(\pi)$ be the largest integer $i \geq 0$ such that there is an irreducible, admissible representation π' of G with $\mathrm{Ext}^i_G[\pi, \pi']$ nonzero. Then,*

1. *There is a unique irreducible representation π' of G with $\mathrm{Ext}^{d(\pi)}_G[\pi, \pi'] \neq 0$.*
2. *The representation π' in (1) is nothing but $D(\pi)$ where $D(\pi)$ is the Aubert-Zelevinsky involution of π, and $d(\pi)$ is the split rank of the Levi subgroup M of G which carries the cuspidal support of π.*
3. $\mathrm{Ext}^{d(\pi)}_G[\pi, D(\pi)] \cong \mathbb{C}$.
4. *For any smooth representation π' of G, the bilinear pairing*

$$(*) \quad \mathrm{Ext}^i_G[\pi, \pi'] \times \mathrm{Ext}^j_G[\pi', D(\pi)] \to \mathrm{Ext}^{i+j=d(\pi)}_G[\pi, D(\pi)] \cong \mathbb{C},$$

is nondegenerate in the sense that if $\pi' = \varinjlim \pi'_n$ of finitely generated G-submodules π'_n, then $\mathrm{Ext}^i_G[\pi, \pi'] = \varinjlim \mathrm{Ext}^i_G[\pi, \pi'_n]$, a direct limit of finite dimensional vector spaces over $\mathbb{C}$, and $\mathrm{Ext}^j_G[\pi', D(\pi)] = \varprojlim \mathrm{Ext}^j_G[\pi'_n, D(\pi)]$, an inverse limit *of finite dimensional vector spaces over $\mathbb{C}$, and the pairing in $(*)$ is the direct limit of perfect pairings on these finite dimensional spaces:*

$$\mathrm{Ext}_G^i[\pi, \pi_n'] \times \mathrm{Ext}_G^j[\pi_n', D(\pi)] \to \mathrm{Ext}_G^{i+j=d(\pi)}[\pi, D(\pi)] \cong \mathbb{C}.$$

(Observe that a compatible family of perfect pairings on finite dimensional vector spaces $B_n : V_n \times W_n \to \mathbb{C}$ with V_n part of an inductive system, and W_n part of a projective system, gives rise to a natural pairing $B : \varinjlim V_n \times \varprojlim W_n \to \mathbb{C}$ such that the associated homomorphism from $(\varinjlim V_n)^\star$ to $\varprojlim W_n$ is an isomorphism.

As an example, the following proposition giving complete classification of irreducible submodules π of the tensor product $\pi_1 \otimes \pi_2$ of two (irreducible, infinite dimensional) representations π_1, π_2 of $\mathrm{GL}_2(F)$ with the product of their central characters trivial, is essentially a translation of vanishing of $\mathrm{Ext}^1_{PGL_2(F)}[\pi_1 \otimes \pi_2, \pi_3]$ by this duality theorem. The vanishing itself follows because $\mathrm{Ext}^2_{PGL_2(F)}[\pi_1 \otimes \pi_2, \pi_3] = 0$ by Proposition 2.9, and both EP and Hom spaces have the same dimension.

Proposition 8.1. *Let π_1, π_2 be two irreducible admissible infinite dimensional representations of $\mathrm{GL}_2(F)$ with product of their central characters trivial. Then the following is the complete list of irreducible sub-representations π of $\pi_1 \otimes \pi_2$ as $\mathrm{PGL}_2(F)$-modules.*

1. *π is a supercuspidal representation of $\mathrm{PGL}_2(F)$, and appears as a quotient of $\pi_1 \otimes \pi_2$.*
2. *π is a twist of the Steinberg representation, which we assume by absorbing the twist in π_1 or π_2 to be the Steinberg representation St of $\mathrm{PGL}_2(F)$. Then St is a submodule of $\pi_1 \otimes \pi_2$ if and only if π_1, π_2 are both irreducible principal series representations, and $\pi_1 \cong \pi_2^\vee$.*

9 Geometrization of Ext groups

A natural way to construct exact sequences in representation theory is via the Bernstein-Zelevinsky exact sequence arising from the inclusion of an open set $X - Y$ in a topological space X equipped with an ℓ-sheaf $\mathfrak{F}$, with Y a closed subspace of X, giving rise to

$$0 \to \mathcal{S}(X - Y, \mathfrak{F}) \to \mathcal{S}(X, \mathfrak{F}) \to \mathcal{S}(Y, \mathfrak{F}) \to 0.$$

Observe that in this exact sequence, the larger space $\mathcal{S}(X - Y, \mathfrak{F})$ arises as a subspace, whereas the smaller space $\mathcal{S}(Y, \mathfrak{F})$ arises as a quotient of $\mathcal{S}(X, \mathfrak{F})$. Assuming that a group G operates on the space X, preserving the closed subspace Y, as well as the sheaf $\mathfrak{F}$, then this exact sequence gives rise to an element of $\mathrm{Hom}_G[\mathcal{S}(X, \mathfrak{F}), \mathcal{S}(Y, \mathfrak{F})]$, as well as an element of $\mathrm{Ext}^1_G[\mathcal{S}(Y,\mathfrak{F}),\mathcal{S}(X-Y,\mathfrak{F})]$. Note that the Hom is from a larger space $\mathcal{S}(X,\mathfrak{F})$ to a smaller space $\mathcal{S}(Y,\mathfrak{F})$, whereas the Ext is between a smaller space and a larger space.

Similarly, if X_2, X_1 are closed subsets of an ℓ-space X with $X_2 \subset X_1 \subset X$, and endowed with an ℓ-sheaf $\mathfrak{F}$, we have exact sequences,

$$0 \to \mathcal{S}(X-X_1,\mathfrak{F}) \to \mathcal{S}(X-X_2,\mathfrak{F}) \to \mathcal{S}(X_1-X_2,\mathfrak{F}) \to 0,$$

$$0 \to \mathcal{S}(X_1-X_2,\mathfrak{F}) \to \mathcal{S}(X_1,\mathfrak{F}) \to \mathcal{S}(X_2,\mathfrak{F}) \to 0,$$

which can be spliced together to give rise to the exact sequence,

$$0 \to \mathcal{S}(X-X_1,\mathfrak{F}) \to \mathcal{S}(X-X_2,\mathfrak{F}) \to \mathcal{S}(X_1,\mathfrak{F}) \to \mathcal{S}(X_2,\mathfrak{F}) \to 0,$$

which gives an element of $\mathrm{Ext}^2_G[\mathcal{S}(X_2,\mathfrak{F}),\mathcal{S}(X-X_1,\mathfrak{F})]$; so as the representation $\pi_2 = \mathcal{S}(X_2,\mathfrak{F})$ becomes smaller and smaller compared to $\pi_1 = \mathcal{S}(X-X_1,\mathfrak{F})$ (as the space X_2 is 'two step smaller' than X), it may be expected to contribute to higher and higher Ext groups $\mathrm{Ext}^i_G[\pi_2,\pi_1]$.

Various examples around the present work suggest that homomorphisms between representations, or extensions between them correspond to some geometric spaces (and ℓ-sheaves on them) as above, in particular, a typical homomorphism is from a larger space to smaller ones, whereas a typical Ext is the other way around!

Although most geometric spaces have algebraic geometric origin, that is not necessarily the case when thinking about the Bernstein-Zelevinsky exact sequence. For instance, one can use the action of G on its Bruhat-Tits building and its various compactifications. If X is the tree associated to $\mathrm{PGL}_2(F)$, then one knows that there is a compactification $\overline{X}$ of X on which $\mathrm{PGL}_2(F)$ continues to act with $\overline{X} - X = \mathbb{P}^1(F)$, a closed subset of $\overline{X}$. The zero-skeleton X^0 of X together with $\overline{X} - X$ is a compact topological space, call it $\overline{X}_0$, with an action of $\mathrm{PGL}_2(F)$ with two orbits: X^0 which is the open orbit, and $\mathbb{P}^1(F)$ which is the closed orbit.

An unramified character χ of B gives rise to a sheaf, say $\mathbb{C}_\chi$, on $\mathbb{P}^1(F)$, which can be extended to a $\mathrm{PGL}_2(F)$-equivariant sheaf on $\overline{X}_0$ by making it $\mathrm{ind}_{\mathrm{PGL}_2(\mathcal{O}_F)}^{\mathrm{PGL}_2(F)}\mathbb{C}$ on X^0. Call the extended sheaf on $\overline{X}_0$ also as $\mathbb{C}_\chi$; note that the restriction of $\mathbb{C}_\chi$ to X^0 is the constant sheaf $\mathbb{C}$. Thus we have an exact sequence,

$$0 \to \mathcal{S}(X^0,\mathbb{C}) \to \mathcal{S}(\overline{X}_0,\mathbb{C}_\chi) \to \mathcal{S}(\mathbb{P}^1(F),\mathbb{C}_\chi) \to 0.$$

Since $\mathrm{PGL}_2(F)$ acts transitively on the zero-skeleton X^0 with stabilizer $\mathrm{PGL}_2(\mathcal{O}_F)$, we have $\mathcal{S}(X^0,\mathbb{C}) \cong \mathrm{ind}_{\mathrm{PGL}_2(\mathcal{O}_F)}^{\mathrm{PGL}_2(F)}\mathbb{C}$. We have thus constructed an element of

$$\mathrm{Ext}^1_{\mathrm{PGL}_2(F)}[\mathrm{Ind}_B^{\mathrm{PGL}_2(F)}\chi, \mathrm{ind}_{\mathrm{PGL}_2(\mathcal{O}_F)}^{\mathrm{PGL}_2(F)}\mathbb{C}]$$

It may be hoped that many extensions which representation theory offers will be matched by geometric action of G on topological spaces with finitely many G-orbits coming either from algebraic geometric spaces, or from the Bruhat-Tits building and its compactifications; there is then also the issue of proving that geometric actions do give non-trivial extensions!

We end with a precise question but before that we need to make a definition. In what follows, groups and spaces are what are called ℓ-groups and ℓ-spaces in Bernstein and Zelevinsky [1976] and Bernstein [1992]; we will also use the notion of an ℓ-sheaf from these references which we recall is a sheaf, say $\mathcal{F}$, over X of vector spaces over $\mathbb{C}$ with the space of compactly supported global sections $\mathcal{S}(X, \mathcal{F}) = \mathcal{F}_c(X)$, a module over $\mathcal{S}(X)$, which is nondegenerate in the sense that $\mathcal{S}(X) \cdot \mathcal{F}_c(X) = \mathcal{F}_c(X)$; the functor $\mathcal{F} \to \mathcal{F}_c(X)$ gives an equivalence between ℓ-sheaves on X and nondegenerate modules over $\mathcal{S}(X)$.

Definition: A complex representation V of $G = G(F)$ is said to be of geometric origin if

1. there is a G-space X_V with finitely many G-orbits,
2. a G-equivariant sheaf $\mathcal{F}_V$ on X_V,

such that on each G-orbit $Y \subset X_V$ of the form G/H_Y, $\mathcal{F}_V|_Y$ is the equivariant sheaf associated to a finite dimensional representation W_Y of H_Y, and $V \cong \mathcal{S}(X_V, \mathcal{F}_V)$ (cf. §1.16 of Bernstein and Zelevinsky [1976] for the definition of the restriction of an ℓ-sheaf to a locally closed subset such as Y).

Example 9.1. Parabolic induction and Jacquet functor take representations of geometric origin to representations of geometric origin. It is expected that all supercuspidal representations are of geometric origin (proved for $\mathrm{GL}_n(F)$ and classical groups in odd residue characteristic). In understanding the class of representations of geometric origin given by the action of a group G on a space X, one difficulty seems to be to glue vector bundles on various orbits to an ℓ-sheaf on X.

Question 9.1. Suppose that we have two complex smooth representations V_1 and V_2 of $G = G(F)$ of geometric origin with $\mathrm{Ext}^1_G[V_1, V_2] \neq 0$ with $V \in \mathrm{Ext}^1_G[V_1, V_2]$ represented by the extension

$$0 \to V_2 \to V \to V_1 \to 0.$$

Then is V of geometric origin?

Remark 9.1. A representation of *geometric origin* comes equipped with considerable additional data as in the Bernstein–Zelevinsky exact sequence, which may be important to refine the question above.

KAC POLYNOMIALS AND LIE ALGEBRAS ASSOCIATED TO QUIVERS AND CURVES

Olivier G. Schiffmann

Abstract

We provide an explicit formula for the following enumerative problem: how many (absolutely) indecomposable vector bundles of a given rank r and degree d are there on a smooth projective curve X of genus g defined over a finite field $\mathbb{F}_q$? The answer turns out to only depend on the genus g, the rank r and the Weil numbers of the curve X. We then provide several interpretations of these numbers, either as the Betti numbers or counting polynomial of the moduli space of stable Higgs bundles (of same rank r and degree d) over X, or as the character of some infinite dimensional graded Lie algebra. We also relate this to the (cohomological) Hall algebras of Higgs bundles on curves and to the dimension of the space of absolutely cuspidal functions on X.

1 Kac polynomials for quivers and curves

1.1 Quivers. Let Q be a locally finite quiver with vertex set I and edge set Ω. For any finite field $\mathbb{F}_q$ and any dimension vector $\mathbf{d} \in \mathbb{N}^I$, let $A_{Q,\mathbf{d}}(\mathbb{F}_q)$ be the number of absolutely indecomposable representations of Q over $\mathbb{F}_q$, of dimension $\mathbf{d}$. Kac proved the following beautiful result:

Theorem 1.1 (Kac [1980]). *There exists a (unique) polynomial $A_{Q,\mathbf{d}}(t) \in \mathbb{Z}[t]$ such that for any finite field $\mathbb{F}_q$,*

$$A_{Q,\mathbf{d}}(\mathbb{F}_q) = A_{Q,\mathbf{d}}(q).$$

Moreover $A_{Q,\mathbf{d}}(t)$ is independent of the orientation of Q and is monic of degree $1 - \langle \mathbf{d}, \mathbf{d} \rangle$.

Here $\langle\ ,\ \rangle$ is the Euler form, see Section 2.1 The fact that the number of (absolutely) indecomposable $\mathbb{F}_q$-representations behaves polynomially in q is very remarkable: the absolutely indecomposable representations only form a *constructible* substack of the stack

MSC2010: primary 17B65; secondary 14D20.

$\mathfrak{M}_{Q,\mathbf{d}}$ of representations of Q of dimension $\mathbf{d}$ and we count them here *up to isomorphism*, i.e. *without* the usual orbifold measure. Let us briefly sketch the idea of a proof. Standard Galois cohomology arguments ensure that it is enough to prove that the number of indecomposable $\mathbb{F}_q$-representations is given by a polynomial $I_{Q,\mathbf{d}}$ in q (this polynomial is not as well behaved as or as interesting as $A_{Q,\mathbf{d}}$). Next, by the Krull-Schmidt theorem, it is enough to prove that the number of *all* $\mathbb{F}_q$-representations of dimension $\mathbf{d}$ is itself given by a polynomial in $\mathbb{F}_q$. This amounts to computing the (orbifold) volume of the *inertia* stack $\mathfrak{I}\mathfrak{M}_{Q,\mathbf{d}}$ of $\mathfrak{M}_{Q,\mathbf{d}}$; performing a unipotent reduction in this context, we are left to computing the volume of the stack $\mathfrak{N}il_{Q,\mathbf{d}}$ parametrizing pairs (M, ϕ) with M a representation of dimension $\mathbf{d}$ and $\phi \in \mathrm{End}(M)$ being nilpotent. Finally, we use a Jordan stratification of $\mathfrak{N}il_{Q,\mathbf{d}}$ and easily compute the volume of each strata in terms of the volumes of the stacks $\mathfrak{M}_{Q,\mathbf{d}'}$ for all $\mathbf{d}'$. This actually yields an explicit formula for $A_{Q,\mathbf{d}}(t)$ (or $I_{Q,\mathbf{d}}(t)$), see Hua [2000]. We stress that beyond the case of a few quivers (i.e. those of finite or affine Dynkin type) it is unimaginable to classify and construct all indecomposable representations; nevertheless, the above theorem says that we can *count* them.

The positivity of $A_{Q,\mathbf{d}}(t)$ was only recently[1]:

Theorem 1.2 (Hausel, Letellier, and Rodriguez-Villegas [2013]). *For any Q and any $\mathbf{d}$ we have $A_{Q,\mathbf{d}}(t) \in \mathbb{N}[t]$.*

The desire to understand the meaning of the Kac polynomials $A_{Q,\mathbf{d}}(t)$, for instance as the dimension of certain natural graded vector spaces (such as the cohomology of some algebraic variety), has been a tremendous source of inspiration in geometric representation theory; it has lead to the development over the years of a beautiful and very rich theory relating various moduli spaces of representations of quivers to Lie algebras and quantum groups, yielding geometric constructions of a host of important objects in representation theory (such as canonical and crystal bases, Yangians, quantum affine algebras, their highest weight or finite-dimensional representations, etc.). We will present here some recent developments in this area, in particular in relation to the structure and representation theory of Kac-Moody algebras and *graded Borcherds algebras*.

1.2 Curves. Now let X be a smooth projective curve defined over some finite field $\mathbb{F}_q$. For any $r \geq 0, d \in \mathbb{Z}$ let $A_{r,d}(X)$ be the number of isomorphism classes of absolutely indecomposable coherent sheaves $\mathfrak{F}$ over X of rank r and degree d. It turns out that this number may also be computed explicitly and depends 'polynomially' on X. In order to make sense of this, we need to introduce a few notations. The action of the geometric Frobenius Fr_X on the l-adic cohomology group $H^1_{et}(X_{\overline{\mathbb{F}_q}}, \overline{\mathbb{Q}_l})$ is semisimple with

[1] the special case of an indivisible dimension vector was proved earlier by Crawley-Boevey and Van den Bergh [2004]

eigenvalues $\{\sigma_1, \ldots, \sigma_{2g}\}$ which may be ordered so that $\sigma_{2i-1}\sigma_{2i} = q$ for all i. Moreover, Fr_X belongs to the general symplectic group $GSp(H^1_{et}(X_{\overline{\mathbb{F}_q}}, \overline{\mathbb{Q}_l}))$ relative to the intersection form on $H^1_{et}(X_{\overline{\mathbb{F}_q}}, \overline{\mathbb{Q}_l})$. We may canonically identify the character ring of $GSp(H^1_{et}(X_{\overline{\mathbb{F}_q}}, \overline{\mathbb{Q}_l}))$ with $R_g = \overline{\mathbb{Q}_l}[T_g]^{W_g}$ where

$$T_g = \{(\eta_1, \ldots, \eta_{2g}) \in \mathbb{G}_m^{2g} \mid \eta_{2i-1}\eta_{2i} = \eta_{2j-1}\eta_{2j}\ \forall\, i, j\}, \qquad W_g = (\mathfrak{S}_2)^g \rtimes \mathfrak{S}_g$$

are the maximal torus, resp. Weyl group of $GSp(2g, \overline{\mathbb{Q}_l})$. We can evaluate any element $f \in R_g$ on Fr_X for any smooth projective curve X of genus g, defined over some[2] finite field $\mathbb{F}_q$; concretely, we have

$$f(Fr_X) = f(\sigma_1, \sigma_2, \ldots, \sigma_{2g}).$$

We will say that a quantity depending on X is *polynomial* if it is the evaluation of some element $f \in R_g$. For instance the size of the field $\mathbb{F}_q$ of definition of X is polynomial in X (take $f = \eta_{2i-1}\eta_{2i}$ for any i), as is the number $|X(\mathbb{F}_q)|$ of $\mathbb{F}_q$-rational points of X (take $f = 1 - \sum_i \eta_i + q$); this is also true of symmetric powers $S^l X$ of X. We extend the above definition to the case $g = 0$ by setting $R_g = \overline{\mathbb{Q}_l}[q^{\pm 1}]$.

Theorem 1.3 (Schiffmann [2016]). *For any fixed g, r, d there exists a (unique) polynomial $A_{g,r,d} \in R_g$ such that for any smooth projective curve X of genus g defined over a finite field, the number of absolutely indecomposable coherent sheaves on X of rank r and degree d is equal to $A_{g,r,d}(Fr_X)$. Moreover, $A_{g,r,d}$ is monic of leading term $q^{1+(g-1)r^2}$.*

The finiteness of the number of absolutely indecomposable coherent sheaves of fixed rank and degree is a consequence of Harder-Narasimhan reduction theory; it suffices to observe that any sufficiently unstable coherent sheaf is decomposable as its Harder-Narasimhan filtration splits in some place. Let us say a few words about the proof of Theorem 1.3: like for quivers, standard Galois cohomology arguments combined with the Krull-Schmidt theorem reduce the problem to counting *all* isomorphism classes of coherent sheaves of rank r and degree d; unfortunately, this number is infinite as soon as $r > 0$ hence it is necessary to introduce a suitable truncation of the category $\mathrm{Coh}(X)$; there are several possibilities here, one of them being to consider the category $\mathrm{Coh}^{\geq 0}(X)$ of positive coherent sheaves, i.e. sheaves whose HN factors all have positive degree. One is thus lead to compute the volumes of the inertia stacks $\mathfrak{I}\mathfrak{M}^{\geq 0}_{X,r,d}$ of the stacks $\mathfrak{M}^{\geq 0}_{X,r,d}$ positive sheaves of rank r and degree d on X. Finally, after a unipotent and Jordan reduction similar to the case of quivers, this last computation boils down to the evaluation of the integral of certain Eisenstein series over the truncated stacks $\mathfrak{M}^{\geq 0}_{X,r,d}$; this is performed using a variant of Harder's method for computing the volume of $\mathfrak{M}_{X,r,d}$, see Schiffmann [ibid.]

[2] technically, of characteristic different from l

for details. The proof is constructive and yields an explicit but complicated formula for $A_{g,r,d}$. Hence, just like for quivers, although classifying all indecomposable vector bundles for curves of genus $g > 1$ is a wild problem, it is nevertheless possible to count them. The explicit formula for $A_{g,r,d}$ was later combinatorially very much simplified by Mellit [2017b], who in particular proved the following result:

Theorem 1.4 (Mellit [ibid.]). *The polynomial $A_{g,r,d}$ is independent of d.*

Thanks to this theorem, we may simply write $A_{g,r}$ for $A_{g,r,d}$. Like their quivery cousins, Kac polynomials of curves satisfy some positivity and integrality property, namely

Theorem 1.5 (Schiffmann [2016]). *For any g, r, $A_{g,r} \in Im(\mathbb{N}[-\eta_1, \ldots, -\eta_g]^{W_g} \to R_g)$.*

In other words, $A_{g,r}$ is a W_g-symmetric polynomial in $-\eta_1, \ldots, -\eta_{2g}$ with positive integral coefficients. However, this is *not* the most natural form of positivity:

Conjecture 1.6. *For any g, r there exists a canonical (*non-*virtual) finite-dimensional representation $\mathbb{A}_{g,r}$ of $GSp(2g, \overline{\mathbb{Q}_l})$ such that $A_{g,r} = \tau(ch(\mathbb{A}_{g,r}))$, where $\tau \in Aut(R_g)$ is the involution mapping η_i to $-\eta_i$ for all i.*

The paper Hua [2000] contains many examples of Kac polynomials for quivers. Let us give here the examples of Kac polynomials for curves (of any genus) for $r = 0, 1, 2$; we will write q for $\eta_{2i-1}\eta_{2i}$.

$$A_{g,0} = 1 - \sum_i \eta_i + q, \qquad A_{g,1} = \prod_{i=1}^{2g} (1 - \eta_i),$$

$$A_{g,2} = \prod_{i=1}^{2g}(1-\eta_i) \cdot \left(\frac{\prod_i (1 - q\eta_i)}{(q-1)(q^2-1)} - \frac{\prod_i (1+\eta_i)}{4(1+q)} + \right. \\ \left. + \frac{\prod_i (1-\eta_i)}{2(q-1)} \left[\frac{1}{2} - \frac{1}{q-1} - \sum_i \frac{1}{1-\eta_i} \right] \right).$$

For $r = 0, 1$ we recognize the number of $\mathbb{F}_q$-rational points of X and $Pic^0(X)$ respectively. In particular, we have $\mathbb{A}_{g,0} = \mathbb{C} \oplus \mathbb{V} \oplus det(V)^{1/g}$ and $\mathbb{A}_{g,1} = \Lambda^\bullet V$, where V is the standard $2g$-dimensional representation of $GSp(2g, \overline{\mathbb{Q}_l})$.

Motivated by the analogy with quivers, it is natural to try to seek a representation-theoretic meaning to the Kac polynomials $A_{g,r}$. What is the analog, in this context, of the Kac-Moody algebra associated to a quiver ? Are the Kac polynomials related to the

Poincaré polynomials of some interesting moduli spaces ? Although it is still much less developed than in the context of quivers, we will illustrate this second theme through two examples of applications of the theory of *Hall algebras* of curves: a case of geometric Langlands duality (in the neighborhood of the trivial local system) and the computation of the Poincaré polynomial of the moduli spaces of semistable Higgs bundles on smooth projective curves.

1.3 Quivers vs. Curves. Kac polynomials of quivers and curves are not merely related by an analogy: they are connected through the following observation, which comes by comparing the explicit formulas for $A_{Q,\mathbf{d}}$ and $A_{g,r}$. Let S_g be the quiver with one vertex and g loops.

Proposition 1.7 (Rodriguez-Villegas)**.** *For any r we have $A_{S_g,r}(1) = A_{g,r}(0,\dots,0)$.*

This relation between the constant term of $A_{g,r}$ and the sum of all the coefficients of $A_{S_g,r}$ has a very beautiful conjectural conceptual explanation in terms of the mixed Hodge structure of the (twisted) genus g character variety, we refer the interested reader to Hausel and Rodriguez-Villegas [2008]. We will provide another conceptual explanation in terms of the geometric Langlands duality in Section 5.4.

Remark. There is an entirely similar story for the category of coherent sheaves on a smooth projective curve equipped with a (quasi-)parabolic structure along an effective divisor D, see Schiffmann [2004], Lin [2014], and Mellit [2017a]. Proposition 1.7 still holds in this case, with the quiver S_g being replaced by a quiver with a central vertex carrying g loops, to which are attached finitely many type A branches, one for each point in D.

Plan of the paper. In Sections 2 to 4 we describe various Lie-theoretical (Sections 2.2, 2.5, 3.3, 4.4 and 4.6) or geometric (Sections 4.1 and 4.4 to 4.6) incarnations (some conjectural) of the Kac polynomials for quivers; in particular we advocate the study of a certain *graded* Borcherds algebra $\widetilde{\mathfrak{g}}_Q$ canonically associated to a quiver, which is a graded extension of the usual Kac-Moody algebra $\mathfrak{g}_Q$ attached to Q. From Section 5 onward, we turn our attention to curves and present several algebraic or geometric constructions suggesting the existence of some hidden, combinatorial and Lie-theoretical structures controlling such things as dimensions of spaces of cuspidal functions (Section 6.2), or Poincaré polynomials of moduli spaces of (stable) Higgs bundles on curves (Sections 7.2 and 7.3).

2 Quivers, Kac polynomials and Kac-Moody algebras

We begin with some recollections of some classical results in the theory of quivers and Kac-Moody algebras, including the definitions of Hall algebras and Lusztig nilpotent varieties, and their relations to (quantized) enveloping algebra of Kac-Moody algebras. This is related to the *constant term* $A_{Q,\mathbf{d}}(0)$ of the Kac polynomials $A_{Q,\mathbf{d}}(t)$. The theory is classically developed for quivers without edge loops. The general case, important for applications, is more recent.

2.1 Kac-Moody algebras from quivers. Let $Q = (I, \Omega)$ be a finite quiver without edge loops. For any field $\mathbf{k}$ we denote by $\mathrm{Rep}_{\mathbf{k}}(Q)$ the abelian category of $\mathbf{k}$-representations of Q and for any dimension vector $\mathbf{d} \in \mathbb{N}^I$ we denote by $\mathfrak{M}_{Q,\mathbf{d}}$ the stack of $\mathbf{d}$-dimensional representations of Q. The category $\mathrm{Rep}_{\mathbf{k}}(Q)$ is of global dimension at most one (and exactly one if Ω is non-empty) with finite-dimensional Ext spaces. As a result, the stack $\mathfrak{M}_Q = \bigsqcup_{\mathbf{d}} \mathfrak{M}_{Q,\mathbf{d}}$ is smooth. The first relation to Lie theory arises when considering the Euler forms

(2-1)

$$\langle M, N\rangle = \dim \mathrm{Hom}(M, N) - \dim \mathrm{Ext}^1(M, N), \qquad (M, N) = \langle M, N\rangle + \langle N, M\rangle.$$

Let c_{ij} be the number of arrows in Q from i to j, and let $C = (c_{ij})_{i,j\in I}$ be the adjacency matrix. Set $A = 2Id - C - {}^tC$. The Euler forms $\langle\ ,\ \rangle$ and $(\ ,\ )$ factor through the map

$$\underline{\dim} : K_0(\mathrm{Rep}_{\mathbf{k}} Q) \to \mathbb{Z}^I, \qquad M \mapsto (\dim M_i)_i$$

and are given by

$$\langle \mathbf{d}, \mathbf{d}'\rangle = {}^t\mathbf{d}\,(Id - C)\,\mathbf{d}', \qquad (\mathbf{d}, \mathbf{d}') = {}^t\mathbf{d}\,A\,\mathbf{d}'.$$

Note that $\dim \mathfrak{M}_{Q,\mathbf{d}} = -\langle \mathbf{d}, \mathbf{d}\rangle$. Now, A is a (symmetric) generalized Cartan matrix in the sense of Kac [1985], to which is attached a Kac-Moody algebra $\mathfrak{g}_Q$. The Euler lattice $(\mathbb{Z}^I, (\ ,\ ))$ of $\mathrm{Rep}_{\mathbf{k}} Q$ is identified to the root lattice[3] $Q_{\mathfrak{g}_Q}$ of $\mathfrak{g}_Q$ together with its standard Cartan pairing, via the map $\mathbb{Z}^I \to Q_{\mathfrak{g}_Q}, \mathbf{d} \mapsto \sum_i d_i\alpha_i$ (here α_i are the simple roots of $\mathfrak{g}_Q$). Accordingly, we denote by $\mathfrak{g}_Q = \bigoplus_{\mathbf{d}} \mathfrak{g}_Q[\mathbf{d}]$ the root space decomposition of $\mathfrak{g}_Q$.

2.2 Kac's theorem and the constant term conjecture. Kac proved that $A_{Q,\mathbf{d}}(t) \neq 0$ if and only if $\mathbf{d}$ belongs to the root system Δ^+ of $\mathfrak{g}_Q$; this generalizes the famous theorem of Gabriel [1972] which concerns the case of finite-dimensional $\mathfrak{g}_Q$. Moreover, he made the following conjecture, which was later proved by Hausel (see Crawley-Boevey and Van den Bergh [2004] for the case of indivisible $\mathbf{d}$):

Theorem 2.1 (Hausel [2010]). *For any* $\mathbf{d} \in \Delta^+$, *we have* $A_{Q,\mathbf{d}}(0) = \dim \mathfrak{g}_Q[\mathbf{d}]$.

[3] we apologize for the unfortunate –yet unavoidable– clash between the traditional notations for the root lattice and for the quiver

We will sketch a proof of Theorems 1.2 and 2.1 using cohomological Hall algebras in Section 4.4. These proofs are different from, but related to the original proofs of Hausel et al.

In the remainder of Section 2, we discuss two (related) constructions of the Kac-Moody algebra $\mathfrak{g}_Q$: as the *spherical Hall algebra* of the categories $\mathrm{Rep}_{\mathbf{k}}(Q)$ for $\mathbf{k}$ a finite field, or in terms of the complex geometry of the *Lusztig nilpotent varieties* $\Lambda_{Q,\mathbf{d}}$.

2.3 Ringel-Hall algebras. It is natural at this point to ask for an actual construction of $\mathfrak{g}_Q$ using the moduli stacks $\mathfrak{M}_{Q,\mathbf{d}}$ of representations of Q. This was achieved by Ringel [1990] and Green [1995] using the *Hall* (or *Ringel-Hall*) algebra of $\mathrm{Rep}_{\mathbf{k}} Q$. Let $\mathbf{k}$ be again a finite field and set $\mathfrak{M}_Q = \bigsqcup_{\mathbf{d}} \mathfrak{M}_{Q,\mathbf{d}}$. The set of $\mathbf{k}$-points $\mathfrak{M}_Q(\mathbf{k}) = \bigsqcup_{\mathbf{d}} \mathfrak{M}_{Q,\mathbf{d}}(\mathbf{k})$ is by construction the set of $\mathbf{k}$-representations of Q (up to isomorphism). Put

$$\mathbf{H}_Q = \bigoplus_{\mathbf{d}} \mathbf{H}_Q[\mathbf{d}], \qquad \mathbf{H}_Q[\mathbf{d}] := \mathrm{Fun}(\mathfrak{M}_{Q,\mathbf{d}}(\mathbf{k}), \mathbb{C})$$

and consider the following convolution diagram

$$\mathfrak{M}_Q \times \mathfrak{M}_Q \xleftarrow{\;q\;} \widetilde{\mathfrak{M}}_Q \xrightarrow{\;p\;} \mathfrak{M}_Q \tag{2-2}$$

where $\widetilde{\mathfrak{M}}_Q$ is the stack parametrizing short exact sequences

$$0 \longrightarrow M \longrightarrow R \longrightarrow N \longrightarrow 0$$

in $\mathrm{Rep}_{\mathbf{k}} Q$ (alternatively, inclusions $M \subset R$ in $\mathrm{Rep}_{\mathbf{k}} Q$); the map p assigns to a short exact sequence as above its middle term R; the map q assigns to it its end terms (N, M). The stack $\widetilde{\mathfrak{M}}_Q$ can be seen as parametrizing extensions between objects in $\mathrm{Rep}_{\mathbf{k}} Q$. The map p is proper and, because $\mathrm{Rep}_{\mathbf{k}} Q$ is of homological dimension one, the map q is a stack vector bundle whose restriction to $\mathfrak{M}_{Q,\mathbf{d}} \times \mathfrak{M}_{Q,\mathbf{d}'}$ is of rank $-\langle \mathbf{d}', \mathbf{d} \rangle$. Following Ringel and Green, we put $v = (\#\mathbf{k})^{\frac{1}{2}}$, let $\mathbf{K} = \mathbb{C}[k_i^{\pm 1}]_i$ be the group algebra of $\mathbb{Z}^I$ and we equip $\widetilde{\mathbf{H}}_Q := \mathbf{H}_Q \otimes \mathbf{K}$ with the structure of a $\mathbb{N}^I$-graded bialgebra by setting

$$f \cdot g = v^{\langle \mathbf{d}, \mathbf{d}' \rangle} p_! q^*(f \otimes g), \qquad k_{\mathbf{n}} f k_{\mathbf{n}}^{-1} = v^{(\mathbf{d}, \mathbf{n})} f \tag{2-3}$$

$$\Delta(f) = \sum_{\mathbf{d}' + \mathbf{d}'' = \mathbf{d}} v^{\langle \mathbf{d}', \mathbf{d}'' \rangle} (q_{\mathbf{d}', \mathbf{d}''})_! p^*_{\mathbf{d}', \mathbf{d}''}(f) \qquad \Delta(k_i) = k_i \otimes k_i \tag{2-4}$$

for $f \in \mathbf{H}_Q[\mathbf{d}]$, $g \in \mathbf{H}_Q[\mathbf{d}']$, $\mathbf{n} \in \mathbb{Z}^I$ and $i \in I$. The bialgebra $\widetilde{\mathbf{H}}_Q$ is equipped with the nondegenerate Hopf pairing

$$(f k_{\mathbf{d}}, g k_{\mathbf{d}'}) = v^{(\mathbf{d}, \mathbf{d}')} \int_{\mathfrak{M}_Q} f \overline{g}, \qquad \forall\ f, g \in \mathbf{H}_Q \tag{2-5}$$

(see Schiffmann [2012] for more details and references). Denoting by $\{\epsilon_i\}_i$ the canonical basis of $\mathbb{Z}^I$ we have $\mathfrak{M}_{\epsilon_i} \simeq B\mathbb{G}_m$ for all i since $\mathfrak{M}_{\epsilon_i}$ has as unique object the simple object S_i of dimension ϵ_i. We define the *spherical* Hall algebra $\widetilde{\mathbf{H}}_Q^{\mathrm{sph}}$ as the subalgebra of $\widetilde{\mathbf{H}}_Q$ generated by $\mathbf{K}$ and the elements 1_{S_i} for $i \in I$. It is a sub-bialgebra.

Theorem 2.2 (Ringel [1990] and Green [1995]). *The assignement $E_i \mapsto 1_{S_i}, K_i^{\pm 1} \mapsto k_i^{\pm 1}$ for $i \in I$ induces an isomorphism $\Psi : U_v(\mathfrak{b}_Q) \xrightarrow{\sim} \widetilde{\mathbf{H}}_Q^{sph}$ between the positive Borel subalgebra of the Drinfeld-Jimbo quantum enveloping algebra $U_v(\mathfrak{g}_Q)$ and the spherical Hall algebra of Q.*

One may recover the entire quantum group $U_v(\mathfrak{g}_Q)$ as the (reduced) Drinfeld double $\mathbf{D}\widetilde{\mathbf{H}}_Q^{\mathrm{sph}}$ of $\widetilde{\mathbf{H}}_Q$ (see e.g. Schiffmann [2012, Lec. 5]).

2.4 Lusztig nilpotent variety. Let $T^*\mathfrak{M}_Q = \bigsqcup_{\mathbf{d}} T^*\mathfrak{M}_{Q,\mathbf{d}}$ be the cotangent[4] stack of $\mathfrak{M}_Q$. This may be realized explicitly as follows. Let $\overline{Q} = (I, \Omega \sqcup \Omega^*)$ be the double of Q, obtained by replacing every arrow h in Q by a pair (h, h^*) of arrows going in opposite directions. The preprojective algebra Π_Q is the quotient of the path algebra $\mathbf{k}\overline{Q}$ by the two-sided ideal generated by $\sum_{h \in \Omega}[h, h^*]$. Unless Q is of finite type, the abelian category $\mathrm{Rep}_{\mathbf{k}}\Pi_Q$ is of global dimension two. The stack of $\mathbf{k}$-representations of Π_Q is naturally identified with $T^*\mathfrak{M}_Q$. We say that a representation M of Π_Q is *nilpotent* if there exists a filtration $M \supset M_1 \supset \cdots \supset M_l = \{0\}$ for which $\Pi_Q^+(M_i) \subseteq M_{i+1}$, where $\Pi_Q^+ \subset \Pi_Q$ is the augmentation ideal. Following Lusztig, we define the *nilpotent variety* (or stack) $\Lambda_Q = \bigsqcup_{\mathbf{d}} \Lambda_{Q,\mathbf{d}} \subset T^*\mathfrak{M}_Q$ as the substack of nilpotent representations of Π_Q.

Theorem 2.3 (Kashiwara and Saito [1997]). *The stack Λ_Q is a lagrangian substack of $T^*\mathfrak{M}_Q$ and for any $\mathbf{d} \in \mathbb{N}^I$ we have $\#Irr(\Lambda_{Q,\mathbf{d}}) = dim\, U(\mathfrak{n}_Q)[\mathbf{d}]$.*

The above theorem is strongly motivated by Lusztig's geometric lift of the spherical Hall algebra to a category of perverse sheaves on $\mathfrak{M}_Q$, yielding the *canonical basis* $\mathbf{B}$ of $U_v(\mathfrak{n}_Q)$, see Lusztig [1991]. It turns out that Λ_Q is precisely the union of the singular support of Lusztig's simple perverse sheaves, hence the above may be seen as a microlocal avatar of Lusztig's construction. Kashiwara and Saito prove much more, namely they equip $Irr(\Lambda)$ with the combinatorial structure of a *Kashiwara crystal* which they identify as the crystal $B(\infty)$ of $U(\mathfrak{n}_Q)$. This also yields a canonical bijection between $\mathbf{B}$ and $Irr(\Lambda_Q)$.

2.5 Arbitrary quivers and nilpotent Kac polynomials. What happens when the quiver Q *does* have edge loops, such as the g-loop quiver S_g ? This means that the matrix of

[4] to be precise, we only consider the underived, or H^0-truncation, of the cotangent stacks here

the Euler form may have some (even) nonpositive entries on the diagonal, hence it is associated to a *Borcherds* algebra rather than to a Kac-Moody algebra. Accordingly, we call *real*, resp. *isotropic*, resp. *hyperbolic* a vertex carrying zero, resp. one, resp. at least two edge loops, and in the last two cases we say that the vertex is *imaginary*. One may try to get Hall-theoretic constructions of the Borcherds algebra $\mathfrak{g}_Q$ associated to Q (see e.g. Kang and Schiffmann [2006] and Kang, Kashiwara, and Schiffmann [2009]) but the best thing to do in order to get a picture as close as possible to the one in **2.1–2.4.** seems to be to consider instead a slightly larger algebra $\mathfrak{g}_Q^B$ defined by Bozec which has as building blocks the usual $\mathfrak{sl}_2$ for real roots, the Heisenberg algebra H for isotropic roots and a free Lie algebra H' with one generator in each degree for hyperbolic roots, see Bozec [2015].

The Hall algebra $\widetilde{\mathbf{H}}_Q$ is defined just as before, but we now let $\widetilde{\mathbf{H}}_Q^{\mathrm{sph}}$ be the subalgebra generated by elements 1_{S_i} for i real vertices and by the characteristic functions $1_{\mathfrak{M}_{l\epsilon_i}}$ for i imaginary and $l \in \mathbb{N}$. The stack of nilpotent representations of Π_Q is not lagrangian anymore in general, we consider instead the stack of *seminilpotent* representations, i.e. representations M for which there exists a filtration $M \supset M_1 \supset \cdots \supset M_l = \{0\}$ such that $h(M_i/M_{i+1}) = 0$ for $h \in \Omega$ or for $h \in \Omega^*$ *not* an edge loop.

Theorem 2.4 (Bozec [2015, 2016] and Kang [2018]). *The following hold:*

i) $\widetilde{\mathbf{H}}_Q^{sph}$ *is isomorphic to* $U_v(\mathfrak{b}_Q^B)$,

ii) The stack Λ_Q *of seminilpotent representations is lagrangian in* $T^*\mathfrak{M}_Q$. *For any* $\mathbf{d} \in \mathbb{N}^I$ *we have* $\#Irr(\Lambda_{Q,\mathbf{d}}) = dim\, U(\mathfrak{n}_Q^B)[\mathbf{d}]$.

The theories of canonical bases and crystal graphs also have a natural extension to this setting. What about the relation to Kac polynomials ? Here as well we need some slight variation; let us call 1-*nilpotent* a representation M of Q in which the edge loops at any given imaginary vertex i generate a nilpotent (associative) subalgebra of $\mathrm{End}(M_i)$. Of course any representation of a quiver with no edge loops is 1-nilpotent.

Theorem 2.5 (Bozec, Schiffmann, and Vasserot [2017]). *For any* $\mathbf{d}$ *there exists a (unique) polynomial* $A^{nil}_{Q,\mathbf{d}} \in \mathbb{Z}[t]$, *independent of the orientation of* Q, *such that for any finite field* $\mathbf{k}$ *the number of isomorphism classes of absolutely indecomposable* 1*-nilpotent* $\mathbf{k}$*-representations of* Q *of dimension* $\mathbf{d}$ *is equal to* $A^{nil}_{Q,\mathbf{d}}(\#\mathbf{k})$. *Moreover, for any* $\mathbf{d} \in \mathbb{N}^I$ *we have*

i) $A^{nil}_{Q,\mathbf{d}}(1) = A_{Q,\mathbf{d}}(1)$,

ii) $A^{nil}_{Q,\mathbf{d}}(0) = dim\, \mathfrak{g}_Q^B[\mathbf{d}]$.

We will sketch a proof of the fact that $A^{\mathrm{nil}}_{Q,\mathbf{d}}(t) \in \mathbb{N}[t]$ in Section 4.4.

3 Quivers, Kac polynomials and graded Borcherds algebras I –counting cuspidals–

Starting form a Kac-Moody algebra $\mathfrak{g}$ (or its variant defined by Bozec) we build a quiver Q by orienting the Dynkin diagram of $\mathfrak{g}$ in any fashion, and obtain a realization of $U_v(\mathfrak{b})$ as the spherical Hall algebra $\widetilde{\mathbf{H}}_Q^{\mathrm{sph}}$; now, we may ask the following question: what is the relation between $\mathfrak{g}$ and the *full* Hall algebra ? Here's a variant of this question: Kac's constant term conjecture gives an interpretation of the constant term of the Kac polynomial $A_{Q,\mathbf{d}}(t)$; is there a similar Lie-theoretic meaning for the *other* coefficients ? As we will explain in **3.3.** below, the two questions turn out to have a beautiful common conjectural answer: the full Hall algebra $\widetilde{\mathbf{H}}_Q$ is related to a *graded* Borcherds algebra $\widetilde{\mathfrak{g}}_Q$ whose *graded* multiplicities $\dim_{\mathbb{Z}} \widetilde{\mathfrak{g}}_Q[\mathbf{d}] = \sum_l \dim \widetilde{\mathfrak{g}}_Q[\mathbf{d}, l]t^l$ are equal to $A_{Q,\mathbf{d}}(t)$. What's more, $\widetilde{\mathfrak{g}}_Q$, like $\mathfrak{g}_Q$, is independent of the choice of the orientation of the quiver and is hence *canonically* attached to $\mathfrak{g}_Q$. Although the above makes sense for an arbitrary quiver Q, there is an entirely similar story in the nilpotent setting (better suited for a quiver with edge loops), replacing $A_{Q,\mathbf{d}}(t)$ by $A^{\mathrm{nil}}_{Q,\mathbf{d}}(t)$ and $\mathbf{H}_Q$ by the subalgebra $\mathbf{H}_Q^{\mathrm{nil}}$ of functions on the stack $\mathfrak{M}_Q^{\mathrm{nil}}$ of 1-nilpotent representations of Q. This is then conjecturally related to a graded Borcherds algebra $\widetilde{\mathfrak{g}}_Q^{\mathrm{nil}}$.

3.1 The full Hall algebra.

The first general result concerning the structure of the full Hall algebra $\widetilde{\mathbf{H}}_Q$ is due to Sevenhant and Van den Bergh. Let us call an element $f \in \mathbf{H}_Q$ is *cuspidal* if $\Delta(f) = f \otimes 1 + k_f \otimes 1$. Denote by $\mathbf{H}_Q^{\mathrm{cusp}} = \bigoplus_{\mathbf{d}} \mathbf{H}_Q^{\mathrm{cusp}}[\mathbf{d}]$ the space of cuspidals, and set $C_{Q/\mathbf{k},\mathbf{d}} = \dim\ \mathbf{H}_Q^{\mathrm{cusp}}[\mathbf{d}]$. We write $Q/\mathbf{k}$ instead of Q to emphasize the dependance on the field. Consider the infinite Borcherds–Cartan data $(A_{Q/\mathbf{k}}, \mathbf{m}_{Q/\mathbf{k}})$, with $\mathbb{N}^I \times \mathbb{N}^I$ Cartan matrix $A_{Q/\mathbf{k}} = (a_{\mathbf{d},\mathbf{d}'})_{\mathbf{d},\mathbf{d}'}$ and charge function $\mathbf{m}_{Q/\mathbf{k}} : \mathbb{N}^I \to \mathbb{N}$ defined as follows:

$$a_{\mathbf{d},\mathbf{d}'} = (\mathbf{d}, \mathbf{d}'), \qquad \mathbf{m}_{Q/\mathbf{k}}(\mathbf{d}) = C_{Q/\mathbf{k},\mathbf{d}} \qquad \forall\ \mathbf{d}, \mathbf{d}' \in \mathbb{N}^I.$$

Denote by $\widetilde{\mathfrak{g}}_{Q/\mathbf{k}}$ the Borcherds algebra associated to $(A_{Q/\mathbf{k}}, \mathbf{m}_{Q/\mathbf{k}})$.

Theorem 3.1 (Sevenhant and Van Den Bergh [2001]). *The Hall algebra $\mathbf{H}_{Q/\mathbf{k}}$ is isomorphic to the positive nilpotent subalgebra $U_v(\widetilde{\mathfrak{n}}_{Q/\mathbf{k}})$ of the Drinfeld-Jimbo quantum enveloping algebra of $\widetilde{\mathfrak{g}}_{Q/\mathbf{k}}$.*

In other words, the cuspidal element span the spaces of *simple root vectors* for the Hall algebra $\mathbf{H}_{Q/\mathbf{k}}$. Note that adding the 'Cartan' $\mathbf{K}$ to $\mathbf{H}_Q$ will only produce a quotient of $U_v(\widetilde{\mathfrak{b}}_{Q/\mathbf{k}})$, whose own Cartan subalgebra is not finitely generated.

3.2 Counting cuspidals for quivers. To understand the structure of $\widetilde{\mathfrak{g}}_{Q/\mathbf{k}}$ better, we first need to understand the numbers $C_{Q/\mathbf{k},\mathbf{d}}$. In this direction, we have the following theorem, proved by Deng and Xiao for quivers with no edge loops, and then extended to the general case in Bozec and Schiffmann [2017]:

Theorem 3.2 (Deng and Xiao [2003] and Bozec and Schiffmann [2017])**.** *For any $Q = (I,\Omega)$ and $\mathbf{d} \in \mathbb{N}^I$ there exists a (unique) polynomial $C_{Q,\mathbf{d}}(t) \in \mathbb{Q}[t]$ such that for any finite field* $\mathbf{k}$*, $C_{Q/\mathbf{k},\mathbf{d}} = C_{Q,\mathbf{d}}(\#\mathbf{k})$.*

Let us say a word about the proof. By the Krull-Schmidt theorem, there is an isomorphism of $\mathbb{N}^I$-graded vector spaces between $\mathbf{H}_{Q/\mathbf{k}}$ and $Sym(\bigoplus_{\mathbf{d}} Fun(\mathfrak{M}^{ind}_{Q/\mathbf{k},\mathbf{d}}(\mathbf{k}),\mathbb{C}))$, where $\mathfrak{M}^{ind}_{Q/\mathbf{k},\mathbf{d}}(\mathbf{k})$ is the groupoid of indecomposable $\mathbf{k}$-representations of Q of dimension $\mathbf{d}$. This translates into the equality of generating series

$$\sum_{\mathbf{d}}(\dim \mathbf{H}_{Q/\mathbf{k}}[\mathbf{d}])z^d = \operatorname{Exp}_z\left(\sum_{\mathbf{d}} I_{Q,\mathbf{d}}(t)z^d\right)_{|t=\#\mathbf{k}} \tag{3-1}$$

where Exp_z stands for the plethystic exponential with respect to the variable z, see e.g. Mozgovoy [2011]. From the PBW theorem,

$$\sum_{\mathbf{d}}(\dim U(\widetilde{\mathfrak{n}}_{Q/\mathbf{k}})[\mathbf{d}])z^d = \operatorname{Exp}_z\left(\sum_{\mathbf{d}}(\dim \widetilde{\mathfrak{n}}_{Q/\mathbf{k}}[\mathbf{d}])z^d\right) \tag{3-2}$$

from which it follows that $\dim \widetilde{\mathfrak{n}}_{Q/\mathbf{k}}[\mathbf{d}] = I_{Q,\mathbf{d}}(\#\mathbf{k})$ for any $\mathbf{d}$. We are in the following situation: we know the character[5] of the Borcherds algebra $\widetilde{\mathfrak{g}}_{Q/\mathbf{k}}$ and from that we want to determine its Borcherds-Cartan data. This amounts to inverting the Borcherds character (or denominator) formula, which may be achieved in each degree by some finite iterative process[6]. Following through this iterative process and using the fact that $I_{Q,d}(\#\mathbf{k})$ is a polynomial in $\#\mathbf{k}$, one checks that the Borcherds-Cartan data, in particular the charge function $\mathbf{m}_{Q/\mathbf{k}}(\mathbf{d}) = C_{Q/\mathbf{k},\mathbf{d}}$ is also polynomial in $\#\mathbf{k}$. This process is constructive, but as far as we know no closed formula is known in general (see Bozec and Schiffmann [2017] for some special cases, such as totally negative quivers like S_g, $g > 1$). And in particular, the structure (and the size) of $\mathbf{H}_{Q/\mathbf{k}}$ depends heavily on $\mathbf{k}$.

[5] there is a subtle point here: $\widetilde{\mathfrak{g}}_{Q/\mathbf{k}}$ is $\mathbb{Z}^{(\mathbb{N}^I)}$-graded, but we only know the character after projection of the grading to $\mathbb{N}^I$.

[6] here we use the fact that the Weyl group of $\widetilde{\mathfrak{g}}_{Q/\mathbf{k}}$ only depends on the subset of real simple roots, which is the same as that of $\mathfrak{g}_Q$.

3.3 Counting absolutely cuspidals for quivers. In order to get a more canonical structure out of $\mathbf{H}_{Q/\mathbf{k}}$ one is tempted to view the polynomial $C_{Q,\mathbf{d}}(t)$ as giving the graded dimension of some vector space. Unfortunately, as can readily be seen for the Jordan quiver S_1 and $\mathbf{d} = 2$, the polynomial $C_{Q,\mathbf{d}}(t)$ fails to be integral or positive in general. This is familiar: the same things happens for Kac's A and I polynomials and one might guess that the better thing to count would be *absolutely* cuspidal elements of $\mathbf{H}_{Q/\mathbf{k}}$. Unfortunately (and contrary to the case of curves), there is at the moment no known definition of an absolutely cuspidal element of $\mathbf{H}_{Q/\mathbf{k}}$! One way around this is to use a well-known identity between Kac A-polynomials and I-polynomials to rewrite (3-1) as

(3-3)
$$\sum_{\mathbf{d}} \dim(U(\widetilde{\mathfrak{n}}_{Q/\mathbf{k}})[\mathbf{d}])z^d = \sum_{\mathbf{d}} \dim(H_{Q/\mathbf{k}}[\mathbf{d}])z^d = \operatorname{Exp}_{z,t}\left(\sum_{\mathbf{d}} A_{Q,\mathbf{d}}(t)z^d\right)_{|t=\#\mathbf{k}}$$

and interpret the right hand side as the character of the enveloping algebra of (the nilpotent subalgebra of) a putative *graded* Borcherds algebra $\widetilde{\mathfrak{g}}_Q$ whose graded character is given by the polynomials $A_{Q,\mathbf{d}}(t)$

$$\dim_{\mathbb{Z}} \widetilde{\mathfrak{g}}_Q[\mathbf{d}] = A_{Q,\mathbf{d}}(t). \tag{3-4}$$

Taking this as a working hypothesis, we can run through the above iterative process (in the graded sense) to get a well-defined family of polynomials $C^{\text{abs}}_{Q,\mathbf{d}}(t)$.

Theorem 3.3 (Bozec and Schiffmann [2017]). *For any Q and $\mathbf{d}$ we have $C^{abs}_{Q,\mathbf{d}}(t) \in \mathbb{Z}[t]$. In addition, we have $C^{abs}_{Q,\mathbf{d}}(t) = C_{Q,\mathbf{d}}(t)$ for any hyperbolic $\mathbf{d}$ (i.e. $(\mathbf{d},\mathbf{d}) < 0$) while for any indivisible isotropic $\mathbf{d}$,*

$$\operatorname{Exp}_z\left(\sum_{l\geq 1} C_{Q,l\mathbf{d}}(t)z^l\right) = \operatorname{Exp}_{t,z}\left(\sum_{l\geq 1} C^{abs}_{Q,l\mathbf{d}}(t)z^l\right)$$

Our definition of $C^{\text{abs}}_{Q,\mathbf{d}}(t)$ was motivated by the putative existence of a graded Borcherds algebra $\widetilde{\mathfrak{g}}_Q$. This existence is *a posteriori* equivalent to the following conjecture:

Conjecture 3.4. *For any Q and $\mathbf{d}$ we have $C^{abs}_{Q,\mathbf{d}} \in \mathbb{N}[t]$.*

We stress that the above positivity conjecture is strictly stronger than the positivity of Kac's A-polynomials. Indeed by construction Kac polynomials are integral positive polynomials in the $C^{\text{abs}}_{Q,\mathbf{d}}(t)$. We will give in Sections 4.4 and 4.6 two other (conjectural) constructions of the Lie algebra $\widetilde{\mathfrak{g}}_Q$, based on the geometry of $T^*\mathfrak{M}_Q, \Lambda_Q$ and on Nakajima quiver varieties respectively, either of which would imply the above positivity conjecture. We finish this section with another (somewhat imprecise) conjecture, which is a quiver analog of a conjecture of Kontsevich and Deligne, see Section 6.1.

Conjecture 3.5. *For any* Q, $\mathbf{d}$ *there exists a 'natural' algebraic variety* $\mathcal{C}_{Q,\mathbf{d}}$ *defined over* $\mathbb{Z}$ *such that for any finite field* $\mathbf{k}$ *we have* $C^{abs}_{Q,\mathbf{d}}(\#\mathbf{k}) = \#\mathcal{C}_{Q,\mathbf{d}}(\mathbf{k})$.

There are obvious variants of this conjecture, replacing $\mathcal{C}_{Q,\mathbf{d}}$ by a complex algebraic variety and the point count by the Poincaré polynomial, fixing the characteristic of $\mathbf{k}$, etc. *Examples:* For Q an affine quiver, we have $C^{\text{abs}}_{Q,\mathbf{d}}(t) = 1, t$ or 0 according to whether $\mathbf{d} \in \{\epsilon_i\}_i$, $\mathbf{d} \in \mathbb{N}\delta$ for δ the indivisible imaginary root, or neither of the above. For $Q = S_3$ and $\mathbf{d} = 3$ we have

$$C^{\text{abs}}_{S_g,3} = \frac{t^{9g-3} - t^{5g+2} - t^{5g-2} - t^{5g-3} + t^{3g+2} + t^{3g-2}}{(t^2-1)(t^3-1)}.$$

3.4 More questions than answers. As we have seen, there is a method for counting cuspidal (or even 'absolutely' cuspidal) functions, via Kac polynomials and the Borcherds character formula. But is it possible to get a geometric parametrization of these cuspidals (either in the sense of Conjecture 3.5, or as in the Langlands program in terms of some 'spectral data' [7]) ? Is it possible to explicitly construct cuspidal functions ? Can one lift a suitable basis of the space of cuspidal functions to some perverse sheaves on $\mathfrak{M}_Q$? In other words, is there a theory of canonical bases for $U_v(\widetilde{\mathbf{n}}_Q)$? If so, can one describe explicitly the Ext-algebra of that category of perverse sheaves ? Equivalently, is there a analog, for $\widetilde{\mathfrak{g}}_Q$, of the Khovanov-Lauda-Rouquier algebra, see Khovanov and Lauda [2009] and Rouquier [2012] ?

4 Quivers, Kac polynomials and graded Borcherds algebras II –Cohomological Hall algebras and Yangians–

The previous section offered a conjectural definition of Lie algebras $\widetilde{\mathfrak{g}}_Q, \widetilde{\mathfrak{g}}^{\text{nil}}_Q$ whose graded multiplicities are $A_{Q,\mathbf{d}}(t)$, $A^{\text{nil}}_{Q,\mathbf{d}}(t)$, but the construction –involving something like a 'generic form' for the full Hall algebras $\mathbf{H}_Q, \mathbf{H}^{\text{nil}}_Q$– was somewhat roundabout. In this section we describe a geometric construction, in terms of the cohomology of $T^*\mathfrak{M}_Q$ or Λ_Q, of algebras –the *cohomological Hall algebras*– which are deformations of the enveloping algebras $U(\bar{\mathfrak{n}}_Q[u]), U(\bar{\mathfrak{n}}^{\text{nil}}_Q[u])$ for certain graded Lie algebras $\bar{\mathfrak{n}}_Q, \bar{\mathfrak{n}}^{\text{nil}}_Q$ satisfying $\dim_{\mathbb{Z}} \bar{\mathfrak{n}}_Q = A_{Q,\mathbf{d}}(t), \dim_{\mathbb{Z}} \bar{\mathfrak{n}}^{\text{nil}}_Q = A^{\text{nil}}_{Q,\mathbf{d}}(t)$. Of course, it is expected that $\bar{\mathfrak{n}}_Q, \bar{\mathfrak{n}}^{\text{nil}}_Q$ are positive halves of Borcherds algebras $\bar{\mathfrak{g}}_Q, \bar{\mathfrak{g}}^{\text{nil}}_Q$ and thus coincide with $\widetilde{\mathfrak{g}}_Q, \widetilde{\mathfrak{g}}^{\text{nil}}_Q$. One nice output of this construction is that it yields for free a whole family of representations (in the cohomology of Nakajima quiver varieties). In this section, $\mathbf{k} = \mathbb{C}$.

[7] a preliminary question: what plays the role of Hecke operators in this context?

4.1 Geometry of the nilpotent variety. Let us begin by mentioning a few remarkable geometric properties of the (generally very singular) stacks $T^*\mathfrak{M}_Q, \Lambda_Q$ introduced in **2.4.** and **2.5.**. Here $Q = (I, \Omega)$ is an arbitrary quiver. Denote by $T = (\mathbb{C}^*)^2$ the two-dimensional torus acting on Λ_Q and $T^*\mathfrak{M}_Q$ by scaling the arrows in Ω and Ω^* respectively.

Theorem 4.1 (Schiffmann and Vasserot [2017a] and Davison [2016])**.** *The T-equivariant Borel-Moore homology space $H_*^T(\Lambda_Q, \mathbb{Q}) = \bigoplus_{\mathbf{d}} H_*^T(\Lambda_{Q,\mathbf{d}}, \mathbb{Q})$ is even, pure, and free over $H_T^*(pt, \mathbb{Q})$. The same holds for $T^*\mathfrak{M}_Q$.*

We will only consider (co)homology with $\mathbb{Q}$-coefficients and drop the $\mathbb{Q}$ in the notation. The above theorem for Λ_Q is proved by constructing a suitable compactification of $\Lambda_{Q,\mathbf{d}}$ for each $\mathbf{d}$, itself defined in terms of Nakajima varieties, see Schiffmann and Vasserot [2017a] and Nakajima [1994]. The second part of the theorem relies on dimensional reduction from a 3d Calabi-Yau category, see Davison [2016]. Kac polynomials are intimately related to the cohomology of Λ_Q and $T^*\mathfrak{M}_Q$. More precisely,

Theorem 4.2 (Bozec-S.-Vasserot, Davison, Mozgovoy)**.** *The Poincaré polynomials of Λ_Q and $T^*\mathfrak{M}_Q$ are respectively given by:*

$$\sum_{i,\mathbf{d}} dim\ H_{2i}(\Lambda_{Q,\mathbf{d}}) t^{\langle \mathbf{d},\mathbf{d}\rangle + i} z^{\mathbf{d}} = Exp\left(\sum_{\mathbf{d}} \frac{A^{nil}_{Q,\mathbf{d}}(t^{-1})}{1-t^{-1}} z^{\mathbf{d}}\right) \tag{4-1}$$

$$\sum_{i,\mathbf{d}} dim\ H_{2i}(T^*\mathfrak{M}_{Q,\mathbf{d}}) t^{\langle \mathbf{d},\mathbf{d}\rangle + i} z^{\mathbf{d}} = Exp\left(\sum_{\mathbf{d}} \frac{A_{Q,\mathbf{d}}(t)}{1-t^{-1}} z^{\mathbf{d}}\right). \tag{4-2}$$

Equality (4-1) is proved in Bozec, Schiffmann, and Vasserot [2017] and hinges again on some partial compactification of the stacks $\Lambda_{Q,\mathbf{d}}$ defined in terms of Nakajima quiver varieties. The second equality (4-2) is obtained by combining the purity results of Davison [2016] with the point count of Mozgovoy [2011]. In some sense, (4-1) and (4-2) are Poincaré dual to each other. Note that $\dim \Lambda_{Q,\mathbf{d}} = -\langle \mathbf{d}, \mathbf{d}\rangle$ hence (4-1) is a series in $\mathbb{C}[[t^{-1}]][z]$. Taking the constant term in t^{-1} yields $\sum_{\mathbf{d}} \#Irr(\Lambda_{\mathbf{d}}) z^{\mathbf{d}} = Exp(\sum_{\mathbf{d}} A^{\text{nil}}_{\mathbf{d}}(0) z^{\mathbf{d}})$, in accordance with Theorem 2.4 ii), Theorem 2.5 ii). In other terms, (4-1) provides a geometric interpretation (as the Poincaré polynomial of some stack) of the *full* Kac polynomial $A^{\text{nil}}_{Q,\mathbf{d}}(t)$ rather than just its constant term and passing from $A^{\text{nil}}_{Q,\mathbf{d}}(0)$ to $A^{\text{nil}}_{Q,\mathbf{d}}(t)$ essentially amounts to passing from $H_{top}(\Lambda_{Q,\mathbf{d}})$ to $H_*(\Lambda_{Q,\mathbf{d}})$. Of course, (4-2) has a similar interpretation.

4.2 Cohomological Hall algebras. The main construction of this section is the following:

Theorem 4.3 (Schiffmann and Vasserot [2013a] and Schiffmann and Vasserot [2017a]). *The spaces $H_*^T(T^*\mathfrak{M}_Q)$ and $H_*^T(\Lambda_Q)$ carry natural $\mathbb{Z}\times\mathbb{N}^I$-graded algebra structures. The direct image morphism $i_* : H_*^T(\Lambda_Q) \to H_*^T(T^*\mathfrak{M}_Q)$ is an algebra homomorphism.*

Let us say a few words about how the multiplication map

$$H_*^T(T^*\mathfrak{M}_{Q,\mathbf{d}_1}) \otimes H_*^T(T^*\mathfrak{M}_{Q,\mathbf{d}_2}) \to H_*^T(T^*\mathfrak{M}_{Q,\mathbf{d}_1+\mathbf{d}_2})$$

is defined. There is a convolution diagram

$$T^*\mathfrak{M}_{Q,\mathbf{d}_1} \times T^*\mathfrak{M}_{Q,\mathbf{d}_2} \xleftarrow{\ q\ } Z_{\mathbf{d}_1,\mathbf{d}_2} \xrightarrow{\ p\ } T^*\mathfrak{M}_{Q,\mathbf{d}_1+\mathbf{d}_2}$$

similar to (2-2), where $Z_{\mathbf{d}_1,\mathbf{d}_2}$ is the stack of inclusions $\bar{M} \subset \bar{R}$ with $\bar{M}, \bar{R}$ representations of Π_Q of respective dimensions $\mathbf{d}_2, \mathbf{d}_1+\mathbf{d}_2$, and p and q are the same as in (2-2). The map p is still proper, so that $p_* : H_*^T(Z_{\mathbf{d}_1,\mathbf{d}_2}) \to H_*^T(T^*\mathfrak{M}_{Q,\mathbf{d}_1+\mathbf{d}_2})$ is well-defined, but q is not regular anymore and we cannot directly define a Gysin map q^*. Instead, we embedd $Z_{\mathbf{d}_1,\mathbf{d}_2}$ and $T^*\mathfrak{M}_{Q,\mathbf{d}_1} \times T^*\mathfrak{M}_{Q,\mathbf{d}_2}$ into suitable *smooth* moduli stacks of representations of the path algebra of the double quiver $\overline{Q}$ (without preprojective relations) and define a refined Gysin map $q^! : H_*^T(T^*\mathfrak{M}_{Q,\mathbf{d}_1} \times T^*\mathfrak{M}_{Q,\mathbf{d}_2}) \to H_*^T(Z_{\mathbf{d}_1,\mathbf{d}_2})$. The multiplication map is then $m = p_*q^!$. Note that it is of cohomological degree $-\langle \mathbf{d}_1,\mathbf{d}_2\rangle - \langle \mathbf{d}_2,\mathbf{d}_1\rangle$; to remedy this, we may (and will) shift the degree of $H_*^T(T^*\mathfrak{M}_{Q,\mathbf{d}})$ by $\langle \mathbf{d},\mathbf{d}\rangle$. There is another notion of cohomological Hall algebra due to Kontsevich and Soibelman, associated to any Calabi-Yau category of dimension *three* (Kontsevich and Y. Soibelman [2011]); as shown by Davison, see the appendix to Ren and Y. Soibelman [2017] (see also Yang and Zhao [2016]) using a dimensional reduction argument, the algebras $H_*^T(T^*\mathfrak{M}_Q)$, $H_*^T(\Lambda_Q)$ arise in that context as well. In addition, the above construction of the cohomological Hall algebras can be transposed to any oriented cohomology theory which has proper pushforwards and refined Gysin maps, such as Chow groups, K-theory, elliptic cohomology or Morava K-theory (see Yang and Zhao [2014]). This yields in a uniform way numerous types of quantum algebras with quite different flavors.

Not very much is known about the precise structure of $H_*^T(T^*\mathfrak{M}_Q)$ or $H_*^T(\Lambda_Q)$ in general (and even less so for other types of cohomology theories). However, it is possible to give a simple set of generators; for any $\mathbf{d}$ there is an embedding of $\mathfrak{M}_{Q,\mathbf{d}}$ in $\Lambda_{Q,\mathbf{d}}$ as the zero-section, the image being one irreducible component of $\Lambda_{Q,\mathbf{d}}$.

Theorem 4.4 (Schiffmann and Vasserot [2017a]). *The algebra $H_*^T(\Lambda_Q)$ is generated over $H_T^*(pt)$ by the collection of subspaces*

$$\{H_*^T(\mathfrak{M}_{Q,\epsilon_i}) \mid i \in I^{re} \cup I^{iso}\} \cup \{H_*^T(\mathfrak{M}_{Q,l\epsilon_i}) \mid i \in I^{hyp}, l \in \mathbb{N}\}$$

Note that $\mathfrak{M}_{Q,\mathbf{d}} = E_{\mathbf{d}}/G_{\mathbf{d}}$, where $E_{\mathbf{d}}$ is a certain representation of $G_{\mathbf{d}} = \prod_i GL(\mathbf{d}_i)$, hence $H_*^T(\mathfrak{M}_{Q,\mathbf{d}}) = H^*_{G_{\mathbf{d}}\times T}(pt) \cdot [\mathfrak{M}_{Q,\mathbf{d}}] \simeq \mathbb{Q}[q_1, q_2, c_l(M_i) \mid i \in I, l \leq \mathbf{d}_i]$, where

q_1, q_2 are the equivariant parameters corresponding to T. The above result is for the nilpotent stack $\Lambda_{Q,\mathbf{d}}$, but one can show that $H_*^T(\Lambda_Q) \otimes \mathbb{Q}(q_1, q_2) = H_*^T(T^*\mathfrak{M}_Q) \otimes \mathbb{Q}(q_1, q_2)$ [8] so that the same generation result holds for $H_*^T(T^*\mathfrak{M}_Q) \otimes \mathbb{Q}(q_1, q_2)$.

4.3 Shuffle algebras. One can also give an algebraic model for a certain *localized* form of $H_*^T(T^*\mathfrak{M}_Q)$ (or $H_*^T(\Lambda_Q)$). Namely, let $\overline{E}_{\mathbf{d}} = T^*E_{\mathbf{d}}$ be the vector space of representations of $\overline{Q}$ in $\bigoplus_i \mathbf{k}^{\mathbf{d}_i}$. The direct image morphism $i_* : H_*^T(T^*\mathfrak{M}_{Q,\mathbf{d}}) \to H_*^T(\overline{E}_{\mathbf{d}}/G_{\mathbf{d}})$ is an isomorphism after tensoring by $Frac(H^*_{T\times G_{\mathbf{d}}}(pt))$. What's more, it is possible to equip

$$Sh_Q^{H_*^T} := \bigoplus_{\mathbf{d}} H_*^T(\overline{E}_{\mathbf{d}}/G_{\mathbf{d}}) \simeq \bigoplus_{\mathbf{d}} H^*_{T\times G_{\mathbf{d}}}(pt)$$

with the structure of an associative algebra (such that i_* becomes an algebra morphism), described explicitly as a *shuffle algebra*. More precisely, let us identify

$$H^*_{T\times G_{\mathbf{d}}}(pt) \simeq \mathbb{Q}[q_1, q_2, z_{i,l} \mid i \in I, l \leq \mathbf{d}_i]^{W_{\mathbf{d}}} \tag{4-3}$$

where $W_{\mathbf{d}} = \prod_i \mathfrak{S}_{\mathbf{d}_i}$ is the Weyl group of $G_{\mathbf{d}}$. To unburden the notation, we will collectively denote the variables $z_{i,1}, \ldots, z_{i,\mathbf{d}_i}$ (for all $i \in I$) by $\underline{z}_{[1,\mathbf{d}]}$, and use obvious variants of that notation. Also, we will regard q_1, q_2 as scalars and omit them from the notation. Fix dimension vectors $\mathbf{d}, \mathbf{e}$ and put $\mathbf{n} = \mathbf{d}+\mathbf{e}$. For two integers r, s we denote by $Sh_{r,s} \subset \mathfrak{S}_{r+s}$ the set of (r,s)-shuffles, i.e. permutations σ satisfying $\sigma(i) < \sigma(j)$ for $1 \leq i < j \leq r$ and $r < i < j \leq r+s$, and we put $Sh_{\mathbf{d},\mathbf{e}} = \prod_i Sh_{\mathbf{d}_i,\mathbf{e}_i} \subset \prod_i \mathfrak{S}_{\mathbf{n}_i} = W_{\mathbf{n}}$. In terms of (4-3), the multiplication map $H^*_{T\times G_{\mathbf{d}}}(pt) \otimes H^*_{T\times G_{\mathbf{e}}}(pt) \to H^*_{T\times G_{\mathbf{n}}}(pt)$ now reads

$$(f * g)(\underline{z}_{[1,\mathbf{n}]}) = \sum_{\sigma \in Sh_{\mathbf{d},\mathbf{e}}} \sigma\left[K_{\mathbf{d},\mathbf{e}}(\underline{z}_{[1,\mathbf{n}]}) \cdot f(\underline{z}_{[1,\mathbf{d}]}) \cdot g(\underline{z}_{[\mathbf{d}+1,\mathbf{n}]})\right]$$

where $K_{\mathbf{d},\mathbf{e}}(\underline{z}_{[1,\mathbf{n}]}) = \prod_{s=0}^2 K^{(s)}_{\mathbf{d},\mathbf{e}}(\underline{z}_{[1,\mathbf{n}]})$ with

$$K^{(0)}_{\mathbf{d},\mathbf{e}}(\underline{z}_{[1,\mathbf{n}]}) = \prod_{i\in I} \prod_{\substack{1\leq l\leq \mathbf{d}_i \\ \mathbf{d}_i+1\leq k\leq \mathbf{n}_i}} (z_{i,l} - z_{i,k})^{-1},$$

$$K^{(1)}_{\mathbf{d},\mathbf{e}}(\underline{z}_{[1,\mathbf{n}]}) = \prod_{h\in\Omega} \prod_{\substack{1\leq l\leq \mathbf{d}_{h'} \\ \mathbf{d}_{h''}+1\leq k\leq \mathbf{n}_{h''}}} (z_{h',l} - z_{h'',k} - q_1) \prod_{\substack{1\leq l\leq \mathbf{d}_{h''} \\ \mathbf{d}_{h'}+1\leq k\leq \mathbf{n}_{h'}}} (z_{h'',l} - z_{h',k} - q_2)$$

[8] in other words $H_*^T(\Lambda_Q)$ and $H_*^T(T^*\mathfrak{M}_Q)$ are two different integral forms of the same $\mathbb{Q}(q_1, q_2)$-algebra; this explains the discrepancy between usual and nilpotent Kac polynomials.

and

$$K^{(2)}_{\mathbf{d},\mathbf{e}}(\underline{z}_{[1,\mathbf{n}]}) = \prod_{i\in I} \prod_{\substack{1\le l\le \mathbf{d}_i \\ \mathbf{d}_i+1\le k\le \mathbf{n}_i}} (z_{i,k} - z_{i,l} - q_1 - q_2).$$

As shown in Schiffmann and Vasserot [2017a], $H^T_*(T^*\mathfrak{M}_{Q,\mathbf{d}})$ and $H^T_*(\Lambda_{Q,\mathbf{d}})$ are torsion-free and of generic rank one as modules over $H^*_{T\times G_{\mathbf{d}}}(pt)$, hence the localization map i_* is injective and Theorem 4.4 yields a description of the cohomological Hall algebra $H^T_*(\Lambda_Q)$ as a subalgebra of the above shuffle algebra, generated by an explicit collection of polynomials. This allows one to identify the rational form of $H^T_*(\mathfrak{M}_Q)$ with the positive half of the Drinfeld Yangian $Y_h(\mathfrak{g}_Q)$ when Q is of finite type and with the positive half of the Yangian version of the elliptic Lie algebra $\mathfrak{g}_{Q_0}[s^{\pm 1}, t^{\pm 1}] \oplus K$ when Q is an affine Dynkin diagram. Here K is the full central extension of the double loop algebra $\mathfrak{g}_{Q_0}[s^{\pm 1}, t^{\pm 1}]$. Beyond these case, shuffle algebras tend to be rather difficult to study and the algebraic structure of $H^T_*(\mathfrak{M}_Q)$ (or $H^T_*(\Lambda_Q)$) is still mysterious (see, however Neguţ [2015, 2016] for some important applications to the geometry of instanton moduli spaces in the case of the Jordan or affine type A quivers).

There are analogous shuffle algebra models in the case of an arbitrary oriented Borel-Moore homology theory, but the torsion-freeness statement remains conjectural in general. In order to give the reader some idea of what these are, as well as for later use, let us describe the localized K-theoretic Hall algebra of the g-loop quiver S_g. In this case, there is a $g+1$-dimensional torus T_g acting by rescaling the arrows:

$$(\xi_1, \xi_2, \dots, \xi_g, p)\cdot(h_1, h_1^*, \dots, h_g, h_g^*) = (\xi_1 h_1, p\xi_1^{-1} h_1^*, \dots, \xi_g h_g, p\xi_g^{-1} h_g^*)$$

and we have an identification

$$Sh^{K^{T_g}}_{S_g} := \bigoplus_d K^{T_g\times G_d}(pt) \simeq \bigoplus_d \mathbb{Q}[\xi_1^{\pm 1}, \dots, \xi_g^{\pm 1}, p^{\pm 1}; z_1^{\pm 1}, \dots, z_d^{\pm 1}]^{\mathfrak{S}_d}.$$

The multiplication takes the form

$$(f * g)(\underline{z}_{[1,n]}) = \sum_{\sigma\in Sh_{d,e}} \sigma\Big[K_{d,e}(\underline{z}_{[1,n]})\cdot f(\underline{z}_{[1,d]})\cdot g(\underline{z}_{[d+1,n]})\Big] \tag{4-4}$$

where $K_{d,e}(\underline{z}_{[1,n]}) = \prod_{s=0}^2 K^{(s)}_{d,e}(\underline{z}_{[1,n]})$ with

$$K^{(0)}_{d,e}(\underline{z}_{[1,n]}) = \prod_{\substack{1\le l\le d \\ d+1\le k\le n}} (1 - z_l/z_k)^{-1}$$

$$K^{(1)}_{d,e}(\underline{z}_{[1,n]}) = \prod_{\substack{1\le l\le d \\ d+1\le k\le n}} \prod_{u=1}^{g} (1 - \xi_u^{-1} z_l/z_k)(1 - p^{-1}\xi_u z_l/z_k)$$

$$K^{(2)}_{d,e}(\underline{z}_{[1,n]}) = \prod_{\substack{1 \le l \le d \\ d+1 \le k \le n}} (1 - p^{-1} z_k / z_l)^{-1}.$$

4.4 PBW theorem. We finish this paragraph with the following important structural result due to Davison and Meinhardt:

Theorem 4.5 (Davison and Meinhardt [2016]). *There exists a graded algebra filtration $\mathbb{Q} = F_0 \subseteq F_1 \subseteq \cdots$ of $H_*(T^*\mathfrak{M}_Q)$ and an algebra isomorphism*

$$gr_{F_\bullet}(H_*(T^*\mathfrak{M}_Q)) \simeq Sym(\bar{\mathfrak{n}}_Q[u]) \tag{4-5}$$

where $\bar{\mathfrak{n}}_Q = \bigoplus_{\mathbf{d} \in \mathbb{N}^I} \bar{\mathfrak{n}}_{Q,\mathbf{d}}$ is a $\mathbb{N}^I \times \mathbb{N}$-graded vector space and $deg(u) = -2$. The same holds for $H_*(\Lambda_Q)$.

The filtration $F_\bullet$ is, essentially, the perverse filtration associated to the projection from the stack $T^*\mathfrak{M}_Q$ to its coarse moduli space. As a direct corollary, $F_1 \simeq \bar{\mathfrak{n}}_Q[u]$ is equipped with the structure of an $\mathbb{N}$-graded Lie algebra; it is easy to see that it is the polynomial current algebra of an $\mathbb{N}$-graded Lie algebra $\bar{\mathfrak{n}}_Q$ (coined the *BPS Lie algebra* in Davison and Meinhardt [ibid.]). Loosely speaking, Theorem 4.5 says that $H_*(T^*\mathfrak{M}_Q)$ is (a filtered deformation of) the enveloping algebra $U(\bar{\mathfrak{n}}_Q[u])$, i.e. some kind of Yangian of $\bar{\mathfrak{n}}_Q$. Comparing graded dimension and using Theorem 4.2 we deduce that for any $\mathbf{d} \in \mathbb{N}^I$

$$\dim_{\mathbb{Z}} \bar{\mathfrak{n}}_{Q,\mathbf{d}} = A_{Q,\mathbf{d}}(t). \tag{4-6}$$

Moreover, when Q has no edge loops, it can be shown that the degree zero Lie subalgebra $\bar{\mathfrak{n}}_Q[0]$ is isomorphic to the positive nilpotent subalgebra $\mathfrak{n}_Q$ of the Kac-Moody algebra $\mathfrak{g}_Q$. This implies at once both the positivity and the constant term conjectures for Kac polynomials, see Section 2.2 The same reasoning also yields a proof of the nilpotent versions of the Kac conjectures (for an arbitrary quiver) of Section 2.5, see Davison [2016].

At this point, the following conjecture appears inevitable:

Conjecture 4.6. *The graded Lie algebra $\bar{\mathfrak{n}}_Q$ is isomorphic to the positive subalgebra $\widetilde{\mathfrak{n}}_Q$ of $\widetilde{\mathfrak{g}}_Q$.*

Notice that the definition of $\widetilde{\mathfrak{g}}_Q$ involves the *usual* Hall algebra of Q (over all the finite fields $\mathbb{F}_q$), while that of $\bar{\mathfrak{n}}_Q$ involves the (two-dimensional) *cohomological* Hall algebra of Q and the complex geometry of $\mathrm{Rep}_{\mathbb{C}}\,\Pi_Q$. Conjecture 4.6 would follow from the fact that $\bar{\mathfrak{n}}_Q$ is the positive half of some graded Borcherds algebra $\bar{\mathfrak{g}}_Q$.

4.5 Action on Nakajima quiver varieties. One important feature of the cohomological Hall algebras $H^T_*(T^*\mathfrak{M}_Q)$, $H^T_*(\Lambda_Q)$ is that they act, via some natural correspondences, on the cohomology of Nakajima quiver varieties. Recall that the Nakajima quiver variety $\mathfrak{M}_Q(\mathbf{v},\mathbf{w})$ associated to a pair of dimension vectors $\mathbf{v},\mathbf{w}\in\mathbb{N}^I$ is a smooth quasi-projective symplectic variety, which comes with a proper morphism $\pi:\mathfrak{M}_Q(\mathbf{v},\mathbf{w})\to\mathfrak{M}_{Q,0}(\mathbf{v},\mathbf{w})$ to a (usually singular) affine variety. The morphism π is an example of a symplectic resolution of singularities, of which quiver varieties provide one of the main sources. The quiver variety also comes with a canonical (in general singular) lagrangian subvariety $\mathfrak{L}(\mathbf{v},\mathbf{w})$ which, when the quiver has no edge loops, is the central fiber of π. Examples include the Hilbert schemes of points on $\mathbb{A}^2$ or on Kleinian surfaces, the moduli spaces of instantons on theses same spaces, resolutions of Slodowy slices in nilpotent cones and many others (see e.g. Schiffmann [2008] for a survey of the theory of Nakajima quiver varieties). The following theorem was proved by Varagnolo [2000], based on earlier work by Nakajima in the context of equivariant K-theory (see Nakajima [1998, 2001]).

Theorem 4.7 (Varagnolo [2000]). *Let Q be without edge loops and $\mathbf{w}\in\mathbb{N}^I$. There is a geometric action of the Yangian $Y_h(\mathfrak{g}_Q)$ on $F_\mathbf{w}:=\bigoplus_\mathbf{v} H_*^{T\times G_\mathbf{w}}(\mathfrak{M}_Q(\mathbf{v},\mathbf{w}))$, preserving the subspace $L_\mathbf{w}:=\bigoplus_\mathbf{v} H_*^{T\times G_\mathbf{w}}(\mathfrak{L}_Q(\mathbf{v},\mathbf{w}))$. For Q of finite type, $L_\mathbf{w}$ is isomorphic to the universal standard $Y_h(\mathfrak{g}_Q)$-module of highest weight $\mathbf{w}$.*

In the above, the Yangian $Y_h(\mathfrak{g}_Q)$ is defined using Drinfeld's new realization, applied to an arbitrary Kac-Moody root system, see Varagnolo [ibid.]. Its precise algebraic structure is only known for Q of finite or affine type.

Theorem 4.8 (Schiffmann and Vasserot [2017a]). *For any Q and any $\mathbf{w}\in\mathbb{N}^I$ there is a geometric action of the cohomological Hall algebra $H_*^T(T^*\mathfrak{M}_Q)$ on $F_\mathbf{w}$. The diagonal action of $H_*^T(T^*\mathfrak{M}_Q)$ on $\prod_\mathbf{w} F_\mathbf{w}$ is faithful. The subalgebra $H_*^T(\Lambda_Q)$ preserves $L_\mathbf{w}$, which is a cyclic module.*

For quivers with no edge loops, we recover Varagnolo's Yangian action by Theorem 4.4; It follows that there exists a surjective map

$$Y_h^+(\mathfrak{g}_Q)\otimes\mathbb{Q}(q_1,q_2)\to H_*^T(T^*\mathfrak{M}_Q)\otimes\mathbb{Q}(q_1,q_2)$$

This map is an isomorphism for Q of finite or affine type. The action of $H_*^T(T^*\mathfrak{M}_Q)$ is constructed by means of general Hecke correspondences; in fact one can view $H_*^T(T^*\mathfrak{M}_Q)$ as the *largest* algebra acting on $F_\mathbf{w}$ via Hecke correspondences. Considering dual Hecke correspondences (or adjoint operators), one defines an opposite action of $H_*^T(T^*\mathfrak{M}_Q)$; it is natural to expect that these two actions extend to an action of some 'Drinfeld double' of $H_*^T(T^*\mathfrak{M}_Q)$, but this remains to be worked out. It is also natural to expect that $L_\mathbf{w}$ is a universal or standard module for $H_*^T(T^*\mathfrak{M}_Q)$, as is suggested by Hausel's formula for the Poincaré polynomial of $\mathfrak{M}_Q(\mathbf{v},\mathbf{w})$ or $\mathfrak{L}_Q(\mathbf{v},\mathbf{w})$, which involves the (full) Kac polynomials, see Hausel [2010] and Bozec, Schiffmann, and Vasserot [2017].

Theorem 4.8 has an obvious analog (with the same proof) for an arbitrary OBM theory (see Yang and Zhao [2014] for the construction of the action).

4.6 Relation to Maulik-Okounkov Yangians. We finish this section by very briefly mentioning yet another (conjectural) construction of the Lie algebra $\widetilde{\mathfrak{g}}_Q$, this time directly by means of the symplectic geometry of Nakajima quiver varieties. Using the theory of *stable enveloppes* for $\mathbb{C}^*$-actions on smooth symplectic varietes, Maulik and Okounkov constructed for any pair of dimension vectors $\mathbf{w}_1, \mathbf{w}_2$ a quantum R-matrix

$$R_{\mathbf{w},\mathbf{w}_2}(t) = 1 + \frac{\hbar}{v^{-1}}\mathbf{r}_{\mathbf{w}_1,\mathbf{w}_2} + O(v^{-2}) \in \mathrm{End}(F_{\mathbf{w}_1} \otimes F_{\mathbf{w}_2})[[v^{-1}]].$$

Applying the RTT formalism, we obtain a graded algebra $\mathbb{Y}_Q$ acting on all the spaces $F_{\mathbf{w}}$; similarly, from the classical R-matrices $\mathbf{r}_{\mathbf{w}_1,\mathbf{w}_2}$ we obtain a $\mathbb{Z}$-graded Lie algebra $\mathbf{g}_Q$. Moreover, $\mathbb{Y}_Q$ is (up to some central elements) a filtered deformation of $U(\mathbf{g}_Q[u])$ (hence the name *Maulik-Okounkov Yangian* see Maulik and Okounkov [2012]). It can be shown that $\mathbf{g}_Q$ is a graded Borcherds algebra. The following conjecture was voiced by Okounkov [n.d.]:

Conjecture 4.9 (Okounkov)**.** *For any Q and any $\mathbf{d} \in \mathbb{N}^I$ we have* $\dim_{\mathbb{Z}}\ \mathbf{g}_Q[\mathbf{d}] = A_{Q,\mathbf{d}}(t)$.

The conjecture is known when Q is of finite type. Comparing with (3-4) and (4-6) leads to the following

Conjecture 4.10. *For any Q we have* $\mathbf{g}_Q \simeq \bar{\mathfrak{g}}_Q \simeq \widetilde{\mathfrak{g}}_Q$.

As a first step towards the above conjecture, we have

Theorem 4.11 (Schiffmann and Vasserot [2017b])**.** *For any Q there is a canonical embedding $H^T_*(\Lambda_Q) \to \mathbb{Y}^+_Q$, compatible with the respective actions on $\prod_{\mathbf{w}} F_{\mathbf{w}}$ of $H^T_*(\Lambda_Q)$ and $\mathbb{Y}_Q$.*

All together, we see that there are conjecturally (at least) *three* different incarnations of the *same* graded Borcherds Lie algebra: as a 'generic form' of the full Hall algebra of the category of representations of Q over finite fields, as a cohomological Hall algebra of the complex (singular) stack $T^*\mathfrak{M}_Q$, or as an algebra acting on the cohomology of Nakajima quiver varieties via R-matrices constructed by means of symplectic geometry. The precise structure of this graded Borcherds algebra, in particular its Cartan matrix (determined by the polynomials $C^{\mathrm{abs}}_{Q,\mathbf{d}}(t)$ counting the dimensions of the spaces of 'absolutely' cuspidal functions for Q) remains however very mysterious. From the symplectic geometry perspective, one might expect the polynomials $C^{\mathrm{abs}}_{Q}(t)$ to be related to some motive inside the Nakajima quiver variety, but there is no conjectural construction of such a motive that we know of.

In the remainder of this paper, we shift gears and consider categories of coherent sheaves on smooth projective curves instead of representations of quivers; motivated by the analogy with quivers, we will describe the spherical Hall algebra, full Hall algebra and $2d$-cohomological Hall algebras (!) of a curve, as well as a geometric interpretation of Kac polynomials in terms of Higgs bundles. We finish with some speculation about the Lie theoretic structures that we believe are lurking in the background.

5 Hall algebras of curves and shuffle algebras

5.1 Notations. We fix an integer $g \geq 0$ and a smooth, geometrically connected, projective curve X of genus g over a field $\mathbf{k}$. We denote by $\mathrm{Coh}(X)$ the category of coherent sheaves on X and by $\mathfrak{M}_{X,r,d}$ the stack of coherent sheaves of rank r and degree d. It is a smooth stack, locally of finite type. The Euler form is given by the Riemann-Roch formula

$$\langle \mathcal{F}, \mathcal{G} \rangle = (1-g)rk(\mathcal{F})rk(\mathcal{G}) + (rk(\mathcal{F})deg(\mathcal{G}) - rk(\mathcal{G})deg(\mathcal{F})).$$

Set $\mathfrak{M}_X = \bigsqcup_{r,d} \mathfrak{M}_{X,r,d}$.

5.2 Ringel–Hall algebra of a curve. Let us now assume that $\mathbf{k}$ is a finite field, and define

$$\mathbf{H}_X = \bigoplus_{r,d} \mathbf{H}_X[r,d], \qquad \mathbf{H}_X[r,d] := \mathrm{Fun}(\mathfrak{M}_{X,r,d}(\mathbf{k}), \mathbb{C}).$$

In an entirely similar fashion to (2-2), there is a convolution diagram

$$\mathfrak{M}_X \times \mathfrak{M}_X \xleftarrow{\;q\;} \widetilde{\mathfrak{M}}_X \xrightarrow{\;p\;} \mathfrak{M}_X \tag{5-1}$$

where $\widetilde{\mathfrak{M}}_X$ is the stack parametrizing short exact sequences

$$0 \longrightarrow \mathcal{F} \longrightarrow \mathcal{H} \longrightarrow \mathcal{G} \longrightarrow 0$$

in $\mathrm{Coh}(X)$; The map p is proper, while the map q is again a stack vector bundle, whose restriction to $\mathfrak{M}_{X,r,d} \times \mathfrak{M}_{X,r',d'}$ is of rank $-\langle (r',d'),(r,d)\rangle$. Setting $v = (\#\mathbf{k})^{\frac{1}{2}}$, $\mathbf{K} = \mathbb{C}[k_{(0,1)}^{\pm 1}, k_{(1,0)}^{\pm 1}]$ we equip, using (2-3) and (2-4), $\widetilde{\mathbf{H}}_X := \mathbf{H}_X \otimes \mathbf{K}$ with the structure of a $\mathbb{Z}^2$-graded bialgebra called the *Hall algebra* of X. It carries a nondegenerate Hopf pairing by (2-5). Finally, $\mathbf{H}_X \simeq \mathbf{H}_X^{\mathrm{bun}} \ltimes \mathbf{H}_X^0$ where $\mathbf{H}_X^{\mathrm{bun}}, \mathbf{H}_X^0$ are the Hall subalgebras of vector bundles, resp. torsion sheaves. The Hall algebra of a curve was first considered by M. M. Kapranov [1997], who established the (direct) dictionary between $\mathbf{H}_X^{\mathrm{bun}}$ and the space of automorphic forms[9] for the groups $GL(n, \mathbb{A}_X)$, together with the operations of parabolic induction (Eisenstein series) and restriction (constant term map), and who observed a striking analogy between $\widetilde{\mathbf{H}}_X$ and quantum loop groups.

Let $\mathbf{H}_X^{\mathrm{sph}}$ (resp. $\mathbf{H}_X^{\mathrm{sph,bun}}$) be the subalgebra of $\mathbf{H}_X$ generated by the constant functions on $\mathfrak{M}_{X,r,d}$ for $r = 0, 1$ (resp. $r = 1$) and $d \in \mathbb{Z}$. From the point of view of automorphic forms, $\mathbf{H}_X^{\mathrm{sph,bun}}$ is the space spanned by all components of Eisenstein series induced from trivial (i.e constant) automorphic forms for the torus (together with a suitable space of Hecke operators in the case of $\mathbf{H}_X^{\mathrm{sph}}$). One can show that $\widetilde{\mathbf{H}}_X^{\mathrm{sph}} := \mathbf{H}_X^{\mathrm{sph}} \otimes \mathbf{K}$ is a self-dual sub-Hopf algebra of $\widetilde{\mathbf{H}}_X$ which contains the characteristic functions of any Harder-Narasimhan strata (see Schiffmann [2011]). Moreover, contrary to $\widetilde{\mathbf{H}}_X$ which depends strongly on the fine arithmetic structure of X, $\widetilde{\mathbf{H}}_X^{\mathrm{sph}}$ only depends on the Weil numbers of X and admits an R_g*-rational form*, i.e. there exists a torsion-free R_g-Hopf algebra $\widetilde{\mathbf{H}}_{\Sigma_g}^{\mathrm{sph}}$ such that for any smooth projective curve X defined over a finite field, $\widetilde{\mathbf{H}}_{\Sigma_g}^{\mathrm{sph}} \otimes_{R_g} \mathbb{C}_X \simeq \widetilde{\mathbf{H}}_X^{\mathrm{sph}}$, where $\mathbb{C}_X$ is the R_g-module corresponding to the evaluation morphism $R_g \to \overline{\mathbb{Q}_l} \simeq \mathbb{C}$, $f \mapsto f(Fr_x)$. We view $\widetilde{\mathbf{H}}_{\Sigma_g}^{\mathrm{sph}}$ as some kind of (half) quantum group which depends on $\dim T_g = g + 1$ quantum parameters, associated to curves of genus g. The full quantum group is, as before, obtained by the Drinfeld double procedure. Hall algebras in genus 0 and 1 are already very interesting:

Theorem 5.1 (M. M. Kapranov [1997],Baumann and Kassel [2001])**.** *The Drinfeld double* $\mathbf{D}\widetilde{\mathbf{H}}_{\Sigma_0}^{sph}$ *is isomorphic to the quantum affine algebra* $U_v(\widehat{\mathfrak{sl}_2})$.

Theorem 5.2 (Burban and Schiffmann [2012],Schiffmann and Vasserot [2011])**.** *The Drinfeld double* $\mathbf{D}\widetilde{\mathbf{H}}_{\Sigma_1}^{sph}$ *is isomorphic to the spherical double affine Hecke algebra* $\mathbf{S}\ddot{\mathbf{H}}_{q,t}(GL_\infty)$ *of type* $GL(\infty)$.

In the above two cases, the structure of the Hall algebra $\widetilde{\mathbf{H}}_{\Sigma_g}^{\mathrm{sph}}$ is rather well understood: it has a PBW-type basis as well as a canonical basis constructed from simple perverse sheaves (Eisenstein sheaves) on the stacks $\mathfrak{M}_X$. The spherical Hall algebra $\widetilde{\mathbf{H}}_{\Sigma_1}^{\mathrm{sph}}$ –also called the *elliptic Hall algebra*– has found a surprising number of applications in representation theory of Cherednik algebras, low-dimensional topology and knot theory (e.g. Morton and Samuelson [2017] , Gorsky and Neguţ [2015]), algebraic geometry and mathematical physics of the instanton spaces on $\mathbb{A}^2$ (e.g. Schiffmann and Vasserot [2013b], Schiffmann and Vasserot [2013a], and Neguţ [2016]), combinatorics of Macdonald polynomials (e.g. Bergeron, Garsia, Leven, and Xin [2016] and Francesco and Kedem [2017]),

[9] one nice feature of the Hall algebra is that it incorporates the algebra of Hecke operators, as the sub Hopf algebra of torsion sheaves $\mathbf{H}_X^0$

categorification (e.g. Cautis, Lauda, Licata, Samuelson, and Sussan [2016]), etc. The elliptic Hall algebra (or close variants thereof) has independently appeared in the work of Miki [2007] and Ding and Iohara [1997] and Feigin and his collaborators (see e.g., B. Feigin, E. Feigin, Jimbo, Miwa, and Mukhin [2011]).

5.3 Shuffle algebra presentation. Although the structure of $\widetilde{\mathbf{H}}^{\mathrm{sph}}_{\Sigma_g}$ for $g > 1$ is much less well understood, we always have a purely algebraic model of $\widetilde{\mathbf{H}}^{\mathrm{sph}}_{\Sigma_g}$ at our disposal, once again[10] in the guise of a shuffle algebra. More precisely, let

$$\zeta_{\Sigma_g}(z) := \frac{\prod_{i=1}^{g}(1-\eta_i z)}{(1-z)(1-qz)} \in R_g(z)$$

be the 'generic' zeta function of a curve of genus g and put $\zeta'_{\Sigma_g}(z) = (1-qz)(1-qz^{-1})\zeta_{\Sigma_g}(z)$. Consider the shuffle algebra

$$Sh_{\Sigma_g} := \bigoplus_d R_g[z_1^{\pm 1}, \ldots, z_d^{\pm 1}]^{\mathfrak{S}_d}$$

with multiplication

$$(f * g)(\underline{z}_{[1,n]}) = \sum_{\sigma \in Sh_{d,e}} \sigma\left[K_{d,e}(\underline{z}_{[1,n]}) f(\underline{z}_{[1,d]}) g(\underline{z}_{[d+1,n]})\right] \tag{5-2}$$

where $K_{d,e}(\underline{z}_{[1,n]}) = \prod_{1 \leq l \leq d < k \leq n} \zeta'_{\Sigma_g}(z_l/z_k)$, for any d, e and $n = d+e$.

Theorem 5.3 (Schiffmann and Vasserot [2012]). *The assignment* $1_{Pic^d} \mapsto z^d \in Sh_{\Sigma_g}[1]$ *extends to an* R_g*-algebra embedding* $\Psi : \mathbf{H}^{sph,bun}_{\Sigma_g} \to Sh_{\Sigma_g}$.

The map Ψ is essentially the iterated coproduct $\Delta^{(r)} : \mathbf{H}^{\mathrm{sph}}_{\Sigma_g}[r] \to (\mathbf{H}^{\mathrm{sph}}_{\Sigma_g}[1])^{\otimes r}$. In the language of automorphic forms, Theorem 5.3 amounts to the Langlands formula for the constant term of Eisenstein series, or equivalently to the Gindikin-Karpelevich formula. One should not be deceived by the apparent simplicity of the shuffle algebra description for $\mathbf{H}^{\mathrm{sph,bun}}_X$. In particular, $\mathbf{H}^{\mathrm{sph,bun}}_{\Sigma_g}$ is *not* free over R_g and the relations satisfied by the generators 1_{Pic^d} of $\mathbf{H}^{\mathrm{sph,bun}}_X$ *do* depend on the arithmetic of the Weil numbers $\sigma_1, \ldots, \sigma_{2g}$ of X (more precisely, on the $\mathbb{Z}$-linear dependence relation between $log(\sigma_1), \ldots log(\sigma_{2g})$, the so-called *wheel relations*).

[10] There is nothing surprising in the ubiquity of shuffle algebras: any finitely generated, $\mathbb{N}$-graded self-dual Hopf algebra has a realization as a shuffle algebra

5.4 Geometric Langlands isomorphism. Comparing (4-4) and (5-2) we immediately see that, up to the identification $p = q^{-1}, \xi_i = \eta_i^{-1}$ we have $Sh_{\Sigma_g} \simeq Sh_{S_g}^{K^{T_g}}$. This implies that there is an isomorphism

$$\Phi : \mathbf{H}_{\Sigma_g}^{\mathrm{sph,bun}} \xrightarrow{\sim} \mathbf{K}_{S_g}^{\mathrm{sph},T_g} \tag{5-3}$$

where $\mathbf{K}_{S_g}^{\mathrm{sph},T_g}$ is the subalgebra of $K^{T_g}(T^*\mathfrak{M}_{S_g})$ generated by its rank one component $K^{T_g}(T^*\mathfrak{M}_{S_g,1})$. The isomorphism (5-3) between the (spherical) Hall algebra of X and the (spherical) K-theoretical Hall algebra of the S_g quiver should be viewed as an incarnation, at the level of Grothendieck groups, of a (linearized) form of geometric Langlands correspondence. Indeed, the Langlands philosophy predicts an equivalence

$$Coh(LocSys_r(X_{\mathbb{C}})) \simeq D\text{–}mod(Bun_r(X_{\mathbb{C}}))$$

between suitable (infinity) categories of coherent sheaves on the moduli stack of GL_r-local systems on $X_{\mathbb{C}}$ and D-modules on the stack of GL_r-bundles on $X_{\mathbb{C}}$. On one hand, the formal neighborhood in $LocSys_r(X_{\mathbb{C}})$ of the trivial local system may be linearized as the formal neighborhood of 0 in $\{(x_1,\dots,x_g,y_1,\dots,y_g) \in \mathfrak{gl}_r(\mathbb{C})^{2g} \mid \sum_i [x_i,y_i] = 0\}/GL_r(\mathbb{C}) \simeq T^*\mathfrak{M}_{S_g,r}$; on the other hand, $\mathbf{H}_{\Sigma_g}^{sph,bun}$ may be lifted to a category of holonomic D-modules (perverse sheaves) on $Bun_r(X_{\mathbb{C}})$. We refer to Schiffmann and Vasserot [2012] for a more detailed discussion.

5.5 Variations. There are several interesting variants of the above constructions and results: one can consider categories of D-parabolic coherent sheaves (see Schiffmann [2004] and Lin [2014]); this yields, for instance, some quantum affine or toroidal algebras. One can also consider arithmetic analogs the Hall algebra, replacing the abelian category of coherent sheaves on a curve X over a finite field by coherent sheaves or vector bundles (in the sense of Arakelov geometry) over $\overline{Spec(\mathcal{O}_K)}$, where K is a number field. The case of $K = \mathbb{Q}$ is discussed in M. Kapranov, Schiffmann, and Vasserot [2014], where the spherical Hall algebra is described as some analytic shuffle algebra with kernel given by the Riemann zeta function $\zeta(z)$.

6 Counting Cuspidals and Cohomological Hall algebras of curves

6.1 Counting cuspidals and the full Hall algebra of a curve. In Sections 5.2 and 5.3 we considered the spherical Hall algebra $\mathbf{H}_X^{\mathrm{sph}}$ for which we provided a shuffle algebra description involving the zeta function $\zeta_X(z)$. What about the whole Hall algebra $\mathbf{H}_X$? As shown in M. Kapranov, Schiffmann, and Vasserot [2017], $\mathbf{H}_X^{bun}$ admits a shuffle description as well, but it is much less explicit than for $\mathbf{H}_X^{\mathrm{sph}}$. Recall that an element $f \in \mathbf{H}_X^{\mathrm{bun}}[r,d]$ is *cuspidal* if it is quasi-primitive, i.e. if

$$\Delta(f) \in f \otimes 1 + k_{r,d} \otimes f + \mathbf{H}_X^0 \otimes \widetilde{\mathbf{H}}_X[r].$$

The algebra $\mathbf{H}_X^{\mathrm{bun}}$ is generated by the spaces of cuspidal elements

$$\mathbf{H}_X^{\mathrm{cusp}} = \bigoplus_{r,d} \mathbf{H}_X^{\mathrm{cusp}}[r,d]$$

and $\dim \mathbf{H}_X^{\mathrm{cusp}}[r,d] < \infty$ for all r,d. The function field Langlands program (Lafforgue [2002]) sets up a correspondence $\chi \mapsto f_\chi$ between characters $\chi : \mathbf{H}_X^0 \to \mathbb{C}$ associated to rank r irreducible local systems on X and cuspidal Hecke eigenfunctions $f_\chi = \sum_d f_{\chi,d} \in \prod_d \mathbf{H}_X^{\mathrm{cusp}}[r,d]$. The shuffle algebra description of $\mathbf{H}_X$ is as follows: we have a family of variables $z_{\chi,i}$, $i \in \mathbb{N}$ for *each* cuspidal Hecke eigenform f_χ (up to $\mathbb{G}_m$-twist) and the shuffle kernels involve the Rankin-Selberg L-functions $L(\chi,\chi',z)$ of pairs of characters χ,χ' in place of $\zeta_X(z)$ (see Fratila [2013] for a full treatment when $g=1$). In principle, one could try, using the PBW theorem and arguing as in the case of quivers (see Section 3.2), to deduce from the above shuffle description of $\mathbf{H}_X$ an expression for the dimensions of the spaces of cuspidal functions $\mathbf{H}_X^{\mathrm{cusp}}[r,d]$ (or better, absolutely cuspidal functions $\mathbf{H}_X^{\mathrm{abs.\ cusp}}[r,d]$) in terms of the Kac polynomials $A_{g,r}$. Very recently H. Yu managed –by other means[11]– to compute the dimension of $\mathbf{H}_X^{\mathrm{abs.\ cusp}}[r,d]$ directly:

Theorem 6.1 (Yu [n.d.]). *For any g,r there exists a (unique) polynomial $C_{g,r}^{abs} \in R_g$ such that for any smooth projective curve X of genus g defined over a finite field, $\dim \mathbf{H}_X^{abs.\ cusp}[r,d] = C_{g,r}^{abs}(Fr_X)$.*

This generalizes a famous result of Drinfeld (for $r=2$, Drinfel'd [1981]) and proves a conjecture of Deligne [2015] and Kontsevich [2009]. Interestingly, the polynomial $C_{g,r}^{\mathrm{abs}}$ is explicit: Yu expresses it in terms of the numbers of rational points of the moduli spaces of stable Higgs bundles over finite fields and hence, by Theorem 7.1 below, in terms of the Kac polynomials $A_{g,r}$! This strengthens our belief that the structure of $\mathbf{H}_X$ as an associative algebra is nice enough that it should have a character formula similar to that of Borcherds algebras. For instance, we have

$$A_{g,1}(F) = C_{g,1}^{\mathrm{abs}}(F), \qquad A_{g,2}(F) = C_{g,2}^{\mathrm{abs}}(F) + (g-1)C_{g,1}^{\mathrm{abs}}(F)^2 + C_{g,1}^{\mathrm{abs}}(F)$$

$$\begin{aligned} A_{g,3}(F) = & C_{g,3}^{\mathrm{abs}}(F) + (g-1)C_{g,1}^{\mathrm{abs}}(F)\left\{4C_{g,2}^{\mathrm{abs}}(F) + C_{g,1}^{\mathrm{abs}}(F^2) + 2(g-1)C_{g,1}^{\mathrm{abs}}(F)^2\right\} \\ & + 4(g-1)C_{g,1}^{\mathrm{abs}}(F)^2 + C_{g,1}^{\mathrm{abs}}(F) \end{aligned}$$

where $F = Fr_X$.

[11] namely, using the Arthur-Selberg trace formula

Conjecture 6.2. *For any g, r there exists a (non-virtual) $GSp(2g, \overline{\mathbb{Q}_l})$-representation $\mathbb{C}^{abs}_{g,r}$ such that $C^{abs}_{g,r} = \tau(ch(\mathbb{C}^{abs}_{g,r}))$.*

6.2 Cohomological Hall algebra of Higgs sheaves. We take $\mathbf{k} = \mathbb{C}$ here. The (underived) cotangent stack $T^*\mathfrak{M}_X = \bigsqcup_{r,d} T^*\mathfrak{M}_{X,r,d}$ is identified with the stack of Higgs sheaves $\mathcal{H}iggs_X = \bigsqcup_{r,d} \mathcal{H}iggs_{X,r,d}$, which parametrizes pairs $(\mathcal{F}, \theta)$ with $\mathcal{F} \in \mathrm{Coh}(X)$ and $\theta \in Hom_{\mathcal{O}_X}(\mathcal{F}, \mathcal{F} \otimes \Omega_X)$. The *global nilpotent cone* $\Lambda_X = \bigsqcup_{r,d} \Lambda_{X,r,d}$ is the closed Lagrangian substack whose objects are Higgs sheaves $(\mathcal{F}, \theta)$ for which θ is nilpotent. Both stacks are singular, locally of finite type and have infinitely many irreducible components. The stack $\Lambda_{X,r,d}$ is slightly better behaved since all irreducible components are of dimension $(g-1)r^2$. We refer to Bozec [2017] for an explicit description of these irreducible components. The torus $T = \mathbb{G}_m$ acts on $\mathcal{H}iggs_X$ and Λ_X by $t \cdot (\mathcal{F}, \theta) = (\mathcal{F}, t\theta)$.

Theorem 6.3 (Sala and Schiffmann [2018] and Minets [2018])**.** *The Borel-Moore homology spaces $H^T_*(\mathcal{H}iggs_X)$ and $H^T_*(\Lambda_X)$ carry natural $\mathbb{Z} \times \mathbb{Z}^2$-graded associative algebra structures. Moreover, the direct image morphism*

$$i_* : H^T_*(\Lambda_X) \to H^T_*(\mathcal{H}iggs_X)$$

is an algebra homomorphism.

The definition of the algebra structure roughly follows the same strategy as for quivers: working in local charts, we use the construction of $\mathcal{H}iggs_X$ as a symplectic reduction to embed everything into some smooth moduli stacks. As before, the morphism i_* becomes invertible after localizing with respect to $H^*_T(pt)$. There is an embedding of $\mathfrak{M}_X$ in Λ_X as the zero section of the projection $p : \mathcal{H}iggs_X \to \mathfrak{M}_X$; its image is an irreducible component of Λ_X.

Theorem 6.4 (Sala and Schiffmann [2018])**.** *The algebra $H^T_*(\Lambda_X)$ is generated by the collection of subspaces $H^T_*(\mathfrak{M}_{X,r,d})$ for $(r, d) \in \mathbb{Z}^2$.*

What about a shuffle algebra description of $H^T_*(\Lambda_X)$? The cohomology ring $\mathbb{H}_{r,d} = H^*(\mathfrak{M}_{X,r,d})$ acts on $H^T_*(\Lambda_{X,r,d})$ by $c \cdot h = p^*(c) \cap h$. By Heinloth's extension of the Atiyah-Bott theorem Heinloth [2012], $\mathbb{H}_{0,d} = S^d(H^*(X)[z])$ for $d \geq 1$ while for $r \geq 1, d \in \mathbb{Z}$, $\mathbb{H}_{r,d} = \mathbb{Q}[c_{i,\gamma}(\mathcal{E}_{r,d}) \mid i \geq 1, \gamma]$ is a polynomial algebra in the Künneth components $c_{i,\gamma}(\mathcal{E}_{r,d})$ of the Chern classes of the tautological sheaf $\mathcal{E}_{r,d}$ over $\mathfrak{M}_{X,r,d} \times X$; here γ runs over a basis $\{1, a_1, b_1, \ldots, a_g, b_g, \varpi\}$ of $H^*(X)$.

Theorem 6.5 (Sala and Schiffmann [2018] and Minets [2018])**.** *The $\mathbb{H}_{r,d}$-module $H^T_*(\Lambda_{X,r,d})$ is torsion-free and of generic rank one.*

This opens up the possibility to construct a (shuffle) algebra structure on $\bigoplus_{r,d} \mathbb{H}_{r,d}$, but this has so far only be achieved for the subalgebra of torsion sheaves, see Minets [2018]. Very similar shuffle algebras occur, not surprisingly, as operators on the cohomology of moduli spaces of semistable sheaves on smooth surfaces, see Neguţ [2017].

7 Kac polynomials and Poincaré polynomials of moduli of stable Higgs bundles

7.1 Moduli spaces of stable Higgs bundles. Recall that a Higgs sheaf (V, θ) on X is *semistable* if for any subsheaf $W \subset V$ such that $\theta(W) \subseteq W \otimes \Omega_X$ we have $\mu(W) \leq \mu(V)$, where $\mu(\mathcal{F}) = deg(\mathcal{F})/rk(\mathcal{F})$ is the usual slope function. Replacing $\leq$ by $<$ we obtain the definition of a *stable* Higgs sheaf. The open substack $\mathcal{H}iggs^{st}_{X,r,d} \subset \mathcal{H}iggs_{X,r,d}$ of stable sheaves is a $\mathbb{G}_m$-gerbe over a smooth quasi-projective symplectic variety $Higgs^{st}_{r,d}$. On the contrary, the open substack $\mathcal{H}iggs^{ss}_{r,d} \subset \mathcal{H}iggs_{X,r,d}$ of semistable sheaves is singular as soon as $gcd(r,d) > 1$; when $gcd(r,d) = 1$, $\mathcal{H}iggs^{ss}_{X,r,d} = \mathcal{H}iggs^{st}_{X,r,d}$. The variety $Higgs^{st}_{X,r,d}$ has played a fundamental role in algebraic geometry, in the theory of integrable systems, in the geometric Langlands program, in the theory of automorphic forms, and is still the focus of intensive research; we refer to e.g. Hausel [2013] for a survey of the many important conjectures in the subject.

7.2 Poincaré polynomials and Kac polynomials. Assume that $\mathbf{k} = \mathbb{F}_q$. The following result provides a very vivid geometric interpretation of the Kac polynomial $A_{g,r}$.

Theorem 7.1 (Schiffmann [2016] and Mozgovoy and Schiffmann [2017]). *For any r, d with $gcd(r,d) = 1$ we have*

$$\#Higgs^{st}_{X,r,d}(\mathbb{F}_q) = q^{(g-1)r^2+1} A_{g,r}(Fr_X).$$

Together with some purity argument and Mellit's simplification of the explicit formula for $A_{g,r}$, this proves the conjecture of Hausel and Rodriguez-Villegas [2008] for the Poincaré polynomial of $Higgs^{st}_{X,r,d}$ (for $\mathbf{k} = \mathbb{C}$ or $\mathbb{F}_q$). There are two proofs of Theorem 7.1: one is based on a deformation argument to relate directly the point count of $Higgs_{X,r,d}(\mathbb{F}_q)$ to the count of indecomposable sheaves; the other uses Hall-theoretic techniques (for the category of positive Higgs sheaves). Both have been generalized or put in a broader context, see Dobrovolska, Ginzburg, and Travkin [2016] and Fedorov, A. Soibelman, and Y. Soibelman [2017].

Concerning the stable global nilpotent cone $\Lambda^{st}_{X,r,d} = \Lambda_{X,r,d} \cap Higgs^{st}_{X,r,d}$ we have the following interpretation of the constant term of the Kac polynomial:

Theorem 7.2 (Schiffmann [2016]). *For any* (r,d) *with* $gcd(r,d)=1$ *we have*

$$\#Irr(\Lambda^{st}_{X,r,d}) = A_{g,r,d}(0)$$

Recall that by Proposition 1.7 we have $A_{g,r}(0) = A_{S_g,r}(1)$; this suggests the existence of some natural partition of $Irr(\Lambda^{st}_{X,r,d})$, but the geometric meaning of such a partition is unclear to us.

7.3 Donaldson-Thomas invariants and Kac polynomials. What about *non* coprime (r,d) ? In this case, it is still possible to perform the (orbifold) point count of the stack $\mathcal{H}iggs_{X,r,d}(\mathbf{k})$ when $\mathbf{k}=\mathbb{F}_q$; this point count is best expressed in terms of the Donaldson-Thomas invariants $\Omega_{X,r,d}$ which are defined by the following generating series:

$$\forall\ \nu\in\mathbb{Q},\qquad \sum_{\frac{d}{r}=\nu}\frac{\Omega_{X,r,d}}{q-1}w^r z^d := \mathrm{Log}\left(\sum_{\frac{d}{r}=\nu} q^{(1-g)r^2}\#(\mathcal{H}iggs^{ss}_{X,r,d}(\mathbb{F}_q))w^r z^d\right).$$

Theorem 7.3 (Mozgovoy and Schiffmann [2017]). *For any* r,d *we have* $\Omega_{X,r,d} = qA_{g,r}(Fr_X)$.

If $gcd(r,d)=1$ then

$$\Omega_{X,r,d} = (q-1)q^{(1-g)r^2}\#(\mathcal{H}iggs^{st}_{X,r,d}(\mathbb{F}_q)) = q^{(1-g)r^2}\#Higgs^{st}_{X,r,d}(\mathbb{F}_q)$$

so that we recover Theorem 7.1.

8 Delirium Tremens: a hierarchy of Lie algebras

We conclude this survey with some wild speculations concerning potential Lie algebras associated to curves, rather than to quivers

8.1 Lie algebras from curves ? Following the analogy with quivers, it is natural to expect the existence of a family of $\mathbb{Z}^2$-graded complex Lie algebras $\mathfrak{g}_g = \bigoplus_{r,d}\mathfrak{g}_g[r,d]$ such that $\mathbf{H}^{\mathrm{sph}}_g$ is a $(g+1)$-quantum parameter deformation of $U^+(\mathfrak{g}_g)$, and

$$\dim\ \mathfrak{g}_g[r,d] = A_{g,r}(0,\ldots,0)$$

for any r,d. This Lie algebra $\mathfrak{g}_g$ would be a curve analog of the Kac-Moody algebra $\mathfrak{g}_Q$ associated to a quiver Q (or its variant $\mathfrak{g}^B_Q$ if Q has edge loops). What about the the analog of the graded Borcherds algebra $\widetilde{\mathfrak{g}}_Q$? Because the grading in the context of curves is by the character ring of $GSp(2g,\overline{\mathbb{Q}_l})$ rather than by $\mathbb{Z}$, it seems natural to expect the existence of a Lie algebra $\widetilde{\mathfrak{g}}_g$ *in the tensor category of finite-dimensional* $GSp(2g, \overline{\mathbb{Q}_l})$*-modules*, with $\mathfrak{g}_g$ being identified with the sub-Lie algebra corresponding to the tensor subcategory of trivial representations (of arbitrary rank). Moreover, we should have

$$\widetilde{\mathfrak{g}}_g[r,d] = \mathbb{A}_{g,r} \in GSp(2g, \overline{\mathbb{Q}_l}) - \text{mod},$$

where $\mathbb{A}_{g,r}$ is as in Conjecture 1.6, and the cuspidal (or 'simple root vectors') of $\widetilde{\mathfrak{g}}_g[r,d]$ should form a subrepresentation isomorphic to $\mathbb{C}^{\text{abs}}_{g,r}$, where $\mathbb{C}^{\text{abs}}_{g,r}$ is as in Conjecture 6.2.

Although we do not have any clue at the moment as to what $\widetilde{\mathfrak{g}}_g$ could be, the Langlands isomorphism (5-3) provides us with a very good guess concerning $\mathfrak{g}_g$. Namely, it is expected that the (spherical) K-theoretical Hall algebra $K^T(T^*\mathfrak{M}_Q)$– by analogy with the (spherical) cohomological Hall algebra $H^T_*(T^*\mathfrak{M}_Q)$– is a deformation of $U^+(\widetilde{\mathfrak{g}}_Q[u^{\pm 1}])$. This strongly suggests that, at least as a vector space, $\mathfrak{g}_g \simeq \widetilde{\mathfrak{g}}_{S_g}[u^{\pm 1}]$. Note that the $\mathbb{N}$-grading of $\widetilde{\mathfrak{g}}_{S_g}$ gets lost in the process since there is no obvious grading in the K-theoretical Hall algebra. Taking graded dimensions, we obtain the equality $A_{S_g,r}(1) = A_{g,r}(0,\ldots,0)$ of Proposition 1.7. Of course, this is not a proof but rather a conceptual explanation of this equality. We summarize this in the chain of inclusions of Lie algebras

$$\mathfrak{g}_{S_g} \subseteq \tilde{\mathfrak{g}}_{S_g} \subset \tilde{\mathfrak{g}}_{S_g}[t,t^{-1}] \simeq \mathfrak{g}_g \subset \tilde{\mathfrak{g}}_g \subset \tilde{\mathfrak{g}}_g[t,t^{-1}].$$

Examples. i) Suppose $g = 0$. Then $\widetilde{\mathfrak{g}}_{S_0} = \mathfrak{g}_{S_0} = \mathfrak{sl}_2$ and $\mathfrak{g}_0 \simeq \widehat{\mathfrak{sl}_2}$, while it is natural to expect that $\widetilde{\mathfrak{g}}_0 = (\mathfrak{sl}_2 \oplus K)[u^{\pm 1}]$, where K is a one dimensional central extension, placed in degree one. Note that we have $A_{0,0} = q+1$, $A_{0,1} = 1$ and $A_{0,r} = 0$ for $r > 1$.
ii) Suppose $g = 1$. Then $\widetilde{\mathfrak{g}}_{S_1} \simeq \mathfrak{g}_{S_1} = \overline{\mathbb{Q}_l}[s^{\pm 1}]$ is the Heisenberg algebra, and $\mathfrak{g}_1 = \overline{\mathbb{Q}_l}[s^{\pm 1}, t^{\pm 1}] \oplus K_1 \oplus K_2$, where $K_1 \oplus K_2$ is a two-dimensional central extension. The Lie algebra structure is not the obvious one however, but rather a central extension of the Lie bracket $[s^r t^d, s^n t^m] = (rm - dn)s^{r+n}t^{d+m}$ (see Schiffmann and Vasserot [2013a], App. F. for the case of the Yangian).

8.2 Summary of Hall algebras, their corresponding Lie algebras and Kac polynomials. We conclude this survey with the following table, containing our heuristics.

Type of Hall Algebras	Quivers	Curves
K-thr. Hall algebra $K^{sph,T}(T^*\mathfrak{M})$	$\widetilde{\mathfrak{g}}_Q[u^{\pm 1}]$; $A_Q(t)\delta(t)$	$\widetilde{\mathfrak{g}}_g[u]$; $A_g(\sigma_1,\ldots,\sigma_{2g})\delta(t)$
Coho. Hall algebra $H^T_*(T^*\mathfrak{M})$	$\widetilde{\mathfrak{g}}_g[u^{\pm 1}]$; $A_Q(t)/(1-t)$	$\widetilde{\mathfrak{g}}_g[u]$; $A_g(\sigma_1,\ldots,\sigma_{2g})/(1-t)$
Hall algebra **H**	$\widetilde{\mathfrak{g}}_Q$; $A_Q(t)$	$\widetilde{\mathfrak{g}}_g$; $A_g(\sigma_1,\ldots,\sigma_{2g})$
Spherical Hall algebra $\mathbf{H}^{\text{sph}}$	$\mathfrak{g}_Q$; $A_Q(0)$	$\mathfrak{g}_g$; $A_g(0,\ldots,0)$

Acknowledgments. It is, of course, impossible to thank here all the people whose work had a strong influence on the research presented here. I would nevertheless like to express my gratitude to the following people for their help throughout the years: R. Bezrukavnikov,

T. Bozec, P.-H. Chaudouard, I. Cherednik, W. Crawley-Boevey, B. Davison, P. Etingof, B. Feigin, D. Fratila, I. Frenkel, T. Hausel, V. Kac, S.-J. Kang, M. Kapranov, M. Kashiwara, M. Khovanov, G. Laumon, E. Letellier, G. Lusztig, S. Meinhardt, A. Mellit, A. Minets, S. Mozgovoy, H. Nakajima, A. Negut, A. Okounkov, C. Ringel, F. Rodriguez-Villegas, F. Sala, P. Samuelson, Y. Soibelman, M. Reineke, E. Vasserot, and B. Webster.

MODULI SPACES OF LOCAL G-SHTUKAS

Eva Viehmann

Abstract

We give an overview of the theory of local **G**-shtukas and their moduli spaces that were introduced in joint work of U. Hartl and the author, and in the past years studied by many people. We also discuss relations to moduli of global **G**-shtukas, properties of their special fiber through affine Deligne-Lusztig varieties and of their generic fiber, such as the period map.

1 Introduction

Local **G**-shtukas are an analog over local function fields of p-divisible groups with additional structure. In this article we give an overview about the theory of moduli spaces of local **G**-shtukas and their relation to moduli of global $\mathfrak{G}$-shtukas. It parallels the theory of Rapoport-Zink moduli spaces of p-divisible groups and their relation to Shimura varieties. Yet it has the additional charm that additional structure given by any parahoric group scheme **G** can be easily encoded and treated in a group-theoretic way.

We begin by defining local **G**-shtukas for a parahoric group scheme **G** over Spec $\mathbb{F}_q[\![z]\!]$ (see Section 2). They are pairs consisting of an $L^+\mathbf{G}$-torsor $\mathcal{G}$ together with an isomorphism $\sigma^*L\mathcal{G} \to L\mathcal{G}$ for the associated $L\mathbf{G}$-torsor. Here for unexplained notation we refer to the respective sections. Local **G**-shtukas are the function field analog of p-divisible groups with additional structure, as well as a group theoretic generalization of Drinfeld's shtukas. Next we discuss possible bounds on the singularities of local **G**-shtukas. These are a more general replacement of the minuscule coweights fixed to define Shimura varieties. In Section 3 we consider deformations for local **G**-shtukas, and the description of the universal deformation in terms of the loop group $L\mathbf{G}$. In Section 4 we describe the analog of Rapoport-Zink moduli spaces for local **G**-shtukas bounded by a given bound $\hat{Z}$ and within a given quasi-isogeny class. They are representable by a formal scheme, locally formally of finite type over Spf$\breve{R}$. Here, $\breve{R}$ is the completion of the maximal unramified extension of the ring of definition of the chosen bound $\hat{Z}$. Also,

MSC2010: primary 11G09; secondary 11G18, 14L05, 14M15.

they admit a tower of coverings indexed by compact open subgroups of $\mathbf{G}(\mathbb{F}_q(\!(z)\!))$. Our next topic is the special fiber of a Rapoport-Zink moduli space of local **G**-shtukas. It can be identified with a so-called affine Deligne-Lusztig variety. In Section 5 we discuss applications of this result to geometric questions such as dimensions and closure relations of Newton strata. In Section 6 we describe the relation between our local **G**-shtukas and global $\mathfrak{G}$-shtukas where $\mathfrak{G}$ is a parahoric group scheme over a smooth projective geometrically irreducible curve C over $\mathbb{F}_q$. There are several results in this direction, the central idea being that one wants to describe a global $\mathfrak{G}$-shtuka by corresponding local $\mathbf{G}_i$-shtukas associated with each of the legs c_i. Due to our choice of definition of local **G**-shtukas, this works particularly well when considering global $\mathfrak{G}$-shtukas with fixed legs. Then one obtains analogues/generalizations of Serre-Tate's theorem, as well as of several classical results comparing Shimura varieties and Rapoport-Zink spaces in the arithmetic case. In the last section we define period spaces as suitable subspaces of an affine Grassmannian. Contrary to the arithmetic case they are no longer subspaces of a classical flag variety because we allow also non-minuscule bounds. We define the period map from the analytic space associated with a Rapoport-Zink space to the corresponding period space, and discuss its image and compatibility with the tower of coverings of the generic fiber of the Rapoport-Zink space.

2 Local G-shtukas

2.1 Generalities. Let $\mathbb{F}_q$ be a finite field of characteristic p with q elements, let $\mathbb{F}$ be a fixed algebraic closure of $\mathbb{F}_q$, and let $\mathbb{F}_q[\![z]\!]$ and $\mathbb{F}_q[\![\zeta]\!]$ be the power series rings over $\mathbb{F}_q$ in the (independent) variables z and ζ. As base schemes we will consider the category $\mathrm{Nilp}_{\mathbb{F}_q[\![\zeta]\!]}$ consisting of schemes over $\operatorname{Spec}\mathbb{F}_q[\![\zeta]\!]$ on which ζ is locally nilpotent. Let **G** be a parahoric group scheme over $\operatorname{Spec}\mathbb{F}_q[\![z]\!]$ with connected reductive generic fiber, compare Bruhat and Tits [1972], Déf. 5.2.6 and Haines and Rapoport [2008].

Let $S \in \mathrm{Nilp}_{\mathbb{F}_q[\![\zeta]\!]}$ and consider any sheaf of groups H on S for the fpqc-topology. By an H-torsor on S we mean a sheaf $\mathcal{H}$ for the fpqc-topology on S together with a (right) action of the sheaf H such that $\mathcal{H}$ is isomorphic to H on an fpqc-covering of S.

Let now $L\mathbf{G}$ and $L^+\mathbf{G}$ be the loop group and the group of positive loops associated with **G**, i.e. for an $\mathbb{F}_q$-algebra R let

$$(L^+\mathbf{G})(R) = \mathbf{G}(R[\![z]\!]) \quad \text{and} \quad (L\mathbf{G})(R) = \mathbf{G}(R(\!(z)\!)).$$

Let $\mathcal{G}$ be an $L^+\mathbf{G}$-torsor on S. Via the inclusion $L^+\mathbf{G} \subset L\mathbf{G}$ we can associate an $L\mathbf{G}$-torsor $L\mathcal{G}$ with $\mathcal{G}$. For any $L\mathbf{G}$-torsor $\mathcal{G}'$ on S we denote by $\sigma^*\mathcal{G}'$ the pullback of $\mathcal{G}'$ under the q-Frobenius morphism $\sigma := \mathrm{Frob}_q : S \to S$.

Definition 2-1. A *local* **G**-*shtuka* over some $S \in \mathrm{Nilp}_{\mathbb{F}_q[\![\zeta]\!]}$ is a pair $\underline{\mathcal{G}} = (\mathcal{G}, \tau_{\mathcal{G}})$ consisting of an $L^+\mathbf{G}$-torsor $\mathcal{G}$ on S and an isomorphism of the associated $L\mathbf{G}$-torsors $\tau_{\mathcal{G}} \colon \sigma^* L\mathcal{G} \xrightarrow{\sim} L\mathcal{G}$.

A *quasi-isogeny* $g \colon (\mathcal{G}', \tau_{\mathcal{G}'}) \to (\mathcal{G}, \tau_{\mathcal{G}})$ between local **G**-shtukas over S is an isomorphism $g \colon L\mathcal{G}' \xrightarrow{\sim} L\mathcal{G}$ of the associated $L\mathbf{G}$-torsors with $g \circ \tau_{\mathcal{G}'} = \tau_{\mathcal{G}} \circ \sigma^* g$.

Local **G**-shtukas were introduced and studied in Hartl and Viehmann [2011], Hartl and Viehmann [2012] in the case where **G** is a constant split reductive group over $\mathbb{F}_q$. The general case was first considered in work of Arasteh Rad and Hartl [2014].

Example 2-2. For $\mathbf{G} = \mathrm{GL}_r$, we have the following more classical description.

A local shtuka over $S \in \mathrm{Nilp}_{\mathbb{F}_q[\![\zeta]\!]}$ (of rank r) is a pair (M, ϕ) where M is a sheaf of $\mathcal{O}_S[\![z]\!]$-modules on S which Zariski-locally is free of rank r, together with an isomorphism of $\mathcal{O}_S(\!(z)\!)$-modules

$$\phi : \sigma^* M \otimes_{\mathcal{O}_S[\![z]\!]} \mathcal{O}_S(\!(z)\!) \xrightarrow{\sim} M \otimes_{\mathcal{O}_S[\![z]\!]} \mathcal{O}_S(\!(z)\!).$$

Then the category of local GL_r-shtukas over S is equivalent to the category of local shtukas of rank r over S, see Hartl and Viehmann [2011], Lemma 4.2.

Local shtukas were first introduced by Anderson [1993] over a complete discrete valuation ring. Genestier [1996] constructed moduli spaces for them in the Drinfeld case and used these to uniformize Drinfeld modular varieties.

An important invariant of local **G**-shtukas is their *Newton point*. To define it let k be an algebraically closed field of characteristic p and let $L = k(\!(z)\!)$. Then every local **G**-shtuka $(\mathcal{G}, \tau_{\mathcal{G}})$ over k has a trivialization $\mathcal{G} \cong (L^+\mathbf{G})_k$. Via this isomorphism the Frobenius map $\tau_{\mathcal{G}}$ corresponds to an element $b \in L\mathbf{G}(k) = \mathbf{G}(L)$. Changing the trivialization replaces b by a different representative of its $L^+\mathbf{G}(k)$-σ-conjugacy class. In the same way, local **G**-shtukas isogenous to $(\mathcal{G}, \tau_{\mathcal{G}})$ correspond to the elements of the σ-conjugacy class

$$[b] = \{g^{-1} b \sigma(g) \mid g \in \mathbf{G}(L)\}.$$

Let G denote the generic fiber of **G**. Then the set of σ-conjugacy classes $B(G) = \{[b] \mid b \in G(L)\}$ for quasi-split G is described by Kottwitz [1985], Kottwitz [1997] by two invariants. Let T be a maximal torus of G. The first invariant is then the Kottwitz point, i.e. the image under the Kottwitz map $\kappa_G : G(L) \to \pi_1(G)_\Gamma$. Here, $\pi_1(G)$ is Borovoi's fundamental group, and Γ is the absolute Galois group of $\mathbb{F}_q(\!(z)\!)$. This invariant is locally constant on LG, and can also be computed using the identification $\pi_0(LG) = \pi_1(G)/\Gamma$, compare Neupert [2016], 2.2. The second invariant is the Newton point ν_b, an element of $X_*(T)^\Gamma_{\mathbb{Q}}$.

Consider now a local $\mathbf{G}$-shtuka $(\mathcal{G}, \tau_{\mathcal{G}})$ over a scheme S. Then we obtain an induced decomposition of $S(k)$ into subsets $\mathfrak{N}_{[b]}(k)$ for $[b] \in B(G)$ with

$$\mathfrak{N}_{[b]}(k) = \{x \in S(k) \mid (\mathcal{G}, \tau_{\mathcal{G}})_x \text{ is in the isogeny class of } [b]\}.$$

By Rapoport and Richartz [1996], this induces a decomposition of S into locally closed subschemes, which we call Newton strata. If S is connected, they correspond to the strata obtained by fixing the Newton point only.

2.2 Bounds. To ensure finiteness properties of moduli spaces of local $\mathbf{G}$-shtukas, or of deformations of local $\mathbf{G}$-shtukas, we bound the singularity of the morphism $\tau_{\mathcal{G}}$. In the arithmetic context, such bounds are usually assumed to be minuscule and correspond to the choice of the Hodge cocharacter defining a Shimura datum. In our context we define bounds more generally as suitable ind-subschemes of the affine flag variety.

The *affine flag variety* $\mathrm{Flag}_{\mathbf{G}}$ *associated with* G is the fpqc-sheaf associated with the presheaf

$$S \mapsto L\mathbf{G}(S)/L^+\mathbf{G}(S) = \mathbf{G}(\mathcal{O}_S(\!(z)\!)(S))/\mathbf{G}(\mathcal{O}_S[\![z]\!](S))$$

on the category of $\mathbb{F}_q$-schemes. By Pappas and Rapoport [2008], Theorem 1.4 and Richarz [2016] Theorem A, $\mathrm{Flag}_{\mathbf{G}}$ is represented by an ind-scheme which is ind-projective over $\mathbb{F}_q$.

Consider further the group scheme $\mathbf{G} \times_{\mathbb{F}_q[\![z]\!]} \mathrm{Spec}\, \mathbb{F}_q(\!(\zeta)\!)[\![z-\zeta]\!]$ under the homomorphism

$$\mathbb{F}_q[\![z]\!] \to \mathbb{F}_q(\!(\zeta)\!)[\![z-\zeta]\!], \qquad z \mapsto z = \zeta + (z-\zeta). \tag{2-3}$$

The associated affine Grassmannian $\mathrm{Gr}_{\mathbf{G}}^{B_{\mathrm{dR}}}$ is the sheaf of sets for the fpqc-topology on $\mathrm{Spec}\, \mathbb{F}_q(\!(\zeta)\!)$ associated with the presheaf

$$X \mapsto \mathbf{G}(\mathcal{O}_X(\!(z-\zeta)\!))/\mathbf{G}(\mathcal{O}_X[\![z-\zeta]\!]). \tag{2-4}$$

Remark 2-5. $\mathrm{Gr}_{\mathbf{G}}^{B_{\mathrm{dR}}}$ is in the same way as $\mathrm{Flag}_{\mathbf{G}}$ above an ind-projective ind-scheme over $\mathrm{Spec}\, \mathbb{F}_q(\!(\zeta)\!)$. Here, note that the homomorphism in (2-3) induces an inclusion $\mathbb{F}_q(\!(z)\!) \to \mathbb{F}_q(\!(\zeta)\!)[\![z-\zeta]\!]$, so the group $\mathbf{G} \times_{\mathbb{F}_q[\![z]\!]} \mathrm{Spec}\, \mathbb{F}_q(\!(\zeta)\!)[\![z-\zeta]\!]$ is reductive, justifying the name affine "Grassmannian". The notation B_{dR} refers to the fact that if C is the completion of an algebraic closure of $\mathbb{F}_q(\!(\zeta)\!)$, then $C(\!(z-\zeta)\!)$ is the function field analog of Fontaine's p-adic period field B_{dR}.

We fix an algebraic closure $\overline{\mathbb{F}_q(\!(\zeta)\!)}$ of $\mathbb{F}_q(\!(\zeta)\!)$, and consider pairs $(R, \hat{Z}_R)$, where $R/\mathbb{F}_q[\![\zeta]\!]$ is a finite extension of discrete valuation rings contained in $\overline{\mathbb{F}_q(\!(\zeta)\!)}$, and where $\hat{Z}_R \subset \widehat{\mathrm{Flag}}_{\mathbf{G},R} := \mathrm{Flag}_{\mathbf{G}} \widehat{\times}_{\mathbb{F}_q} \mathrm{Spf} R$ is a closed ind-subscheme that is contained in a bounded (or: projective) subscheme of $\widehat{\mathrm{Flag}}_{\mathbf{G},R}$. Two such pairs $(R, \hat{Z}_R)$ and $(R', \hat{Z}'_{R'})$ are equivalent if they agree over a finite extension of the rings R, R'.

A *bound* is then abstractly defined as an equivalence class $\hat{Z} := [(R, \hat{Z}_R)]$ of such pairs $(R, \hat{Z}_R)$ satisfying certain properties (for the precise conditions compare Hartl and Viehmann [2017], Def. 2.1), in particular

1. $\hat{Z}_R \subset \widehat{\mathrm{Flag}}_{\mathbf{G},R}$ is a ζ-adic formal scheme over $\mathrm{Spf} R$ that is stable under the left $L^+\mathbf{G}$-action.
2. The special fiber $Z_R := \hat{Z}_R \widehat{\times}_{\mathrm{Spf} R} \mathrm{Spec}\, \kappa_R$ is a quasi-compact subscheme of $\mathrm{Flag}_G \widehat{\times}_{\mathbb{F}_q} \kappa_R$ where κ_R is the residue field of R.
3. Let $\hat{Z}_R^{\mathrm{an}}$ be the strictly $R[\frac{1}{\zeta}]$-analytic space associated with $\hat{Z}_R$. Then the $\hat{Z}_R^{\mathrm{an}}$ are invariant under the left multiplication of $\mathbf{G}(\cdot[\![z-\zeta]\!])$ on $\mathrm{Gr}_{\mathbf{G}}^{\mathbf{B}_{\mathrm{dR}}}$.

The reflex ring $R_{\hat{Z}}$ of $[(R, \hat{Z}_R)]$ is the intersection in $\overline{\mathbb{F}_q(\!(\zeta)\!)}$ of the fixed field of $\{\gamma \in \mathrm{Aut}_{\mathbb{F}_q[\![\zeta]\!]}(\overline{\mathbb{F}_q(\!(\zeta)\!)}) \mid \gamma(\hat{Z}) = \hat{Z}\}$ with all finite extensions of $\mathbb{F}_q[\![\zeta]\!]$ over which a representative $\hat{Z}_R$ of the given bound exists.

Let $(\mathcal{G}, \tau_{\mathcal{G}})$ be a local **G**-shtuka over some $S \in \mathrm{Nilp}_{R_{\hat{Z}}}$ and let S' be an étale covering of S over which a trivialization $\mathcal{G} \cong (L^+\mathbf{G})_{S'}$ exists. Then $(\mathcal{G}, \tau_{\mathcal{G}})$ (or $\tau_{\mathcal{G}}$) is *bounded by* $\hat{Z}$ if for every such trivialization and for every finite extension R of $\mathbb{F}_q[\![\zeta]\!]$ over which a representative $\hat{Z}_R$ of $\hat{Z}$ exists, the morphism

$$S' \widehat{\times}_{R_{\hat{Z}}} \mathrm{Spf} R \to L\mathbf{G} \widehat{\times}_{\mathbb{F}_q} \mathrm{Spf} R \to \widehat{\mathrm{Flag}}_{\mathbf{G},R}$$

induced by $\tau_{\mathcal{G}}$ factors through $\hat{Z}_R$.

The above definition of bounds follows the strategy to allow as general bounds as possible. On the other hand, classically and by analogy with the arithmetic case, one considers bounds given as Schubert varieties. They are described as follows (compare Arasteh Rad and Hartl [2014], Example 4.12).

Example 2-6. Consider the base change G_L of G to $L = \mathbb{F}(\!(z)\!)$. Let A be a maximal split torus in G_L and let T be its centralizer, a maximal torus. Let $N = N(T)$ be the normalizer of T and let $\mathcal{T}^0$ be the identity component of the Néron model of T over $\mathcal{O}_L = \mathbb{F}[\![z]\!]$.

Consider the Iwahori–Weyl group $\widetilde{W} = N(L)/\mathcal{T}^0(\mathcal{O}_L)$ and let $\widetilde{W}^{\mathbf{G}} = (N(L) \cap \mathbf{G}(\mathcal{O}_L))/\mathcal{T}^0(\mathcal{O}_L)$. Then by the Bruhat-Tits decomposition we have a bijection

$$\widetilde{W}^{\mathbf{G}} \backslash \widetilde{W} / \widetilde{W}^{\mathbf{G}} \to L^+\mathbf{G}(\mathbb{F}) \backslash L\mathbf{G}(\mathbb{F}) / L^+\mathbf{G}(\mathbb{F}). \tag{2-7}$$

Let ω be in the right hand side, and let $\mathbb{F}_\omega$ be a finite extension of $\mathbb{F}_q$ such that ω has a representative $g_\omega \in L\mathbf{G}(\mathbb{F}_\omega)$. We define the *Schubert variety* S_ω as the ind-scheme theoretic closure of the $L^+\mathbf{G}$-orbit of g_ω in $\mathrm{Flag}_{\mathbf{G}} \widehat{\times}_{\mathbb{F}_q} \mathbb{F}_\omega$. Let $R = \mathbb{F}_\omega[\![\zeta]\!]$ and let $\hat{Z}_{\mathbb{F}_\omega[\![\zeta]\!]} =$

$S_\omega \widehat{\times}_{\mathbb{F}_\omega} \mathrm{Spf} R$. Then the equivalence class of $(R, \hat{Z}_R)$ defines a bound. In this case we also say "bounded by ω" instead of "bounded by $(R, \hat{Z}_R)$".

3 Deformations

Let $\mathrm{Flag}_{\mathbf{G}}$ denote again the affine flag variety, i.e. the quotient sheaf $\mathrm{Flag}_{\mathbf{G}} = L\mathbf{G}/L^+\mathbf{G}$, an ind-scheme over $\mathbb{F}_q$ which is of ind-finite type. Let $\widehat{\mathrm{Flag}}_{\mathbf{G}}$ be the fiber product $\mathrm{Flag}_{\mathbf{G}} \times_{\mathrm{Spec}\ \mathbb{F}_q} \mathrm{Spf}\ \mathbb{F}_q(\!(\zeta)\!)$.

Then generalizing Hartl and Viehmann [2011, Prop. 5.1] (where the case that $\mathbf{G}$ is split is considered) the ind-scheme $\widehat{\mathrm{Flag}}_{\mathbf{G}}$ pro-represents the functor $\mathrm{Nilp}_{\mathbb{F}_q[\![\zeta]\!]}{}^o \to (\mathrm{Sets})$

$$\begin{aligned} S \mapsto & \{(\mathcal{G}, \delta) \mid \mathcal{G} \text{ a } \mathbf{G}\text{-torsor on } S, \\ & \quad \delta : L\mathcal{G} \to L\mathbf{G}_S \text{ an isomorphism of the associated } L\mathbf{G}\text{-torsors}\}/\cong . \end{aligned}$$

Here $(\mathcal{G}, \delta)$ and $(\mathcal{G}', \delta)$ are isomorphic if $\delta^{-1} \circ \delta'$ is an isomorphism $\mathcal{G}' \to \mathcal{G}$.

We fix a bound $[(R, \hat{Z}_R)]$ and a local $\mathbf{G}$-shtuka $\underline{\mathbb{G}} = (\mathbb{G}, \phi_{\mathbb{G}})$ over a field $k \in \mathrm{Nilp}_{\mathbb{F}_q[\![\zeta]\!]}$ which is bounded by $\hat{Z}_R$. We consider the functor of bounded deformations of $\underline{\mathbb{G}}$ on the category of Artinian local $k[\![\zeta]\!]$-algebras with residue field k,

$$\begin{aligned} \mathrm{Def}_{\underline{\mathbb{G}}, \hat{Z}_R} : (\mathrm{Art}_k) \to & (\mathrm{Sets}) \\ A \mapsto & \{(\underline{\mathcal{G}}, \beta) \mid \underline{\mathcal{G}} \text{ a local } \mathbf{G}\text{-shtuka over Spec } A \text{ bounded by } \hat{Z}_R \\ & \quad \beta : \underline{\mathbb{G}} \to \underline{\mathcal{G}} \otimes_A k \text{ an isomorphism of local } \mathbf{G}\text{-shtukas}\}/\cong \end{aligned}$$

and require isomorphisms to be compatible with the maps β.

Remark 3-1. In Hartl and Viehmann [ibid.], 5 this functor and the deformation space representing it are explicitly described in case that $\mathbf{G}$ is split and $\hat{Z}_R$ associated with some $\omega \in \widetilde{W}$ as in Example 2-6, see below. This is generalized to reductive groups $\mathbf{G}$ in Viehmann and Wu [2016]. It would be interesting to have these results also in the more general context of parahoric group schemes.

Assume that $\mathbf{G}$ is a reductive group scheme over $\mathrm{Spec}\ \mathbb{F}_q[\![z]\!]$. Then the left hand side of Equation (2-7) is $W_0 \backslash \widetilde{W} / W_0$ where W_0 is the finite Weyl group of $\mathbf{G}_{\mathbb{F}_q}$. This double quotient is isomorphic to $X_*(T)_{\mathrm{dom}}$. Let $\mu \in X_*(T)_{\mathrm{dom}}$ and $(R, \hat{Z}_R)$ be the corresponding bound as in Example 2-6. Let $\underline{\mathbb{G}}$ be a local $\mathbf{G}$-shtuka bounded by μ over a field $k \in \mathrm{Nilp}_{\mathbb{F}_q[\![\zeta]\!]}$. Assume that there is a trivialization $\alpha : \underline{\mathbb{G}} \to (\mathbf{G}_k, b_0\sigma)$ for some $b_0 \in L\mathbf{G}(k)$. Using the boundedness, let $x \in Z_R(k)$ be the point defined by b_0^{-1}. By Hartl and Viehmann [2011], Thm. 5.6 and Viehmann and Wu [2016], Proposition 2.6 we have

Theorem 3-2. *Let* **G** *be reductive, and* $\hat{Z}_R$ *as in Example 2-6. Let* $\underline{\mathbb{G}}$ *and* α *be as above. Let* D *be the complete local ring of* $\hat{Z}_R$ *at the point* x. *It is a complete noetherian local ring over* $k[\![\zeta]\!]$. *Then* D *pro-represents the formal deformation functor* $\mathrm{Def}_{\underline{\mathbb{G}},\hat{Z}_R}$.

To study Newton strata in a family of local **G**-shtukas it is helpful to also have a corresponding stratification on deformations. However, for infinitesimal deformations such a question does not make sense. Instead we will replace the formal deformation space $\mathrm{Spf} D$ by $\mathrm{Spec}\, D$, using the following proposition. Here, a linearly topologized $\mathbb{F}_q[\![z]\!]$-algebra R is admissible if $R = \varprojlim R_\alpha$ for a projective system $(R_\alpha, u_{\alpha\beta})$ of discrete rings such that the filtered index-poset has a smallest element 0, all maps $R \to R_\alpha$ are surjective, and the kernels $I_\alpha := \ker u_{\alpha,0} \subset R_\alpha$ are nilpotent.

Proposition 3-3. *Let* R *be an admissible* $\mathbb{F}_q[\![z]\!]$*-algebra as above with filtered index-poset* $\mathbb{N}_0$. *Then the pullback under the natural morphism* $\mathrm{Spf} R \to \mathrm{Spec}\, R$ *defines a bijection between local* **G***-shtukas bounded by* μ *over* $\mathrm{Spec}\, R$ *and over* $\mathrm{Spf} R$.

Remark 3-4. Without a boundedness condition the pullback map is in general only injective. The corresponding result for p-divisible groups is shown by Messing and by de Jong. The above proposition is proved for split **G** in Hartl and Viehmann [2011], Proposition 3.16. However, the same proof also shows this assertion for all **G** that are reductive over $\mathrm{Spec}\, \mathbb{F}_q[\![z]\!]$.

4 Moduli spaces

In this section we fix **G**, an isogeny class of local **G**-shtukas and a bound $\hat{Z}$. We then define moduli spaces of local **G**-shtukas bounded by $\hat{Z}$ in the same way as Rapoport-Zink define their moduli spaces of p-divisible groups in Rapoport and Zink [1996].

Definition 4-1. Let $\underline{\mathbb{G}}_0$ be a local **G**-shtuka over $\mathbb{F}$. Let $\hat{Z} = [(R, \hat{Z}_R)]$ be a bound and denote its reflex ring by $R_{\hat{Z}} = \kappa[\![\xi]\!]$. It is a finite extension of $\mathbb{F}_q[\![\zeta]\!]$. Set $\breve{R}_{\hat{Z}} := \mathbb{F}[\![\xi]\!]$, and consider the functor

$$\begin{aligned}\breve{\mathfrak{M}} : (\mathrm{Nilp}_{\breve{R}_{\hat{Z}}})^\circ &\to (\mathrm{Sets})\\ S &\mapsto \{(\underline{\mathcal{G}}, \bar{\delta}) \mid \underline{\mathcal{G}} \text{ a local } \mathbf{G}\text{-shtuka over } S \text{ bounded by } \hat{Z}^{-1},\\ &\qquad \bar{\delta} : \underline{\mathcal{G}}_{\bar{S}} \to \underline{\mathbb{G}}_{0,\bar{S}} \text{ a quasi-isogeny}\}/\cong\end{aligned}$$

Here $\bar{S} := V_S(\zeta)$ is the zero locus of ζ in S, and two pairs $(\underline{\mathcal{G}}, \bar{\delta})$, $(\underline{\mathcal{G}}', \bar{\delta}')$ are isomorphic if $\bar{\delta}^{-1} \circ \bar{\delta}'$ lifts to an isomorphism $\underline{\mathcal{G}}' \to \underline{\mathcal{G}}$.

By Hartl and Viehmann [2017], 2.2 $\underline{\mathcal{G}}$ is bounded by $\hat{Z}^{-1}$ if and only if $\tau_{\mathcal{G}}^{-1}$ is bounded by $\hat{Z}_R$.

Let $\mathrm{QIsog}_{\mathbb{F}}(\underline{\mathbb{G}}_0)$ be the group of self-quasi-isogenies of $\underline{\mathbb{G}}_0$. It naturally acts on the functor $\breve{\mathfrak{M}}$. Since $\mathbb{F}$ has no non-trivial étale coverings, we may fix a trivialization $\underline{\mathbb{G}}_0 \cong ((L^+\mathbf{G})_{\mathbb{F}}, b\sigma^*)$ where $b \in L\mathbf{G}(\mathbb{F})$ represents the Frobenius morphism. Via such a trivialization, $\mathrm{QIsog}_{\mathbb{F}}(\underline{\mathbb{G}}_0)$ is identified with

$$J_b(\mathbb{F}_q((z))) := \{g \in G(\mathbb{F}((z))) \mid g^{-1}b\sigma(g) = b\}. \tag{4-2}$$

This is the set of $\mathbb{F}_q((z))$-valued points of an algebraic group J_b over $\mathbb{F}_q((z))$.

Theorem 4-3 (Arasteh Rad and Hartl [2014], Thm. 4.18 and Cor. 4.26, Hartl and Viehmann [2017], Rem. 3.5)**.** *The functor* $\breve{\mathfrak{M}}$ *is ind-representable by a formal scheme over* $\mathrm{Spf}\breve{R}_{\hat{Z}}$ *which is locally formally of finite type and separated. It is an ind-closed ind-subscheme of* $\mathrm{Flag}_{\mathbf{G}}\widehat{\times}_{\mathbb{F}_q}\mathrm{Spf}\breve{R}_{\hat{Z}}$.

By its analogy with moduli spaces of p-divisible groups, the formal scheme representing $\breve{\mathfrak{M}}$ is called a Rapoport-Zink space for bounded local $\mathbf{G}$-shtukas.

Let E be the quotient field of $R_{\hat{Z}}$, and $\breve{E} \cong \mathbb{F}((\xi))$ the completion of its maximal unramified extension. We write $\breve{\mathfrak{M}}^{\mathrm{an}}$ for the strictly $\breve{E}$-analytic space associated with $\breve{\mathfrak{M}}$.

Next we explain the construction of a tower of coverings of $\breve{\mathfrak{M}}^{\mathrm{an}}$. Roughly spoken, it is obtained by trivializing the (dual) Tate module of the universal local $\mathbf{G}$-shtuka over $\breve{\mathfrak{M}}^{\mathrm{an}}$.

Definition 4-4. Let S be an $\mathbb{F}((\zeta))$-scheme or a strictly $\mathbb{F}((\zeta))$-analytic space. Then an *étale local* $\mathbf{G}$*-shtuka* over S is a pair $\underline{\mathcal{G}} = (\mathcal{G}, \tau_{\mathcal{G}})$ consisting of an $L^+\mathbf{G}$-torsor $\mathcal{G}$ on S and an isomorphism $\tau_{\mathcal{G}} : \sigma^*\mathcal{G} \to \mathcal{G}$ of $L^+\mathbf{G}$-torsors.

Remark 4-5. Let $S = \mathrm{Spf}B$ be an affinoid admissible formal $\breve{R}_{\hat{Z}}$-scheme and S^{an} the associated strictly $\breve{E}$-analytic space. Consider a trivialized local $\mathbf{G}$-shtuka $((L^+\mathbf{G})_S, A\sigma^*)$ over S. Then $A \in \mathbf{G}(B[\![z]\!][\frac{1}{z-\zeta}])$. Note that

$$(z-\zeta)^{-1} = -\sum_{i=0}^{\infty} \zeta^{-i-1}z^i \in \mathcal{O}_{S^{\mathrm{an}}}(S^{\mathrm{an}})[\![z]\!]$$

implies $B[\![z]\!][\frac{1}{z-\zeta}] \subset \mathcal{O}_{S^{\mathrm{an}}}(S^{\mathrm{an}})[\![z]\!]$. Therefore $((L^+\mathbf{G})_S, A\sigma^*)$ induces an étale local $\mathbf{G}$-shtuka $((L^+\mathbf{G})_{S^{\mathrm{an}}}, A\sigma^*)$ over S^{an}.

To obtain similarly a universal family of étale local $\mathbf{G}$-shtukas over $\breve{\mathfrak{M}}^{\mathrm{an}}$, we cover $\breve{\mathfrak{M}}$ by affinoid admissible formal $\breve{R}_{\hat{Z}}$-schemes. For each of them one chooses a finite étale covering trivializing the local $\mathbf{G}$-shtuka, and applies the above construction. Descending the étale local $\mathbf{G}$-shtuka then yields the desired universal family, compare Hartl and Viehmann [ibid.], 6.

There are two approaches to construct the (dual) Tate module of an étale local $\mathbf{G}$-shtuka $\underline{\mathcal{G}}$ over a connected strictly $\breve{E}$-analytic space X. To define it directly, following Neupert

[2016], 2.6, consider for each $n \in \mathbb{N}$ the $L^+\mathbf{G}/\mathbf{G}_n$-torsor associated with $\mathcal{G}$ where $\mathbf{G}_n$ is the kernel of the projection $\mathbf{G}(\mathbb{F}_q[\![z]\!]) \to \mathbf{G}(\mathbb{F}_q[\![z]\!]/(z^n))$. The isomorphisms $\tau_{\mathcal{G}} : \sigma^*\mathcal{G} \to \mathcal{G}$ and $\sigma^* : \mathcal{G} \to \sigma^*\mathcal{G}$ then induce corresponding maps of $L^+\mathbf{G}/\mathbf{G}_n$-torsors. The invariants of $\tau \circ \sigma^*$ form a $\mathbf{G}(\mathbb{F}_q[\![z]\!]/(z^n))$-torsor which is trivialized by a finite étale covering of X. One can then define the Tate module of $\underline{\mathcal{G}}$ as the inverse limit over n of these torsors.

Alternatively, one can define it as a tensor functor, following Arasteh Rad and Hartl [2014], or Hartl and Viehmann [2017], 7: Fix a geometric base point $\bar{x}$ of X. We consider representations $\rho : \mathbf{G} \to \mathrm{GL}_r$ in $\mathrm{Rep}_{\mathbb{F}_q[\![z]\!]}(\mathbf{G})$. Let $\underline{M} = (M, \tau_M)$ be the étale local shtuka of rank r associated with $\rho_*\underline{\mathcal{G}}$ as in Example 2-2. Let $\underline{M}_{\bar{x}}$ denote its fiber over $\bar{x}$. The (dual) Tate module of $\underline{\mathcal{G}}$ with respect to ρ is the (dual) Tate module of $\underline{M}_{\bar{x}}$,

$$\check{T}\underline{M}_{\bar{x}} = \{m \in \underline{M}_{\bar{x}} \mid \tau_M(\sigma^* m) = m\},$$

a free $\mathbb{F}_q[\![z]\!]$-module of rank r. It carries a continuous monodromy action of $\pi_1^{\text{ét}}(X, \bar{x})$, which also factors through $\pi_1^{\text{alg}}(X, \bar{x})$. We obtain the *dual Tate module* of $\underline{\mathcal{G}}$ as a tensor functor

$$\check{T}_{\underline{\mathcal{G}},\bar{x}} : \mathrm{Rep}_{\mathbb{F}_q[\![z]\!]}\mathbf{G} \to \mathrm{Rep}^{\text{cont}}_{\mathbb{F}_q[\![z]\!]}(\pi_1^{\text{alg}}(X, \bar{x})).$$

Similarly, using rational representations in $\mathrm{Rep}_{\mathbb{F}_q(\!(z)\!)}\mathbf{G}$ one can define the *rational dual Tate module*

$$\check{V}_{\underline{\mathcal{G}},\bar{x}} : \mathrm{Rep}_{\mathbb{F}_q(\!(z)\!)}\mathbf{G} \to \mathrm{Rep}^{\text{cont}}_{\mathbb{F}_q(\!(z)\!)}(\pi_1^{\text{et}}(X, \bar{x})).$$

The two constructions of dual Tate modules are compatible in the sense that the tensor functor associated with the above torsor coincides with the tensor functor $\check{T}_{\mathcal{G},\bar{x}} : \mathrm{Rep}_{\mathbb{F}_q[\![z]\!]}\mathbf{G} \to (\mathbb{F}_q[\![z]\!]\text{-Loc})_X$ with values in the local systems of $\mathbb{F}_q[\![z]\!]$-lattices on X that can be associated with $\check{T}_{\underline{\mathcal{G}},\bar{x}}$ as in the second construction (compare Hartl and Viehmann [ibid.], Prop. 5.3).

We can now proceed to define level structures and the tower of coverings of $\breve{\mathfrak{M}}^{\text{an}}$. Let FMod_A denote the category of finite locally free A-modules. We consider the forgetful functors

$$\omega_A^\circ : \mathrm{Rep}_A\mathbf{G} \to \mathrm{FMod}_A \tag{4-6}$$

and

$$\mathit{forget} : \mathrm{Rep}_A^{\text{cont}}(\pi_1^{\text{et}}(X, \bar{x})) \to \mathrm{FMod}_A. \tag{4-7}$$

For an étale local **G**-shtuka $\underline{\mathcal{G}}$ over X the two sets

$$\mathrm{Triv}_{\underline{\mathcal{G}},\bar{x}}(\mathbb{F}_q[\![z]\!]) = \mathrm{Isom}^{\otimes}(\omega^\circ_{\mathbb{F}_q[\![z]\!]}, \mathit{forget} \circ \check{T}_{\underline{\mathcal{G}},\bar{x}})(\mathbb{F}_q[\![z]\!])$$
$$\mathrm{Triv}_{\underline{\mathcal{G}},\bar{x}}(\mathbb{F}_q(\!(z)\!)) = \mathrm{Isom}^{\otimes}(\omega^\circ_{\mathbb{F}_q(\!(z)\!)}, \mathit{forget} \circ \check{V}_{\underline{\mathcal{G}},\bar{x}})(\mathbb{F}_q(\!(z)\!))$$

are non-empty and carry natural actions of $\mathbf{G}(\mathbb{F}_q[\![z]\!]) \times \pi_1^{\mathrm{alg}}(X, \bar{x})$ and $G(\mathbb{F}_q(\!(z)\!)) \times \pi_1^{\mathrm{et}}(X, \bar{x})$, respectively. Here, the first factor acts via ω° and the second via the action on the Tate module. Note that non-emptiness needs our assumption that $\mathbf{G}$ has connected fibers, and thus slightly differs from the setting of Rapoport and Zink.

In the same way as in the arithmetic case we define coverings of $\breve{\mathfrak{M}}$.

Definition 4-8. Let $\underline{\mathcal{G}}$ be an étale local $\mathbf{G}$-shtuka over a connected $\breve{E}$-analytic space X, and let K be an open compact subgroup of $\mathbf{G}(\mathbb{F}_q[\![z]\!])$. An *integral K-level structure* on $\underline{\mathcal{G}}$ is a $\pi_1^{\mathrm{alg}}(X, \bar{x})$-invariant K-orbit in $\mathrm{Triv}_{\underline{\mathcal{G}},\bar{x}}(\mathbb{F}_q[\![z]\!])$.

For an open subgroup $K \subset \mathbf{G}(\mathbb{F}_q[\![z]\!])$ let X^K be the functor on the category of $\breve{E}$-analytic spaces over X parametrizing integral K-level structures on the local $\mathbf{G}$-shtuka $\underline{\mathcal{G}}$ over X.

Let $K \subset \mathbf{G}(\mathbb{F}_q(\!(z)\!))$ be compact open. Let $K' \subset K$ be a normal subgroup of finite index with $K' \subset \mathbf{G}(\mathbb{F}_q[\![z]\!])$. Then $gK' \in K/K'$ acts on $X^{K'}$ by sending the triple $(\underline{\mathcal{G}}, \delta, \eta K')$ over $X^{K'}$ to the triple $(\underline{\mathcal{G}}, \delta, \eta g K')$.

We define $\breve{\mathfrak{M}}^K$ as the $\breve{E}$-analytic space which is the quotient of $\breve{\mathfrak{M}}^{K'} := \breve{\mathfrak{M}}^{\mathrm{an},K'}$ by the finite group K/K'. It is independent of the choice of K'. In particular, $\breve{\mathfrak{M}}^{K_0} = (\breve{\mathfrak{M}})^{\mathrm{an}}$ for $K_0 = \mathbf{G}(\mathbb{F}_q[\![z]\!])$.

By Hartl and Viehmann [2017], Cor. 7.13 one can also describe $\breve{\mathfrak{M}}^K$ directly as a parameter space of local $\mathbf{G}$-shtukas with level structure.

Furthermore, if $K' \subseteq K$ is as above, the action of $gK' \in K/K'$ on $\breve{\mathfrak{M}}^{K'}$ can be described in this interpretation as a Hecke correspondence.

5 The geometry of the special fiber

We fix again a bound $(R, \hat{Z}_R)$ and let κ be the residue field of R. Let Z^{-1} be the special fiber of the inverse bound $\hat{Z}^{-1}$ over κ. The affine Deligne-Lusztig variety associated with an element $b \in L\mathbf{G}(\mathbb{F})$ and Z^{-1} is the reduced closed ind-subscheme $X_{Z^{-1}}(b) \subset \mathrm{Flag}_{\mathbf{G}}$ whose k-valued points (for any field extension k of $\mathbb{F}$) are given by

$$X_{Z^{-1}}(b)(k) = \{g \in \mathrm{Flag}_{\mathbf{G}}(k) \mid g^{-1}b\sigma(g) \in Z^{-1}(k)\}. \tag{5-1}$$

Our conditions on the bound imply that Z^{-1} is a left-$L^+\mathbf{G}$-invariant subscheme of $\mathrm{Flag}_{\mathbf{G}}$. The $L^+\mathbf{G}$-orbits in $\mathrm{Flag}_{\mathbf{G}}$ correspond bijectively to the elements of $\widetilde{W}^{\mathbf{G}} \backslash \widetilde{W} / \widetilde{W}^{\mathbf{G}}$, compare Example 2-6. For $x \in \widetilde{W}$ let

$$X_x(b)(k) = \{g \in \mathrm{Flag}_{\mathbf{G}}(k) \mid g^{-1}b\sigma(g) \in L^+\mathbf{G}xL^+\mathbf{G}\}. \tag{5-2}$$

Thus by left invariance every $X_{Z^{-1}}(b)(k)$ is a union of affine Deligne-Lusztig varieties of the form $X_x(b)$. By the boundedness condition on $\hat{Z}_R$, this union is finite. In the arithmetic context, such unions of affine Deligne-Lusztig varieties have been studied for example in He [2016].

Affine Deligne-Lusztig varieties are the underlying reduced subschemes of Rapoport-Zink spaces:

Theorem 5-3 (Hartl and Viehmann [2011], 6, Arasteh Rad and Hartl [2014], Thm. 4.18, Cor. 4.26)**.** *The underlying reduced subscheme of the moduli space* $\breve{\mathfrak{M}}$ *associated with* $\hat{Z}_R$ *and* b *as in Theorem 4-3 equals* $X_{Z^{-1}}(b)$. *It is a scheme locally of finite type and separated over* $\mathbb{F}$, *all of whose irreducible components are projective.*

Thus to describe the special fiber of the Rapoport-Zink spaces $\breve{\mathfrak{M}}$ it is enough to study the affine Deligne-Lusztig varieties $X_x(b)$. For an overview of the current state of the art of this field compare Viehmann [2015] and X. He's talk at this ICM He [2018]. We will here only discuss one class of results that were obtained as an application of the relation to local **G**-shtukas, and that were one of the initial goals of this theory. For the following result it is essential to assume that **G** is reductive over $\mathbb{F}_q[\![z]\!]$. For more general groups there are counterexamples to all assertions in the theorem. Recall that for reductive groups $\widetilde{W}^{\mathbf{G}}\backslash\widetilde{W}/\widetilde{W}^{\mathbf{G}} \cong X_*(T)_{\mathrm{dom}}$. Let $\mathrm{def}(b) = \mathrm{rk}\, G - \mathrm{rk}_{\mathbb{F}_q((z))} J_b$ where J_b is as in (4-2). Note that $X_*(T)_{\mathrm{dom}}$ is partially ordered by the Bruhat ordering. Via the induced ordering on the Newton points (requiring equality of Kottwitz points) also $B(G)$ inherits an ordering. Let l denote the length of a maximal chain between two elements in the partially ordered set $B(G)$, and let ρ be the half-sum of the positive roots of **G**.

Theorem 5-4 (Viehmann [2013], Hamacher and Viehmann [2017], 3.2)**.** *Let* $\mu_1 \preceq \mu_2 \in X_*(T)$ *be dominant coweights and* $[b] \in B(G)$. *Assume that* $\kappa_G(b) = \mu_2$ *in* $\pi_1(G)_\Gamma$ *and that* $\nu_b \preceq \mu_2$.

1. *Let*

$$S_{\mu_1,\mu_2} = \bigcup_{\mu_1 \preceq \mu' \preceq \mu_2} L^+\mathbf{G}\mu'(z)L^+\mathbf{G}.$$

Then the Newton stratum $\mathfrak{N}_{[b]} = [b] \cap S_{\mu_1,\mu_2}$ *is pure of codimension*

$$l([b],[\mu_2]) = \langle \rho, \mu_2 - \nu_b \rangle + \frac{1}{2}\mathrm{def}(b)$$

in S_{μ_1,μ_2}. *The closure of* $\mathfrak{N}_{[b]}$ *in* S_{μ_1,μ_2} *is the union of all* $\mathfrak{N}_{[b']}$ *for* $[b']$ *with* $\kappa_G(b') = \mu_2$ *in* $\pi_1(\mathbf{G})_\Gamma$ *and* $\nu_{b'} \preceq \nu_b$.

2. $X_{\mu_2}(b)$ *and* $X_{\preceq\mu_2}(b) = \bigcup_{\mu\preceq\mu_2} X_\mu(b)$ *are equidimensional of dimension*

$$\dim X_{\mu_2}(b) = \dim\ X_{\preceq\mu_2}(b) = \langle \rho, \mu_2 - \nu_b \rangle - \frac{1}{2}\mathrm{def}(b).$$

Here, the first assertion is most useful for $\mu_1 = \mu_2$, or for μ_1 the unique minuscule coweight with $\mu_1 \preceq \mu_2$.

Note that one needs to define the notions of codimension and of the closure of the infinite-dimensional schemes $\mathfrak{N}_{[b]}$. Both of these definitions use that there is an open subgroup H of $L\mathbf{G}^+$ such that the Newton point of an element of S_{μ_1,μ_2} only depends on its H-coset, an element of the finite-dimensional scheme $S_{\mu_1,\mu_2}/H$, compare Viehmann [2013], 4.3. These (co)dimensions are directly linked to the dimensions of Newton strata in the universal deformation of a local $\mathbf{G}$-shtuka as in Section 3. In fact, Theorem 5-4 is equivalent to a completely analogous result on dimensions and closure relations in that context, and this equivalence is also used in the proof of Theorem 5-4.

The proofs of the two parts of the theorem are closely linked: One first shows the upper bound on $\dim X_{\preceq\mu_2}(b)$ and how to compute $\dim \mathfrak{N}_{[b]}$ from $\dim X_{\preceq\mu_2}(b)$. Then a purity result for the Newton stratification proves the lower bound and equidimensionality. For the proof compare Hamacher and Viehmann [2017], 3.2 explaining how the proof for split $\mathbf{G}$ in Viehmann [2013] can be generalized. The theorem also inspired a corresponding theory for Newton strata in Shimura varieties of Hodge type by Hamacher.

6 Comparison to global $\mathfrak{G}$-shtukas

6.1 Global $\mathfrak{G}$-shtukas. Moduli spaces of bounded global $\mathfrak{G}$-shtukas are the function field analogue of Shimura varieties. Using these moduli spaces Lafforgue [2012] showed one direction of the global Langlands correspondence for all groups $\mathfrak{G}$ in the function field case. In this section we describe the relation between moduli spaces of bounded local $\mathbf{G}$-shtukas and global $\mathfrak{G}$-shtukas.

To define them, let C be a smooth projective geometrically irreducible curve over $\mathbb{F}_q$, and let $\mathfrak{G}$ be a parahoric group scheme over C, i.e. a smooth affine group scheme with connected fibers whose generic fiber is reductive over $\mathbb{F}_q(C)$ and such that for every point v of C for which the fiber above v is not reductive, the group scheme $\mathfrak{G}_v$ is a parahoric group scheme over A_v, as defined by Bruhat and Tits. Here A_v denotes the completion of $k[C]$ at v.

Definition 6-1. A *global shtuka* with n legs over a scheme S is a tuple $(\mathcal{G}, s_1, \dots, s_n, \varphi)$ where

1. $\mathcal{G} \in \mathcal{H}^1(C, \mathfrak{G})(S)$ is a $\mathfrak{G}$-torsor over $C \times_{\mathbb{F}_q} S$
2. the $s_i \in C(S)$ are pairwise disjoint S-valued points, called the legs
3. φ is an isomorphism

$$\varphi : \sigma^*\mathcal{G}|_{C\times_{\mathbb{F}_q} S\setminus\{\bigcup_i \Gamma_{s_i}\}} \to \mathcal{G}|_{C\times_{\mathbb{F}_q} S\setminus\{\bigcup_i \Gamma_{s_i}\}},$$

called the Frobenius isomorphism.

The stack $\nabla_n\mathcal{H}^1(C,\mathfrak{G})$ over $\operatorname{Spec}\mathbb{F}_q$ is the *moduli stack of global $\mathfrak{G}$-shtukas with n legs*.

There is a canonical morphism $\nabla_n\mathcal{H}^1(C,\mathfrak{G})\to C^n\setminus\Delta$ mapping a global $\mathfrak{G}$-shtuka to its legs.

We fix distinct places $c_i\in C(\mathbb{F})$ for $1\le i\le n$, and write $c=(c_1,\dots,c_n)$. Let A_c be the completion of the local ring $\mathcal{O}_{C^n,c}$, and let $\mathbb{F}_c$ be the residue field. Then $A_c\cong\mathbb{F}_c[\![\zeta_1,\dots,\zeta_n]\!]$.

Writing $A_{c_i}\cong\mathbb{F}_{c_i}[\![z]\!]$, let $\mathbf{G}_{c_i}=\mathfrak{G}\times_C\operatorname{Spec}A_{c_i}$, a parahoric group scheme over $\operatorname{Spec}\mathbb{F}_{c_i}[\![z]\!]$, and $\mathbf{G}_i:=\operatorname{Res}_{\mathbb{F}_{c_i}[\![z]\!]/\mathbb{F}_q[\![z]\!]}\mathbf{G}_{c_i}$.

Let

$$\nabla_n\mathcal{H}^1(C,\mathfrak{G})^c=\nabla_n\mathcal{H}^1(C,\mathfrak{G})\widehat{\times}_{C^n}\operatorname{Spf}A_c$$

be the formal completion of the stack $\nabla_n\mathcal{H}^1(C,\mathfrak{G})$ along c. It parametrizes global $\mathfrak{G}$-shtukas with n legs in the formal neighborhoods of the c_i. We want to define a global-local functor associating with such a global $\mathfrak{G}$-shtuka local shtukas at each of these places, compare Arasteh Rad and Hartl [2014], or Neupert [2016], 3.2. Let $(\mathcal{G},(s_i),\varphi)\in\nabla_n\mathcal{H}^1(C,\mathfrak{G})^c(S)$. In other words, $s_i:S\to C$ factors through $\operatorname{Spf}A_{c_i}$. We consider each place c_i separately. Let $S_{c_i}=\operatorname{Spec}\mathbb{F}_{c_i}\times_{\operatorname{Spec}\mathbb{F}_q}S$. The base change of $\mathcal{G}$ to $\operatorname{Spf}A_{c_i}\widehat{\times}_{\mathbb{F}_q}S=S_{c_i}[\![z]\!]$ defines an element of $\mathcal{H}^1(\mathbb{F}_q,\mathbf{G}_{c_i})(S_{c_i}[\![z]\!])$. We now use the following translation, cf. Hartl and Viehmann [2011], Prop. 2.2a, Neupert [2016], Prop. 3.2.4, or Arasteh Rad and Hartl [2014], 2.4.

Proposition 6-2. *Let S be a scheme over $\mathbb{F}_q$. There is a natural equivalence of categories*

$$\mathcal{H}^1(\mathbb{F}_q,\mathbf{G})(S[\![z]\!])\to\mathcal{H}^1(\mathbb{F}_q,L^+\mathbf{G})(S).$$

We thus obtain an element of

$$\mathcal{H}^1(\mathbb{F}_q,L^+\mathbf{G}_{c_i})(S_{c_i})=\mathcal{H}^1(\mathbb{F}_q,L^+\mathbf{G}_i)(S),$$

or an $L^+\mathbf{G}_i$-torsor $\mathcal{G}_i$ over S.

Also, the Frobenius morphism φ induces local Frobenius morphisms φ_i on the $\mathbf{G}_i$-torsors for each i. Altogether we obtain a functor

$$\mathfrak{L}=(\mathfrak{L}_1,\dots,\mathfrak{L}_n):\nabla_n\mathcal{H}^1(C,\mathfrak{G})^c\to\prod_i Sht_{\mathbf{G}_i},\qquad(\mathcal{G},(s_i),\varphi)\mapsto((\mathcal{G}_i,\varphi_i))$$

called the global-local functor.

In the same way, one can associate with every global $\mathfrak{G}$-shtuka $\underline{\mathcal{G}}\in\nabla_n\mathcal{H}^1(C,\mathfrak{G})^c(S)$ for some scheme S and every fixed place $s\in C\setminus\{c_i\}$ an étale local $\mathbf{G}_s$-shtuka $\mathfrak{L}_s(\underline{\mathcal{G}})=$

$\underline{\mathcal{G}}_s$. One can then define level structures on global $\mathfrak{G}$-shtukas away from the legs using the corresponding notion for local $\mathbf{G}$-shtukas. For a detailed discussion compare Neupert [2016], 3.4.

Definition 6-3. Let $\underline{\mathcal{G}} = (\mathcal{G}, (s_i), \varphi)$ be a global $\mathfrak{G}$-shtuka over S, let $D_0 \subset C$ be a finite reduced subscheme with $s_i \in (C \setminus D_0)(S)$ for every i. For every $v \in D_0$ fix an open subgroup $U_v \subseteq L^+G_v(\mathbb{F}_q)$ and let $U = \prod U_v$. Then an *integral U-level structure* on $\underline{\mathcal{G}}$ consists of an integral U_v-level structure of $\mathfrak{L}_v(\underline{\mathcal{G}})$ for every $v \in D_0$.

We denote by $\nabla \mathcal{H}^1_U(C, \mathfrak{G})^c$ the *stack of global $\mathfrak{G}$-shtukas* in $\nabla \mathcal{H}^1(C, \mathfrak{G})^c$ with U-level structure.

Rather ad hoc boundedness conditions are defined as follows (compare Arasteh Rad and Hartl [2013]).

Definition 6-4. Let $\hat{Z}_c = (\hat{Z}_i)_i$ be a tuple of bounds $\hat{Z}_i \subset \widehat{\mathrm{Flag}}_{\mathbf{G}_i}$. Then $(\mathcal{G}, (s_i), \varphi) \in \nabla_n \mathcal{H}^1(C, \mathfrak{G})^c(S)$ is *bounded by* $\hat{Z}_c$ if for every i the associated local $\mathbf{G}_i$-shtuka $(\mathcal{G}_i, \varphi_i)$ is bounded by $\hat{Z}_i$. We denote by $\nabla_n^{\hat{Z}_c} \mathcal{H}^1(C, \mathfrak{G})^c$ the substack of $\nabla_n \mathcal{H}^1(C, \mathfrak{G})^c$ of global $\mathfrak{G}$-shtukas bounded by $\hat{Z}_c$, and analogously for $\nabla_n^{\hat{Z}_c} \mathcal{H}^1_U(C, \mathfrak{G})^c$.

There are two other definitions of boundedness: A (seemingly more natural) one by Varshavsky [2004], Def. 2.4b for which, however, it is not clear how to establish a compatibility between bounded global and local shtukas. In Neupert [2016], 3.3 Neupert gives a global definition of boundedness, generalizing that of Varshavsky and he shows that it coincides with the one presented here.

6.2 The Serre-Tate theorem. Classically, the Serre-Tate theorem gives an equivalence of categories between deformations of an abelian variety over a scheme on which p is locally nilpotent, and its p-divisible group. By work of Arasteh Rad and Hartl, the analog in our situation also holds, taking into account that shtukas have several legs, and requiring them to be in the formal neighborhoods of fixed places of C.

Let S be in Nilp_{A_c} and let $j : \overline{S} \to S$ be a closed subscheme defined by a locally nilpotent sheaf of ideals. Let $c_1, \dots, c_n \in C$ and let $(\mathcal{G}, (s_i), \varphi) \in \nabla_n \mathcal{H}^1(C, \mathfrak{G})^c(\overline{S})$. Let $((\mathcal{G}_i, \varphi_i)) = \mathfrak{L}(\mathcal{G}, (s_i), \varphi)$.

Let $\mathrm{Def}_S((\mathcal{G}, (s_i), \varphi))$ be the category of lifts of $(\mathcal{G}, (s_i), \varphi)$ to S, i.e. of pairs $(\underline{\mathcal{H}}, \alpha)$ where $\underline{\mathcal{H}} \in \nabla_n \mathcal{H}^1(C, \mathfrak{G})^c(S)$ and where α is an isomorphism between $(\mathcal{G}, (s_i), \varphi)$ and the base change of $\underline{\mathcal{H}}$ to $\overline{S}$. Morphisms of lifts are isomorphisms compatible with the morphisms α. For the local $\mathbf{G}_i$-shtukas we define analogously a category of lifts $\mathrm{Def}_S((\mathcal{G}_i, \varphi_i))$.

Theorem 6-5 (Arasteh Rad and Hartl [2014], Th. 5.10)**.** *Let $(c_i)_i \in C^n$, let $(\mathcal{G}, (s_i), \varphi) \in \nabla_n \mathcal{H}^1(C, \mathfrak{G})^c(\overline{S})$ and let $((\mathcal{G}_i, \varphi_i)) = \mathfrak{L}(\mathcal{G}, (s_i), \varphi)$. Then the global-local functor induces an equivalence of categories* $\mathrm{Def}_S((\mathcal{G}, (s_i), \varphi)) \to \prod_i \mathrm{Def}_S((\mathcal{G}_i, \varphi_i))$.

6.3 Foliations. We begin by considering the uniformization morphism for Newton strata by Rapoport-Zink spaces, following Neupert [2016], 5 and Arasteh Rad and Hartl [2014], 5, and paralleling the uniformization result for p-divisible groups of Rapoport and Zink [1996]. In this subsection we assume that $\mathfrak{G}$ is the base change to C of a reductive group G over $\mathbb{F}_q$. It would be interesting to have a generalization of this result to the more general context considered before.

Let T denote a maximal torus of G, and fix a Borel subgroup B containing T. Let C be as above and fix characteristic places $c_1, \dots, c_n \in C$. Let $\mu_i \in X_*(T)$ be dominant cocharacters defined over a finite extension E of $\mathbb{F}_q$, and $\mu = (\mu_1, \dots, \mu_n) \in X_*(T)^n$. Fix decent local $\mathbf{G}_i$-shtukas $\underline{\mathbb{G}_i} = (L^+\mathbf{G}_{iE}, b_i\sigma^*)$ over Spec E, in particular $b_i \in L\mathbf{G}_i(E)$. Let $\mathfrak{M}_{b_i}^{\preceq\mu_i}$ be the Rapoport-Zink space associated with $[b_i]$ and the bound given by μ_i.

Theorem 6-6 (Neupert [2016], Theorem 5.1.18, Arasteh Rad and Hartl [2013], Theorem 7.4)**.** *Let S be a DM-stack over* $\operatorname{Spf} E[\![\zeta_1, \dots, \zeta_n]\!]$ *such that* $(\zeta_1, \dots, \zeta_n)$ *is locally nilpotent on S. Let $(\mathscr{G}_0, \phi_0, \psi_0) \in \nabla_n \mathscr{H}_U^1(C, \mathfrak{G})^c(S)$ for some congruence subgroup U. For each place c_i assume that there is, and fix, an isomorphism $\mathfrak{L}_{c_i}(\mathscr{G}_0, \phi_0) \cong \underline{\mathbb{G}_i}_S$. Then there is a morphism of formal DM-stacks over* $\operatorname{Spf} E[\![\zeta_1, \dots, \zeta_n]\!]$

$$S \times_{\operatorname{Spf} E[\![\zeta_1,\dots,\zeta_n]\!]} \prod_i \mathfrak{M}_{b_i}^{\preceq\mu_i} \to \nabla_n^{\mu} \mathscr{H}_U^1(C, \mathfrak{G})^c$$

which is ind-proper and formally étale.

This theorem has also generalizations to coverings of the moduli spaces associated with compatible level structures, and is then equivariant with respect to the action of $\mathfrak{G}(\mathbb{A}_{\mathbb{Q}}^{c_i})$ by Hecke correspondences.

We consider for the universal global $\mathfrak{G}$-shtuka $\underline{\mathscr{G}}$ over $\nabla_n^{\mu} \mathscr{H}_U^1(C, \mathfrak{G})^c$ the strata

$$\mathfrak{N}_{\underline{\mathscr{G}}}^{([b_i])_i} = \bigcap_i \mathfrak{N}_{[b_i], \mathfrak{L}_i(\underline{\mathscr{G}})} \subseteq \nabla_n^{\mu} \mathscr{H}_U^1(C, \mathfrak{G})^c.$$

Here, the $\mathfrak{N}_{[b_i], \mathfrak{L}_i(\underline{\mathscr{G}})}$ are the Newton strata in $\nabla_n^{\mu} \mathscr{H}_U^1(C, \mathfrak{G})^c$ associated with the local $\mathbf{G}_i$-shtuka $\mathfrak{L}_i(\underline{\mathscr{G}})$.

Then the uniformization morphism of Theorem 6-6 maps each geometric point of the left hand side to $\mathfrak{N}_{\underline{\mathscr{G}}}^{([b_i])_i}$ where the $[b_i]$ are the classes of the elements used to define the Rapoport-Zink space. Refining this description we now consider a foliation structure on these Newton strata, following Neupert [2016], 5.

In the arithmetic case, Oort and later Mantovan [2004] defined a foliation structure on Newton strata on Shimura varieties, by Rapoport-Zink spaces and so-called Igusa varieties. The latter are defined as covers of a central leaf, i.e. the locus in the Shimura variety where the p-divisible group is in a very particular isomorphism class. In our situation, the definition is slightly more involved. One needs to pass to the perfection of all involved moduli spaces to define the analog of Igusa varieties, and then to construct the foliation morphism.

Recall that a Newton stratum only depends on $L\mathbf{G}_i$-σ-conjugacy classes $[b_i]$, and not on individual representatives. A fundamental alcove in $[b_i]$ is an element x_{b_i} of $\widetilde{W}$ such that all (or one) representative $b_{i,0}$ in $N(L)$ is contained in $[b_i]$, and such that the length $\ell(x_{b_i})$ is minimal with that property, compare Viehmann [2014], Theorem 6.5, or Nie [2015]. One can then show that this length is equal to $\langle 2\rho_G, \nu_{b_i}\rangle$ where ρ_G is the half-sum of the positive roots of G and where ν_{b_i} is the dominant Newton point of $[b_i]$. Fundamental alcoves are a group-theoretic generalization of the minimal p-divisible groups studied by Oort. For each $[b_i]$ we fix such a representative $b_{i,0}$. The central leaf

$$\mathcal{C}_U^{(b_{i,0})} \subseteq \mathcal{N}_{\underline{\mathcal{G}}}^{([b_i])_i}$$

is then defined as the locus where the associated local $\mathbf{G}_i$-shtukas are isomorphic to $((L^+\mathbf{G}_i)_k, b_{i,0}$
It depends on the choice of the fundamental alcove, but not on that of the representative in $N(L)$.

We now define formal versions of these subschemes of $\nabla_n^{\mu}\mathcal{H}_U^1(C,G)$.

Definition 6-7. Recall that the formal completion of $C^n \setminus (c_1,\dots,c_n)$ is isomorphic to $\mathrm{Spf} A_c = \mathrm{Spf}\, \mathbb{F}_c[\![\zeta_1,\dots,\zeta_n]\!]$.

Let $\mathfrak{N}_U^{([b_i])_i}$ denote the formal completion of $\nabla_n^{\mu}\mathcal{H}_U^1(C,G)^c$ along the Newton stratum $\mathcal{N}_{\underline{\mathcal{G}}}^{([b_i])_i}$. This is not $(\zeta_1,\dots,\zeta_n)$-adic.

Let $\mathfrak{C}_U^{(b_{i,0})}$ be the locus in $\nabla_n^{\mu}\mathcal{H}_U^1(C,G)^c$ such that after an fpqc-covering each local $\mathbf{G}_i$-shtuka associated with the universal global $\mathfrak{G}$-shtuka is isomorphic to $(L^+\mathbf{G}_i, b_{i,0}\sigma^*)$. One can then show that this is represented by a $(\zeta_1,\dots,\zeta_n)$-adic formal scheme over $\mathrm{Spf} A_c$, called the *central leaf.* (Neupert [2016], Prop. 6.1.7)

By $X^\sharp$ we denote the perfection of a formal scheme X. It is again a formal scheme.

For $d \in \mathbb{N}$ we consider the subgroups $K_d = \{g \in L^+\mathbf{G}_i \mid g \equiv 1 \pmod{z^{d+1}}\}$ and

$$I_d(b_{i,0}) = \bigcap_{N \geq 0} \phi^N(K_d)$$

where $\phi(g) = b_{i,0}^{-1}\sigma^{-1}(g)b_{i,0}$.

The following theorem shows existence of the formal Igusa varieties.

Theorem 6-8 (Neupert [ibid.], Cor. 6.1.9)**.** *For all tuples $(d_i)_i$, define $\mathfrak{Ig}_U^{(d_i)\sharp}(T)$ as the set of pairs consisting of an element of $\mathfrak{C}_U^{(b_i)\sharp}(T)$ together with I_{d_i}-truncated isomorphisms between the associated local G_i-shtukas and $(L^+G_i, b_{i,0}\sigma^*)$ for all i. Then this* *defines a sheaf* $\mathfrak{Ig}_U^{(d_i)\sharp}$ *over* $\mathfrak{C}_U^{(b_i)\sharp}$ *representable by a* $(\zeta_1, \dots, \zeta_n)$*-adic formal scheme which is finite étale over* $\mathfrak{C}_U^{(b_i)\sharp}$*. It is called a* formal Igusa variety *of level* (d_i)*.*

Similarly, $\mathfrak{Ig}_U^{(\infty_i)\sharp}$ *parametrizing trivializations of the whole local* G_i*-shtukas is representable by a formal scheme, isomorphic to* $\varprojlim \mathfrak{Ig}_U^{(d_i)\sharp}$*.*

The foliation structure is then established by the following result.

Theorem 6-9 (Neupert [ibid.], Thm. 6.2.1)**.** *There is a natural formally étale morphism of formal schemes over* $\operatorname{Spf} A_c^\sharp$

$$\hat{\pi}_{(\infty_i)} : \prod_i \mathfrak{M}_{b_{i,0}}^{\preceq \mu_i \sharp} \times_{\operatorname{Spf} A_c^\sharp} \mathfrak{Ig}_U^{(\infty_i)\sharp} \to \mathfrak{N}_U^{[b_i]\sharp}.$$

There are also variants of this result for the special fiber of the spaces, using bounds on the quasi-isogenies, and for the associated adic spaces in the sense of Huber.

The very rough idea of the construction of this morphism is the following: A point in the Igusa variety gives us a global shtuka, such that at each place c_i the associated local $\mathbf{G}_i$-shtuka is the one defined by $b_{i,0}$. Then a point in the Rapoport-Zink space $\mathfrak{M}_{b_{i,0}}^{\preceq \mu_i}$ gives us a modification by a quasi-isogeny of this local $\mathbf{G}_i$-shtuka, and we define a new global $\mathfrak{G}$-shtuka by keeping the old one away from the c_i and replacing it in a formal neighborhood of c_i by this new local $\mathbf{G}_i$-shtuka.

Applying the theorem to the cohomology of the moduli space of global $\mathfrak{G}$-shtukas, and its decomposition into Newton strata, one can express the cohomology of Newton strata, and therefore of the whole moduli space of global $\mathfrak{G}$-shtukas in terms of the cohomology of Rapoport-Zink moduli spaces and of Igusa varieties. For technical reasons the statement is only known over a finite extension E' of $\mathbb{F}_q$ that can be described in terms of $\mathfrak{G}$ and μ. Denote by K the function field of the curve C, by $\overline{K}$ an algebraic closure, and by $\Gamma_{E'}$ the absolute Galois group of E'.

Theorem 6-10 (Neupert [ibid.], Main Theorem 2)**.** *Let* $\nabla_n^\mu \mathscr{H}^1(C, \mathfrak{G})$ *be a moduli space of global* $\mathfrak{G}$*-shtukas, such that all connected components of* $\nabla_n^\mu \mathscr{H}^1(C, \mathfrak{G}) \times_{C^n \setminus \Delta} \operatorname{Spec} E'[\![\zeta_1, \dots, \zeta_n]\!]$ *are proper over* $\operatorname{Spec} E'[\![\zeta_1, \dots, \zeta_n]\!]$.
Then there exists a canonical isomorphism between the virtual $\mathfrak{G}(\mathbb{A}_{\mathbb{Q}}^{c_i}) \times \Gamma_{E'}$*-representations*

$$\sum_j (-1)^j H_c^j \left(\nabla_n^\mu \mathscr{H}^1(C, \mathfrak{G}) \times \overline{K}, \mathbb{Q}_\ell\right)$$

and

$$\sum_{[b_i]} \sum_{d,e,f} (-1)^{d+e+f} \mathrm{Tor}_d^{\mathcal{H}(\prod J_{b_{i,0}})} \Big(H_c^e \big(\prod \mathfrak{M}_{b_{i,0}}^{\preceq \mu_i} \times \mathbb{F}, R\Psi_\eta^{\mathrm{an}} \mathbb{Q}_\ell\big), \varinjlim_U \varinjlim_{d_i} H_c^f \big(\mathrm{Ig}_U^{(d_i)} \times \mathbb{F}, R\Psi_\eta^{\mathrm{an}} \mathbb{Q}_\ell\big)\Big).$$

7 Period spaces and the period map

In our context, period spaces are constructed as strictly $\mathbb{F}_q((\zeta))$-analytic spaces in the sense of Berkovich. In the generality presented here, they are introduced and studied in Hartl and Viehmann [2017]. We allow more general bounds than those associated with minuscule coweights. Even if the bound is given by a coweight as in Example 2-6, the bound is in general a union of Schubert cells, and not a single one as in the minuscule case. For these two reasons the period spaces have to be defined as subspaces of an affine Grassmannian instead of a (classical) flag variety. To define them, we consider the affine Grassmannian $\mathrm{Gr}_{\mathbf{G}}^{B_{\mathrm{dR}}}$ of Remark 2-5. The space of Hodge-Pink $\mathbf{G}$-structures bounded by $\hat{Z}$ is defined as $\mathcal{H}_{\mathbf{G},\hat{Z}} := \hat{Z}_E$. It is a projective subscheme of $\mathrm{Gr}_G^{B_{\mathrm{dR}}} \widehat{\times}_{\mathbb{F}_q((\zeta))} E$. Fix a local $\mathbf{G}$-shtuka $\underline{\mathbb{G}}_0$ over $\mathbb{F}$ and a trivialization $\underline{\mathbb{G}}_0 \cong (L^+\mathbf{G}_{\mathbb{F}}, b\sigma^*)$.

A z-isocrystal over $\mathbb{F}$ is a pair (D, τ_D) consisting of a finite-dimensional $\mathbb{F}((z))$-vector space D and an isomorphism $\tau_D : \sigma^* D \to D$ of $\mathbb{F}((z))$-vector spaces. A Hodge-Pink structure on (D, τ_D) over a field extension L of $\mathbb{F}((\zeta))$ is a free $L[\![z-\zeta]\!]$-submodule $\mathfrak{q}_D \subset D \otimes_{\mathbb{F}((z))} L((z-\zeta))$ of full rank, compare Hartl and Kim [2016], 5.

Definition 7-1. Let L and b be as above and let $\gamma \in \mathrm{Gr}_G^{B_{\mathrm{dR}}}(L)$. Let $\rho : G_{\mathbb{F}_q((z))} \to \mathrm{GL}_{n,\mathbb{F}_q((z))}$ be a representation and let V be the representation space. Then we associate with b (and ρ) the z-isocrystal $(V \otimes_{\mathbb{F}_q((z))} \mathbb{F}((z)), \rho(\sigma^* b)\sigma^*)$ over $\mathbb{F}$. With γ we associate the Hodge-Pink structure over L defined by

$$\mathfrak{q}_D(V) = \rho(\gamma) \cdot V \otimes_{\mathbb{F}_q((z))} L[\![z-\zeta]\!] \subset D \otimes_{\mathbb{F}((z))} L((z-\zeta)).$$

Let

$$\underline{D}_{b,\gamma}(V) = (V \otimes_{\mathbb{F}_q((z))} \mathbb{F}((z)), \rho(\sigma^* b)\sigma^*, \mathfrak{q}_D(V)).$$

Consider the Newton point $\nu_b \in X_*(T)$ as a homomorphism $\mathbb{D}_{\mathbb{F}((z))} \to G_{\mathbb{F}((z))}$. Recall the Kottwitz map $\kappa_G : G(\mathbb{F}((z))) \to \pi_1(G)_\Gamma$. We then define the *Hodge degree* and the *Newton degree* as

$$t_H(\underline{D}_{b,\gamma}(V)) = \rho_*(\kappa_G(\gamma)) \qquad \text{and} \qquad t_N(\underline{D}_{b,\gamma}(V)) = \det{}_V \circ \rho \circ \nu_b.$$

Using $\pi_1(\mathrm{GL}(V))_\Gamma = \mathbb{Z}$ and $\mathrm{Hom}(\mathbb{D}_{\mathbb{F}((z))}, \mathbb{G}_m) = \mathbb{Q}$ we can view these as rational numbers. (Compare Hartl and Viehmann [2017], 4 for a definition in terms of $\underline{D}_{b,\gamma}(V)$ only.)

We call $\underline{D}_{b,\gamma}(V)$ *weakly admissible* if the images of $[b]$ and γ in $\pi_1(G)_{\Gamma,\mathbb{Q}}$ coincide and for all subobjects the Hodge degree is less or equal to the Newton degree. Finally, the pair (b,γ) is weakly admissible if $\underline{D}_{b,\gamma}(V)$ is weakly admissible for a faithful representation ρ of G.

Let $\breve{\mathcal{H}}_{\mathbf{G},\hat{Z}} := \mathcal{H}_{\mathbf{G},\hat{Z}} \widehat{\times}_E \breve{E}$ where $\mathcal{H}_{\mathbf{G},\hat{Z}} = \hat{Z}_E$. The *period space* $\breve{\mathcal{H}}^{wa}_{\mathbf{G},\hat{Z},b}$ is then defined as the set of all γ in the associated $\breve{E}$-analytic space $\breve{\mathcal{H}}^{\mathrm{an}}_{\mathbf{G},\hat{Z}}$ such that (b,γ) is weakly admissible.

To define the admissible locus $\breve{\mathcal{H}}^{a}_{\mathbf{G},\hat{Z},b} \subset \breve{\mathcal{H}}^{\mathrm{an}}_{\mathbf{G},\hat{Z}}$, one associates with $\underline{D}$ a pair of σ-bundles $\underline{\mathcal{E}}(\underline{D}) = \underline{\mathcal{E}}_{b,\gamma}(V)$ and $\underline{\mathcal{F}}(\underline{D}) = \underline{\mathcal{F}}_{b,\gamma}(V)$. The *admissible locus* is then defined as the subset over which $\underline{\mathcal{F}}_{b,\gamma}(V)$ has slope zero. Then $\breve{\mathcal{H}}^{wa}_{\mathbf{G},\hat{Z},b}$ and $\breve{\mathcal{H}}^{a}_{\mathbf{G},\hat{Z},b}$ are open paracompact strictly $\breve{E}$-analytic subspaces of $\breve{\mathcal{H}}^{\mathrm{an}}_{\mathbf{G},\hat{Z}}$ (Hartl and Viehmann [ibid.], Theorem 4.20).

The neutral admissible locus $\breve{\mathcal{H}}^{na}_{\mathbf{G},\hat{Z},b} \subset \breve{\mathcal{H}}^{a}_{\mathbf{G},\hat{Z},b}$ is defined by the condition that the images of $[b]$ and γ in $\pi_1(G)_\Gamma$ coincide.

We have the analog of the theorem of Colmez and Fontaine that "admissible implies weakly admissible", see Hartl [2011],Theorem 2.5.3. In other words, we have an inclusion

$$\breve{\mathcal{H}}^{a}_{\mathbf{G},\hat{Z},b} \subseteq \breve{\mathcal{H}}^{wa}_{\mathbf{G},\hat{Z},b}.$$

Furthermore, we have $\breve{\mathcal{H}}^{a}_{\mathbf{G},\hat{Z},b}(L) = \breve{\mathcal{H}}^{wa}_{\mathbf{G},\hat{Z},b}(L)$ for all finite field extensions $L/\breve{E}$. If L is algebraically closed, weakly admissible does *not* imply admissible in general.

For an $\mathbb{F}[\![\zeta]\!]$-algebra B, complete and separated with respect to a bounded norm $|\cdot| : B \to [0,1] \subset \mathbb{R}$ with $0 < |\zeta| < 1$, we consider the $\mathbb{F}((z))$-algebra

$$B[\![z,z^{-1}\} = \{\sum_{i\in\mathbb{Z}} b_i z^i \mid b_i \in B, |b_i|\,|\zeta|^{ri} \to 0\ (i \to -\infty) \text{ for all } r > 0\}$$

and the element $t_- = \prod_{i\in\mathbb{N}_0}(1 - \frac{\zeta^{q^i}}{z}) \in B[\![z,z^{-1}\}$.

We want to define the *period morphism*

$$\breve{\pi} : \breve{\mathfrak{M}}^{\mathrm{an}} \to \breve{\mathcal{H}}^{a}_{\mathbf{G},\hat{Z},b}$$

as in Hartl and Viehmann [2017], 6 where $\mathfrak{M}$ is the Rapoport-Zink space associated with $\hat{Z}$ and b. Let S be an affinoid, strictly $\breve{E}$-analytic space and let $S \to \breve{\mathfrak{M}}^{\mathrm{an}}$ be a morphism of

$\breve{E}$-analytic spaces. With it we have to associate a morphism $S \to \breve{\mathcal{H}}^{\mathrm{an}}_{\mathbf{G},\hat{Z}}$. By construction of $\breve{\mathfrak{M}}^{\mathrm{an}}$ a morphism $S \to \breve{\mathfrak{M}}^{\mathrm{an}}$ is induced by a morphism from a quasi-compact admissible formal $\breve{R}_{\hat{Z}}$-scheme $\mathcal{S}$ with $\mathcal{S}^{\mathrm{an}} = S$ to $\breve{\mathfrak{M}}$. The latter corresponds to some $(\underline{\mathcal{G}}, \bar{\delta}) \in \breve{\mathfrak{M}}(\mathcal{S})$. After an étale covering $\mathcal{S}' = \mathrm{Spf}B' \to \mathcal{S}$ of admissible formal $\breve{R}_{\hat{Z}}$-schemes there is a trivialization $\alpha : \underline{\mathcal{G}}_{\mathcal{S}'} \cong ((L^+\mathbf{G})_{\mathcal{S}'}, A\sigma^*)$ for some $A \in \mathbf{G}(B'[\![z]\!][\frac{1}{z-\zeta}])$.

Denote by $\bar{\cdot}$ the reduction to $V(\zeta)$. Then the quasi-isogeny $\bar{\delta}$ induces via $\bar{\alpha}$ an element $\overline{\Delta} \in L\mathbf{G}(\overline{B}')$. One then shows that there is a uniquely determined element $\Delta \in \mathbf{G}(B'[\![z, z^{-1}\}[\frac{1}{t_-}])$ lifting $\overline{\Delta}$ with $\Delta A = b\sigma^*(\Delta)$ for A as above and b defining the Rapoport-Zink space. Consider the element

$$\gamma = \sigma^*(\Delta)A^{-1} \cdot \mathbf{G}(B'[\tfrac{1}{\zeta}][\![z-\zeta]\!]) \in \mathbf{G}(B'[\tfrac{1}{\zeta}](\!(z-\zeta)\!))/\mathbf{G}(B'[\tfrac{1}{\zeta}][\![z-\zeta]\!]).$$

The boundedness of $\underline{\mathcal{G}}$ then implies that γ factors through $\breve{\mathcal{H}}^{\mathrm{an}}_{\mathbf{G},\hat{Z}}$. It descends to a well-defined element of $\breve{\mathcal{H}}^{\mathrm{an}}_{\mathbf{G},\hat{Z}}(S)$ which is the image under the period morphism.

Proposition 7-2 (Hartl and Viehmann [2017], Prop. 6.9, 6.10)**.** *The period morphism factors through the open $\breve{E}$-analytic subspace $\breve{\mathcal{H}}^{a}_{G,\hat{Z},b}$ and induces an étale morphism*

$$\breve{\pi} : \breve{\mathfrak{M}}^{\mathrm{an}} \to \breve{\mathcal{H}}^{a}_{\mathbf{G},\hat{Z},b}.$$

To describe the image of $\breve{\pi}$ recall the tensor functors of (4-6) and (4-7). The construction of the σ-bundle $\underline{\mathcal{F}}_{b,\gamma}(V)$ of Definition 7-1 has a generalization to a σ-bundle $\underline{\mathcal{F}}_b(V)$ over $\breve{\mathcal{H}}_{G,\hat{Z}}$ with fibers $\underline{\mathcal{F}}_{b,\gamma}(V)$. It further induces a canonical local system $\underline{\mathcal{V}}_b(V)$ of $\mathbb{F}_q(\!(z)\!)$-vector spaces on $\breve{\mathcal{H}}^{a}_{G,\hat{Z},b}$ with $\underline{\mathcal{V}}_b(V)_{\bar{\gamma}} = \bar{\gamma}^*\underline{\mathcal{F}}_b(V)^{\tau}$ where we take invariants under the isomorphism τ defining the σ-bundle. Let $\omega_{b,\bar{\gamma}} : \mathrm{Rep}_{\mathbb{F}_q(\!(z)\!)}G \to \mathrm{FMod}_{\mathbb{F}_q(\!(z)\!)}$ be the fiber functor with $\omega_{b,\bar{\gamma}}(V) := \underline{\mathcal{V}}_b(V)_{\bar{\gamma}} = \bar{\gamma}^*\underline{\mathcal{F}}_b(V)^{\tau}$. Then, one of the main results of Hartl and Viehmann [ibid.] is the following description of the image of the period map. The condition that G be unramified can also be replaced by another, more technical, but possibly more general condition.

Theorem 7-3. *Assume that G is unramified.*

1. *The image $\breve{\pi}(\breve{\mathfrak{M}}^{\mathrm{an}})$ of the period morphism is equal to the union of those connected components of $\breve{\mathcal{H}}^{a}_{\mathbf{G},\hat{Z},b}$ on which there is an $\mathbb{F}_q(\!(z)\!)$-rational isomorphism $\beta : \omega^{\circ} \to \omega_{b,\bar{\gamma}}$.*

2. *The rational dual Tate module $\check{V}_{\underline{\mathcal{G}}}$ of the universal local $\mathbf{G}$-shtuka $\underline{\mathcal{G}}$ over $\breve{\mathfrak{M}}^{\mathrm{an}}$ descends to a tensor functor $\check{V}_{\underline{\mathcal{G}}}$ from $Rep_{\mathbb{F}_q(\!(z)\!)}G$ to the category of local systems of $\mathbb{F}_q(\!(z)\!)$-vector spaces on $\breve{\pi}(\breve{\mathfrak{M}}^{\mathrm{an}})$. It carries a canonical $J_b(\mathbb{F}_q(\!(z)\!))$-linearization and is canonically $J_b(\mathbb{F}_q(\!(z)\!))$-equivariantly isomorphic to the tensor functor $\underline{\mathcal{V}}_b$.*

3. *The tower of strictly $\breve{E}$-analytic spaces $(\breve{\mathfrak{M}}^K)_{K\subset \mathbf{G}(\mathbb{F}_q((z)))}$ is canonically isomorphic over $\breve{\pi}(\breve{\mathfrak{M}}^{\mathrm{an}})$ in a Hecke and $J_b(\mathbb{F}_q((z)))$-equivariant way to the tower of étale covering spaces of $\breve{\pi}(\breve{\mathfrak{M}}^{\mathrm{an}})$ that is naturally associated with the tensor functor $\underline{\mathcal{V}}_b$.*

HITCHIN TYPE MODULI STACKS IN AUTOMORPHIC REPRESENTATION THEORY

Zhiwei Yun (恽之玮)

Abstract

In the study of automorphic representations over a function field, Hitchin moduli stack and its variants naturally appear and their geometry helps the comparison of trace formulae. We give a survey on applications of this observation to a relative fundamental lemma, the arithmetic fundamental lemma and to the higher Gross-Zagier formula.

1 Introduction

1.1 Hitchin's original construction. In an influential paper by Hitchin [1987], he introduced the famous integrable system, the moduli space of Higgs bundles. Let X be a smooth proper and geometrically connected curve over a field k. Let G be a connected reductive group over k. Let $\mathcal{L}$ be a line bundle over X. An *$\mathcal{L}$-twisted G-Higgs bundle* over X is a pair $(\mathcal{E}, \varphi)$ where $\mathcal{E}$ is a principal G-bundle over X and φ is a global section of the vector bundle $\mathrm{Ad}(\mathcal{E}) \otimes \mathcal{L}$ over X. Here, $\mathrm{Ad}(\mathcal{E})$ is the vector bundle associated to $\mathcal{E}$ and the adjoint representation of G. The moduli stack $\mathcal{M}_{G,\mathcal{L}}$ of $\mathcal{L}$-twisted Higgs G-bundles over X is called the Hitchin moduli stack. Hitchin defined a map

$$f : \mathcal{M}_{G,\mathcal{L}} \to \mathcal{A}_{G,\mathcal{L}} \tag{1-1}$$

to some affine space $\mathcal{A}_{G,\mathcal{L}}$ by collecting invariants of φ such as its trace and determinant in the case $G = \mathrm{GL}_n$. The map f is called the *Hitchin fibration*. When $\mathcal{L} = \omega_X$ is the line bundle of 1-forms on X, Hitchin showed that f exhibited the stable part of $\mathcal{M}_{G,\omega_X}$ as a completely integrable system. He also gave concrete descriptions of the fibers of f in terms of spectral curves.

The works presented here have been supported by the NSF grants DMS-0969470/1302071/1736600 and the Packard Foundation.

1.2 Applications in geometric representation theory. Although discovered in the context of Yang-Mills theory, Hitchin moduli stacks have subsequently played important roles in the development of geometric representation theory.

When $\mathcal{L} = \omega_X$, $\mathfrak{M}_{G,\omega_X}$ is essentially the total space of the cotangent bundle of the moduli stack Bun_G of G-bundles over X. Therefore the categories of twisted D-modules on Bun_G give quantizations of $\mathfrak{M}_{G,\omega_X}$. Beilinson and Drinfeld studied such quantizations and used them to realize part of the geometric Langlands correspondence (namely when the $\widehat{G}$-connection comes from an oper). This can be viewed as a global analogue of the Beilinson-Bernstein localization theorem. A related construction in positive characteristic was initiated by Braverman and Bezrukavnikov [2007] for GL_n and extended to any G by Chen and Zhu [2017]. Hitchin's integrable system also plays a key role in the work of Kapustin and Witten [2007] which ties geometric Langlands correspondence to quantum field theory.

Hitchin moduli stacks have also been used to construct representations of the double affine Hecke algebra, giving global analogues of Springer representations. See Yun [2011a], Yun [2012] and Oblomkov and Yun [2016].

1.3 Applications in automorphic representation theory. Ngô [2006] made the fundamental observation that point-counting on Hitchin fibers is closely related to orbital integrals that appear in the study of automorphic representations. This observation, along with ingenious technical work, allowed Ngô to prove the Lie algebra version of the Fundamental Lemma conjectured by Langlands and Shelstad in the function field case, see Ngô [2010].

Group versions of the Hitchin moduli stack were introduced by Ngô using Vinberg semigroups. They are directly related to the Arthur-Selberg trace formula, as we will briefly review in Section 2.1. See recent works by Ngô [2014], Bouthier [2017] and Bouthier, Ngô, and Sakellaridis [2016] for applications of group versions of the Hitchin moduli stack.

1.4 Contents of this report. This report will focus on further applications of variants of Hitchin moduli stacks to automorphic representation theory.

In Section 2, we explain, in heuristic terms, why Hitchin-type moduli stacks naturally show up in the study of Arthur-Selberg trace formula and more generally, relative trace formulae. A relative trace formula calculates the L^2-pairing of two distributions on the space of automorphic forms of G given by two subgroups. Such pairings, when restricted to cuspidal automorphic representations, are often related to *special values* of automorphic L-functions. In Section 2.3, we will elaborate on the relative trace formulae introduced by Jacquet and Rallis, for which the fundamental lemma was proved in Yun [2011b].

In Section 3, we point out a new direction initiated in the works Yun [n.d.], Yun and Zhang [2017] and Yun and Zhang [n.d.]. Drinfeld introduced the moduli stack of Shtukas as an analogue of Shimura varieties for function fields, which turns out to allow richer variants than Shimura varieties. Cohomology classes of these moduli of Shtukas generalize the notion of automorphic forms. In Section 3.1 we review the basic definitions of Shtukas, and discuss the spectral decomposition for the cohomology of moduli of Shtukas. In Section 3.2, we introduce Heegner-Drinfeld cycles on the moduli of G-Shtukas coming from subgroups H of G. The relative trace in the context of Shtukas is then defined in Section 3.3 as the intersection pairing of two Heegner-Drinfeld cycles. We believe that such pairings, when restricted to the isotypical component of a cuspidal automorphic representation, are often related to *higher derivatives* of automorphic L-functions. We then explain why Hitchin-type moduli stacks continue to play a key role in the Shtuka context, and what new geometric ingredients are needed to study relative trace formulae in this setting.

In Section 3.4-Section 3.5 we survey what has been proven in this new direction. In Section 3.4, we review Yun and Zhang [2017] and Yun and Zhang [n.d.], in which we obtain formulae relating higher derivatives of automorphic L-functions for PGL_2 and the intersection numbers of Heegner-Drinfeld cycles. Our results generalize the Gross-Zagier formula in the function field case. In Section 3.5 we discuss the analogue of the fundamental lemma in the Shtuka setting. This was originally conjectured by W.Zhang under the name *arithmetic fundamental lemma*. We state an extension of his conjecture for function fields involving higher derivatives of orbital integrals, and sketch our strategy to prove it.

Acknowledgments. I would like to thank my mentors for bringing me to the exciting crossroads of algebraic geometry, representation theory and number theory. The influences of R. MacPherson, P. Deligne, G. Lusztig, B. Gross, B.C. Ngô and R. Bezrukavnikov on my career are especially important. I also learned a lot from my collaborators, colleagues and fellow students, to whom I would like to express my deep gratitude.

2 Hitchin moduli stack and trace formulae

Throughout this article we fix a finite field $k = \mathbb{F}_q$. Let X be a smooth, projective and geometrically connected curve over k of genus g. Let $F = k(X)$ be the function field of X. The places of F can be identified with the set $|X|$ of closed points of X. Let $\mathbb{A}$ denote the ring of adèles of F. For $x \in |X|$, let $\mathcal{O}_x$ be the completed local ring of X at x, and F_x (resp. k_x) be its fraction field (resp. residue field). We also use ϖ_x to denote a uniformizer of $\mathcal{O}_x$.

In this section we work with the classical notion of automorphic forms for groups over function fields. We shall briefly review the Arthur-Selberg trace formula and the relative trace formulae, and explain why Hitchin type moduli stacks naturally show up in the study of these trace formulae.

2.1 Arthur-Selberg trace formula. The Arthur-Selberg trace formula is an important tool in the theory of automorphic representations. For a detailed introduction to the theory over a number field we recommend Arthur's article Arthur [2005]. Here we focus on the function field case. The idea that Hitchin moduli stacks give a geometric interpretation of Arthur-Selberg trace formula is due to B.C. Ngô. For more details, we refer to Ngô [2006] for the Lie algebra version, and Frenkel and Ngô [2011] for the group version.

We ignore the issue of convergence in the discussion (i.e., we pretend to be working with an anisotropic group G), but we remark that the convergence issue lies at the heart of the theory of Arthur and we are just interpreting the easy part of his theory from a geometric perspective.

2.1.1 The classical setup. Let G be a split connected reductive group over k and we view it as a group scheme over X (hence over F) by base change. Automorphic forms for G are $\mathbb{C}$-valued smooth functions on the coset space $G(F)\backslash G(\mathbb{A})$. Fix a Haar measure μ_G on $G(\mathbb{A})$. Let $\mathfrak{A}$ be the space of automorphic forms for G. For any smooth compactly supported function f on $G(\mathbb{A})$, it acts on $\mathfrak{A}$ by right convolution $R(f)$.

The Arthur-Selberg trace formula aims to express the trace of $R(f)$ on $\mathfrak{A}$ in two different ways: one as a sum over conjugacy classes of $G(F)$ (the geometric expansion) and the other as a sum over automorphic representations (the spectral expansion). The primitive form of the geometric expansion reads

$$\mathrm{Tr}(R(f),\mathfrak{A})'' ='' \sum_{\gamma\in G(F)/\sim} J_\gamma(f) \tag{2-1}$$

where γ runs over $G(F)$-conjugacy classes in $G(F)$, and $J_\gamma(f)$ is the orbital integral

$$J_\gamma(f)=\mathrm{vol}(G_\gamma(F)\backslash G_\gamma(\mathbb{A}),\mu_{G_\gamma})\int_{G_\gamma(\mathbb{A})\backslash G(\mathbb{A})} f(g^{-1}\gamma g)\frac{\mu_G}{\mu_{G_\gamma}}(g)$$

where μ_{G_γ} is any Haar measure on the centralizer $G_\gamma(\mathbb{A})$ of γ. We write the equality sign in quotation marks [1] to indicate that the convergence issue has been ignored in (2-1). We will give a geometric interpretation of the geometric expansion.

[1] Later we will use the same notation (equal signs in quotation marks) to indicate heuristic identities.

Fix a compact open subgroup $K = \prod_{x\in|X|} K_x \subset G(\mathbb{A})$ and assume $\mathrm{vol}(K, \mu_G) = 1$. Let $\mathcal{Q}_K = C_c(G(F)\backslash G(\mathbb{A})/K)$ on which the Hecke algebra $C_c(K\backslash G(\mathbb{A})/K)$ acts. For $g \in G(\mathbb{A})$, there is a Hecke correspondence attached to the double coset $KgK \subset G(\mathbb{A})$

$$G(F)\backslash G(\mathbb{A})/K \xleftarrow{p_0} G(F)\backslash G(\mathbb{A})/(K \cap gKg^{-1}) \xrightarrow{q_0} G(F)\backslash G(\mathbb{A})/K \tag{2-2}$$

where p_0 is the natural projection and q_0 is induced by right multiplication by g. The action of $f = \mathbf{1}_{KgK}$ on $\mathcal{Q}_K$ is given by $\varphi \mapsto q_{0!}p_0^*\varphi$, where $q_{0!}$ means summing over the fibers of q_0. Upon ignoring convergence issues, the trace of $R(\mathbf{1}_{KgK})$ on $\mathcal{Q}_K$ is equal to the cardinality of the restriction of $G(F)\backslash G(\mathbb{A})/(K \cap gKg^{-1})$ to the diagonal $G(F)\backslash G(\mathbb{A})/K$ via the maps (p_0, q_0). In other words, we should form the pullback diagram of groupoids

$$\begin{array}{ccc} M_{G,KgK} & \longrightarrow & G(F)\backslash G(\mathbb{A})/(K \cap gKg^{-1}) \\ \downarrow & & \downarrow (p_0,q_0) \\ G(F)\backslash G(\mathbb{A})/K & \xrightarrow{\Delta} & G(F)\backslash G(\mathbb{A})/K \times G(F)\backslash G(\mathbb{A})/K \end{array} \tag{2-3}$$

and we have a heuristic identity

$$\mathrm{Tr}(R(\mathbf{1}_{KgK}), \mathcal{Q}_K)'' ='' \#M_{G,KgK}. \tag{2-4}$$

Here $\#\mathcal{X}$ of a groupoid $\mathcal{X}$ is a counting of isomorphism classes of objects in $\mathcal{X}$ weighted by the reciprocals of the sizes of automorphism groups.

2.1.2 Weil's interpretation. Let $K_0 = \prod_{x\in|X|} G(\mathcal{O}_x)$. It was observed by Weil that the double coset groupoid $G(F)\backslash G(\mathbb{A})/K_0$ is naturally isomorphic to the groupoid of G-bundles over X that are trivial at the generic point of X. In fact, starting from $g = (g_x) \in G(\mathbb{A})$, one assigns the G-bundle on X that is glued from the trivial bundles on the generic point $\mathrm{Spec}\, F$ and the formal disks $\mathrm{Spec}\, \mathcal{O}_x$ via the "transition matrices" g_x. For a compact open $K \subset K_0$, one can similarly interpret $G(F)\backslash G(\mathbb{A})/K$ as the groupoid of G-bundles with K-level structures. There is an algebraic stack $\mathrm{Bun}_{G,K}$ classifying G-bundles on X with K-level structures, and the above observation can be rephrased as a fully faithful embedding of groupoids

$$G(F)\backslash G(\mathbb{A})/K \hookrightarrow \mathrm{Bun}_{G,K}(k). \tag{2-5}$$

A priori, the groupoid $\mathrm{Bun}_{G,K}(k)$ contains also G-bundles that are not trivial at the generic point, or equivalently G'-bundles for certain inner forms G' of G. Since we assume G is split, the embedding (2-5) is in fact an equivalence.

In the same spirit, we interpret $G(F)\backslash G(\mathbb{A})/(K\cap gKg^{-1})$ as the groupoid of triples $(\mathcal{E},\mathcal{E}',\alpha)$ where $\mathcal{E},\mathcal{E}'$ are G-bundles with K-level structures on X, and $\alpha:\mathcal{E}\dashrightarrow\mathcal{E}'$ is a *rational* isomorphism between $\mathcal{E}$ and $\mathcal{E}'$ (i.e., an isomorphism of G-bundles over the generic point Spec F) such that the relative position of $\mathcal{E}$ and $\mathcal{E}'$ at each closed point $x\in|X|$ is given by the double coset $K_xg_xK_x$. For example, when $G=\mathrm{GL}_n$, $K_x=\mathrm{GL}_n(\mathcal{O}_x)$ and $g_x=\mathrm{diag}(\varpi_x,1,\cdots,1)$, then α has relative position $K_xg_xK_x$ at x if and only if α extends to a homomorphism $\alpha_x:\mathcal{E}|_{\mathrm{Spec}\,\mathcal{O}_x}\to\mathcal{E}'|_{\mathrm{Spec}\,\mathcal{O}_x}$, and that $\mathrm{coker}(\alpha_x)$ is one-dimensional over the residue field k_x. There is a moduli stack $\mathrm{Hk}_{G,KgK}$ classifying such triples $(\mathcal{E},\mathcal{E}',\alpha)$. The above discussion can be rephrased as an equivalence of groupoids

(2-6) $$\mathrm{Hk}_{G,KgK}(k)\cong G(F)\backslash G(\mathbb{A})/(K\cap gKg^{-1}).$$

Moreover, $\mathrm{Hk}_{G,KgK}$ is equipped with two maps to $\mathrm{Bun}_{G,K}$ by recording $\mathcal{E}$ and $\mathcal{E}'$, which allow us to view it as a self-correspondence of $\mathrm{Bun}_{G,K}$

(2-7) $$\mathrm{Bun}_{G,K}\xleftarrow{p}\mathrm{Hk}_{G,KgK}\xrightarrow{q}\mathrm{Bun}_{G,K}$$

Under the equivalences (2-5) and (2-6), the diagram (2-7) becomes the diagram (2-2) after taking k-points.

2.1.3 Geometric interpretation of the trace. Continuing further with Weil's observation, we can form the stack-theoretic version of (2-3), and define the stack $\mathfrak{M}_{G,KgK}$ by the Cartesian diagram

(2-8) $$\begin{array}{ccc}\mathfrak{M}_{G,KgK} & \longrightarrow & \mathrm{Hk}_{G,KgK}\\ \downarrow & & \downarrow{\scriptstyle(p,q)}\\ \mathrm{Bun}_{G,K} & \xrightarrow{\Delta} & \mathrm{Bun}_{G,K}\times\mathrm{Bun}_{G,K}\end{array}$$

so that $\mathfrak{M}_{G,KgK}(k)=M_{G,KgK}$.

By the defining Cartesian diagram (2-8), $\mathfrak{M}_{G,KgK}$ classifies pairs $(\mathcal{E},\varphi)$ where $\mathcal{E}$ is a G-bundle over X with K-level structures, and $\varphi:\mathcal{E}\dashrightarrow\mathcal{E}$ is a rational *automorphism* with relative position given by KgK.

Recall the classical Hitchin moduli stack $\mathfrak{M}_{G,\mathcal{L}}$ in Section 1.1. If we write $\mathcal{L}=\mathcal{O}_X(D)$ for some effective divisor D, $\mathfrak{M}_{G,\mathcal{L}}$ then classifies pairs $(\mathcal{E},\varphi)$ where $\mathcal{E}$ is a G-bundle over X and φ is a rational section of $\mathrm{Ad}(\mathcal{E})$ (an infinitesimal automorphism of $\mathcal{E}$) with poles controlled by D. Therefore $\mathfrak{M}_{G,\mathcal{L}}$ can be viewed as a Lie algebra version of $\mathfrak{M}_{G,KgK}$, and $\mathfrak{M}_{G,KgK}$ is a group version of $\mathfrak{M}_{G,\mathcal{L}}$.

Let $\mathfrak{C}_G$ be the GIT quotient of G by the conjugation action of G; $\mathfrak{C}_G(F)$ is the set of *stable conjugacy classes* in $G(F)$. There is an affine scheme $\mathfrak{B}_{G,KgK}$ classifying rational maps $X\dashrightarrow\mathfrak{C}_G$ with poles controlled by KgK. The Hitchin fibration (1-1) has an analogue

$$h_G : \mathfrak{M}_{G,KgK} \to \mathfrak{B}_{G,KgK}. \tag{2-9}$$

Using the map h_G, the counting of $M_{G,KgK}$, hence the trace of $R(\mathbf{1}_{KgK})$, can be decomposed into a sum over certain stable conjugacy classes a

$$\mathrm{Tr}(R(\mathbf{1}_{KgK}), \mathfrak{A}_K)'' ='' \sum_{a\in\mathfrak{B}_{G,KgK}(k)} \#\mathfrak{M}_{G,KgK}(a)(k). \tag{2-10}$$

Here $\mathfrak{M}_{G,KgK}(a)$ (a stack over k) is the fiber $h_G^{-1}(a)$. To tie back to the classical story, $\#\mathfrak{M}_{G,KgK}(a)(k)$ is in fact a sum of orbital integrals

$$\#\mathfrak{M}_{G,KgK}(a)(k) = \sum_{\gamma\in G(F)/\sim,[\gamma]=a} J_\gamma(\mathbf{1}_{KgK})$$

over $G(F)$-conjugacy classes γ that belong to the stable conjugacy class a.

By the Lefschetz trace formula, we can rewrite (2-10) as

$$\mathrm{Tr}(R(\mathbf{1}_{KgK}), \mathfrak{A}_K)'' ='' \sum_{a\in\mathfrak{B}_{G,KgK}(k)} \mathrm{Tr}(\mathrm{Frob}_a, (\mathbf{R}h_{G!}\mathbb{Q}_\ell)_a). \tag{2-11}$$

This formula relates the Arthur-Selberg trace to the direct image complex of the Hitchin fibration h_G (called the *Hitchin complex* for G). Although it is still difficult to get a closed formula for each term in (2-11), this geometric point of view can be powerful in comparing traces for two different groups G and H by relating their Hitchin bases and Hitchin complexes.

In the work of Ngô [2010], where the Lie algebra version was considered, the Hitchin complex was studied in depth using tools such as perverse sheaves and the decomposition theorem. When H is an endoscopic group of G, Ngô shows that the stable part of the Hitchin complex for H appears as a direct summand of the Hitchin complex for G, from which he deduces the Langlands-Shelstad fundamental lemma for Lie algebras over function fields.

2.2 Relative trace formulae.

2.2.1 Periods of automorphic forms. For simplicity we assume G is semisimple. Let $H \subset G$ be a subgroup defined over F, and μ_H a Haar measure on $H(\mathbb{A})$. For a cuspidal automorphic representation π of $G(\mathbb{A})$, the linear functional on π

$$\begin{aligned} \mathcal{P}^G_{H,\pi} : \pi &\to \mathbb{C} \\ \varphi &\mapsto \int_{H(F)\backslash H(\mathbb{A})} \varphi\mu_H \end{aligned} \tag{2-12}$$

is called the H-*period* of π. It factors through the space of coinvariants $\pi_{H(\mathbb{A})}$.

One can also consider variants where we integrate φ against an automorphic character χ of $H(\mathbb{A})$. If π has nonzero H-period, it is called H-distinguished. Distinguished representations are used to characterize important classes of automorphic representations such as those coming by functoriality from another group. In case the local coinvariants $(\pi_x)_{H(F_x)}$ are one-dimensional for almost all places x (as in the case for many spherical subgroups of G), one expects the period $\mathcal{P}^G_{H,\pi}$ to be related to special values of L-functions of π.

2.2.2 Example. Let $G = \mathrm{PGL}_2$ and $H = A$ be the diagonal torus. Then by Hecke's theory, for a suitably chosen $\varphi \in \pi$, $\int_{H(F)\backslash H(\mathbb{A})} \varphi(t)|t|^{s-1/2}dt$ gives the standard L-function $L(s,\pi)$.

2.2.3 Relative trace formulae. Now suppose H_1, H_2 are two subgroups of G. Let π be a cuspidal automorphic representation of $G(\mathbb{A})$ and $\widetilde{\pi}$ its contragradient. We get a bilinear form

$$\mathcal{P}^G_{H_1,\pi} \otimes \mathcal{P}^G_{H_2,\widetilde{\pi}} : \pi \otimes \widetilde{\pi} \to \mathbb{C}$$

In case the local coinvariants $(\pi_x)_{H_i(F_x)}$ are one-dimensional for all places x and $i = 1, 2$, the $H_1(\mathbb{A}) \times H_2(\mathbb{A})$ invariant bilinear forms on $\pi \times \widetilde{\pi}$ are unique up to scalar. Therefore $\mathcal{P}^G_{H_1,\pi} \otimes \mathcal{P}^G_{H_2,\widetilde{\pi}}$ is a multiple of the natural pairing on $\pi \times \widetilde{\pi}$ given by the Petersson inner product. This multiple is often related to special values of L-functions attached to π. For a systematic treatment of this topic, see Sakellaridis and Venkatesh [n.d.].

An important tool to study the pairing $\mathcal{P}^G_{H_1,\pi} \otimes \mathcal{P}^G_{H_2,\widetilde{\pi}}$ is the relative trace formula. We have natural maps of cosets

(2-13) $$H_1(F)\backslash H_1(\mathbb{A}) \xrightarrow{\varphi_1} G(F)\backslash G(\mathbb{A}) \xleftarrow{\varphi_2} H_2(F)\backslash H_2(\mathbb{A})$$

Consider the push-forward of the constant functions on $H_i(F)\backslash H_i(\mathbb{A})$ along φ_i, viewed as distributions on $G(F)\backslash G(\mathbb{A})$. Since we will only give a heuristic discussion of the relative trace formula, we will pretend that the L^2-pairing of two distributions makes sense. The relative trace of a test function $f \in C_c^\infty(G(\mathbb{A}))$ is the L^2-pairing

(2-14) $$\mathrm{RTr}^G_{H_1,H_2}(f) \text{''}=\text{''} \langle \varphi_{1,!}\mathbf{1}_{H_1(F)\backslash H_1(\mathbb{A})}, R(f)\varphi_{2,!}\mathbf{1}_{H_2(F)\backslash H_2(\mathbb{A})}\rangle_{L^2(G(F)\backslash G(\mathbb{A}),\mu_G)}$$

A variant of this construction is to replace the constant function 1 on $H_i(F)\backslash H_i(\mathbb{A})$ by an automorphic quasi-character χ_i of $H_i(\mathbb{A})$.

The relative trace formula is an equality between a spectral expansion of $\mathrm{RTr}^G_{H_1,H_2}(f)$ into quantities related to $\mathcal{P}^G_{H_1,\pi} \otimes \mathcal{P}^G_{H_2,\widetilde{\pi}}$ and a geometric expansion into a sum of orbital integrals $J^G_{H_1,H_2,\gamma}(f)$ indexed by double cosets $H_1(F)\gamma H_2(F) \subset G(F)$

(2-15)
$$J^G_{H_1,H_2,\gamma}(f) = \mathrm{vol}(H_\gamma(F)\backslash H_\gamma(\mathbb{A}), \mu_{H_\gamma}) \int_{H_\gamma(\mathbb{A})\backslash(H_1\times H_2)(\mathbb{A})} f(h_1^{-1}\gamma h_2)\frac{\mu_{H_1\times H_2}}{\mu_{H_\gamma}}(h_1,h_2)$$

where H_γ is the stabilizer of γ under the left-right translation on G by $H_1 \times H_2$.

Let $\mathfrak{C}^G_{H_1,H_2} = \mathrm{Spec}\ F[G]^{H_1\times H_2}$. We may call elements in $\mathfrak{C}^G_{H_1,H_2}(F)$ *stable orbits* of G under the action of $H_1 \times H_2$. There is a tautological map

$$\mathrm{inv} : H_1(F)\backslash G(F)/H_2(F) \to \mathfrak{C}^G_{H_1,H_2}(F).$$

We define

$$J^G_{H_1,H_2}(a, f) = \sum_{\gamma\in H_1(F)\backslash G(F)/H_2(F),\mathrm{inv}(\gamma)=a} J^G_{H_1,H_2,\gamma}(f). \tag{2-16}$$

Now we fix a compact open subgroup $K \subset G(\mathbb{A})$ and let $K_i = K\cap H_i(\mathbb{A})$ for $i = 1, 2$. Choose Haar measures on $H_i(\mathbb{A})$ and $G(\mathbb{A})$ so that K_i and K have volume 1. Consider the test function $f = \mathbf{1}_{KgK}$ as before. Unwinding the definition of the relative trace, we can rewrite (2-14) as

$$\mathrm{RTr}^G_{H_1,H_2}(\mathbf{1}_{KgK})'' ='' \#M^G_{H_1,H_2,KgK} \tag{2-17}$$

where $M^G_{H_1,H_2,KgK}$ is defined by the Cartesian diagram of groupoids

$$\begin{array}{ccc} M^G_{H_1,H_2,KgK} & \longrightarrow & G(F)\backslash G(\mathbb{A})/(K\cap gKg^{-1}) \\ \downarrow & & \downarrow{\scriptstyle (p_0,q_0)} \\ H_1(F)\backslash H_1(\mathbb{A})/K_1 \times H_2(F)\backslash H_2(\mathbb{A})/K_2 & \xrightarrow{(\varphi_1,\varphi_2)} & G(F)\backslash G(\mathbb{A})/K \times G(F)\backslash G(\mathbb{A})/K \end{array}$$

2.2.4 Geometric interpretation of the relative trace. Now we give a geometric interpretation of $M^G_{H_1,H_2,KgK}$. We assume H_1 and H_2 are also obtained by base change from split reductive groups over k, which we denote by the same notation. We have maps

$$\mathrm{Bun}_{H_1,K_1} \xrightarrow{\Phi_1} \mathrm{Bun}_{G,K} \xleftarrow{\Phi_2} \mathrm{Bun}_{H_2,K_2}.$$

Taking k-points of the above diagram we recover (2-13) up to modding out by the compact open subgroups K_i and K. We may form the Cartesian diagram of stacks

$$\begin{array}{ccc} \mathfrak{M}^G_{H_1,H_2,KgK} & \longrightarrow & \mathrm{Hk}_{G,KgK} \\ \downarrow & & \downarrow{\scriptstyle (p,q)} \\ \mathrm{Bun}_{H_1,K_1} \times \mathrm{Bun}_{H_2,K_2} & \xrightarrow{(\Phi_1,\Phi_2)} & \mathrm{Bun}_{G,K} \times \mathrm{Bun}_{G,K} \end{array}$$

We have $\mathfrak{M}^G_{H_1,H_2,KgK}(k) = M^G_{H_1,H_2,KgK}$.

2.2.5 Example. Consider the special case $G = G_1 \times G_1$ (G_1 is a semisimple group over k) and $H_1 = H_2$ is the diagonal copy of G_1, $K_1 = K_2$, $K = K_1 \times K_2$. Taking $g = (1, g_1)$ for some $g_1 \in G_1(\mathbb{A})$, we get a canonical isomorphism between the stacks $\mathfrak{M}^{G_1\times G_1}_{\Delta(G_1),\Delta(G_1),K(1,g_1)K}$ and $\mathfrak{M}_{G_1,K_1g_1K_1}$. In this case, the relative trace is the usual trace of $R(\mathbf{1}_{K_1g_1K_1})$ on the space of automorphic forms for G_1.

The moduli stack $\mathfrak{M}^G_{H_1,H_2,KgK}$ classifies $(\mathcal{E}_1, \mathcal{E}_2, \alpha)$ where $\mathcal{E}_i$ is an H_i-bundle with K_i-structure over X for $i = 1, 2$; α is a rational isomorphism between the G-bundles induced from $\mathcal{E}_1$ and $\mathcal{E}_2$, with relative position given by KgK.

One can construct a scheme $\mathfrak{B}^G_{H_1,H_2,KgK}$ classifying rational maps $X \dashrightarrow \mathfrak{C}^G_{H_1,H_2}$ with poles controlled by KgK, so that $\mathfrak{B}^G_{H_1,H_2,KgK}(k) \subset \mathfrak{C}^G_{H_1,H_2}(F)$. For $(\mathcal{E}_1, \mathcal{E}_2, \alpha) \in \mathfrak{M}^G_{H_1,H_2,KgK}$, we may restrict α to the generic point of X and take its invariants as a rational map $X \dashrightarrow \mathfrak{C}^G_{H_1,H_2}$. This way we get a map of algebraic stacks

$$h^G_{H_1,H_2} : \mathfrak{M}^G_{H_1,H_2,KgK} \to \mathfrak{B}^G_{H_1,H_2,KgK}. \tag{2-18}$$

In the situation of Example 2.2.5, $h^G_{H_1,H_2}$ specializes to the usual Hitchin map (2-9) for G_1, so we may think of $h^G_{H_1,H_2}$ as an analogue of the Hitchin map for the Hitchin-like moduli $\mathfrak{M}^G_{H_1,H_2,KgK}$. Taking k-points of (2-18) we get a map

$$M^G_{H_1,H_2,KgK} \to [H_1\backslash G/H_2](F) \xrightarrow{\text{inv}} \mathfrak{C}^G_{H_1,H_2}(F) \tag{2-19}$$

whose fiber over $a \in \mathfrak{C}^G_{H_1,H_2}(F)$ has cardinality equal to $J^G_{H_1,H_2}(a, \mathbf{1}_{KgK})$ defined in (2-16). We may thus decompose the relative trace into a sum of point-counting along the fibers of the map (2-19)

$$\begin{aligned} \mathrm{RTr}^G_{H_1,H_2}(\mathbf{1}_{KgK})'' =''& \sum_{a\in\mathfrak{C}^G_{H_1,H_2}(F)} J^G_{H_1,H_2}(a, \mathbf{1}_{KgK}) \\ =& \sum_{a\in\mathfrak{B}^G_{H_1,H_2,KgK}(k)} \mathrm{Tr}(\mathrm{Frob}_a, (\mathbf{R}h^G_{H_1,H_2,!}\mathbb{Q}_\ell)_a). \end{aligned} \tag{2-20}$$

The above formula relates the relative trace to the direct image complex $\mathbf{R}h^G_{H_1,H_2,!}\mathbb{Q}_\ell$. As in the case of the Arthur-Selberg trace formula, we may apply sheaf-theoretic tools to study this direct image complex, especially when it comes to comparing two such complexes.

2.2.6 Example. Consider the case $G = \mathrm{PGL}_2$, and $H_1 = H_2 = A \subset G$ is the diagonal torus. Let $K_1 = K_2 = \prod_x A(\mathcal{O}_x)$ and $K = \prod_x G(\mathcal{O}_x)$. Let $D = \sum_x n_x x$ be an effective divisor. Define the function h_D on $G(\mathbb{A})$ to be the characteristic function of $\mathrm{Mat}_2(\mathbb{O})_D = \{(g_x) | g_x \in \mathrm{Mat}_2(\mathcal{O}_x), v_x(\det g_x) = n_x, \forall x \in |X|\}$. Then $\mathrm{Mat}_2(\mathbb{O})_D$ is a finite union of K-double cosets Kg_iK. We will define a stack $\mathfrak{M}^G_{A,A,D}$ which turns out to be the union of the $\mathfrak{M}^G_{A,A,Kg_iK}$.

Consider the stack $\widetilde{\mathfrak{M}}^G_{A,A,D}$ classifying the data $(\mathcal{L}_1, \mathcal{L}_2, \mathcal{L}'_1, \mathcal{L}'_2, \varphi)$ where

- $\mathcal{L}_i$, $\mathcal{L}'_i$ are line bundles over X, for $i = 1, 2$;
- $\varphi : \mathcal{L}_1 \oplus \mathcal{L}_2 \to \mathcal{L}'_1 \oplus \mathcal{L}'_2$ is an injective map of coherent sheaves such that $\det(\varphi)$, viewed as a section of the line bundle $\mathcal{L}_1^{-1} \otimes \mathcal{L}_2^{-1} \otimes \mathcal{L}'_1 \otimes \mathcal{L}'_2$, has divisor D.

The Picard stack Pic_X acts on $\widetilde{\mathfrak{M}}^G_{A,A,D}$ by simultaneously tensoring on $\mathcal{L}_i$ and $\mathcal{L}'_i$. We define

$$\mathfrak{M}^G_{A,A,D} \cong \widetilde{\mathfrak{M}}^G_{A,A,D} / \mathrm{Pic}_X.$$

The bi-A-invariant regular functions on G are generated by $\begin{pmatrix} a & b \\ c & d \end{pmatrix} \mapsto \frac{bc}{ad-bc}$, therefore the space $\mathfrak{C}^G_{A,A}$ is isomorphic to $\mathbb{A}^1$. Define the Hitchin base $\mathfrak{B}^G_{A,A,D}$ to be the affine space $\mathrm{H}^0(X, \mathcal{O}_X(D))$.

To define the Hitchin map in this case, we write φ above as a matrix $\begin{pmatrix} \varphi_{11} & \varphi_{12} \\ \varphi_{21} & \varphi_{22} \end{pmatrix}$ where φ_{ij} is a section of $\mathcal{L}_j^{-1} \otimes \mathcal{L}'_i$. The determinant $\det(\varphi)$ gives an isomorphism $\mathcal{L}_1^{-1} \otimes \mathcal{L}_2^{-1} \otimes \mathcal{L}'_1 \otimes \mathcal{L}'_2 \cong \mathcal{O}_X(D)$. On the other hand, $\varphi_{12}\varphi_{21}$ gives another section of $\mathcal{L}_1^{-1} \otimes \mathcal{L}_2^{-1} \otimes \mathcal{L}'_1 \otimes \mathcal{L}'_2$. The Hitchin map

$$h^G_{A,A} : \mathfrak{M}^G_{A,A,D} \to \mathrm{H}^0(X, \mathcal{O}_X(D)) = \mathfrak{B}^G_{A,A,D}$$

then sends $(\mathcal{L}_1, \mathcal{L}_2, \mathcal{L}'_1, \mathcal{L}'_2, \varphi)$ to $\varphi_{12}\varphi_{21}$, viewed as a section of $\mathcal{O}_X(D)$ via the identification given by $\det(\varphi)$.

Although $\mathfrak{M}^G_{A,A,D}$ is not of finite type, it is the disjoint union of finite type substacks indexed by a subset of $\mathbb{Z}^4/\Delta(\mathbb{Z})$. Indeed, for $\underline{d} = (d_1, d_2, d'_1, d'_2) \in \mathbb{Z}^4/\Delta(\mathbb{Z})$ such that $d'_1 + d'_2 = d_1 + d_2 + \deg D$, the substack ${}^{\underline{d}}\mathfrak{M}^G_{A,A,D}$ where $\deg \mathcal{L}_i = d_i$ and $\deg \mathcal{L}'_i = d'_i$ is of finite type. We may write $\mathrm{RTr}^G_{A,A}(h_D)$ as a formal sum of

$${}^{\underline{d}}\mathrm{RTr}^G_{A,A}(h_D) = \#{}^{\underline{d}}\mathfrak{M}^G_{A,A,D}(k) = \mathrm{Tr}(\mathrm{Frob}, \mathrm{H}^*_c({}^{\underline{d}}\mathfrak{M}^G_{A,A,D} \otimes \overline{k}, \overline{\mathbb{Q}}_\ell)).$$

2.3 Relative fundamental lemma. In many cases we do not expect to prove closed formulae for relative traces of the form (2-14). Instead, for applications to problems on automorphic representations, it often suffices to establish an identity between relative traces for two different situations (G, H_1, H_2) and (G', H'_1, H'_2).

2.3.1 General format of RTF comparison. In order to establish such an identity, we need the following structures or results:

1. There should be an isomorphism between the spaces of invariants $\mathfrak{C}^G_{H_1,H_2} \cong \mathfrak{C}^{G'}_{H'_1,H'_2}$.

2. (fundamental lemma) For almost all $x \in |X|$, and

$$a_x \in \mathfrak{C}^G_{H_1,H_2}(F_x) \cong \mathfrak{C}^{G'}_{H'_1,H'_2}(F_x)$$

   we should have an identity of local orbital integrals up to a transfer factor

$$J^G_{H_1,H_2,x}(a_x, \mathbf{1}_{G(\mathcal{O}_x)}) \sim J^{G'}_{H'_1,H'_2,x}(a_x, \mathbf{1}_{G'(\mathcal{O}_x)}).$$

   Here $J^G_{H_1,H_2,x}(a_x, f_x)$ is the local analogue of $J^G_{H_1,H_2}(a, f)$ defined in (2-16).

3. (smooth matching) For any $x \in |X|$, $a_x \in \mathfrak{C}^G_{H_1,H_2}(F_x) \cong \mathfrak{C}^{G'}_{H'_1,H'_2}(F_x)$, and $f_x \in C^\infty_c(G(F_x))$, there exists $f'_x \in C^\infty_c(G'(F_x))$ such that $J^G_{H_1,H_2,x}(a_x, f_x) = J^{G'}_{H'_1,H'_2,x}(a_x, f'_x)$.

The geometric interpretation (2-20) of the relative trace gives a way to prove the fundamental lemma by comparing the direct image complexes of the Hitchin maps $h^G_{H_1,H_2}$ and $h^{G'}_{H'_1,H'_2}$. Below we discuss one such example.

2.3.2 The relative trace formulae of Jacquet and Rallis. 2011 proposed a relative trace formula approach to the Gan-Gross-Prasad conjecture for unitary groups. They considered two relative trace formulae, one involving general linear groups, and the other involving unitary groups. They formulated both the fundamental lemma and the smooth matching in this context as conjectures. In Yun [2011b], we used the geometric interpretation sketched in Section 2.2.4 to prove the fundamental lemma conjectured by Jacquet and Rallis, in the case of function fields. In the appendix to Yun [ibid.], J.Gordon used model theory to deduce the mixed characteristic case from the function field case. On the other hand, W. Zhang [2014] proved the smooth matching for the Jacquet-Rallis relative trace formula at non-archimedean places. Together with the fundamental lemma proved in Yun [2011b], W.Zhang deduced the Gan-Gross-Prasad conjecture for unitary groups under some local restrictions.

In the next two examples, we introduce the groups involved in the two trace formulae in Jacquet and Rallis [2011], and sketch the definition of the moduli stacks relevant to the orbital integrals. Since we proved the fundamental lemma by reducing to its Lie algebra analogue, our moduli stacks will be linearized versions of the Hitchin-type moduli stacks introduced in Section 2.2.4, which are closer to the classical Hitchin moduli stack.

2.3.3 Example. Let F'/F be a separable quadratic extension corresponding to a double cover $\nu : X' \to X$. Let $\sigma \in \mathrm{Gal}(F'/F)$ be the nontrivial involution. Consider $G = \mathrm{Res}_{F'/F}\mathrm{GL}_n \times \mathrm{Res}_{F'/F}\mathrm{GL}_{n-1}$, $H_1 = \mathrm{Res}_{F'/F}\mathrm{GL}_{n-1}$ and $H_2 = \mathrm{GL}_n \times \mathrm{GL}_{n-1}$ (over F). The embedding $H_1 \to G$ sends $h \in H_1$ to $(\begin{pmatrix} h & \\ & 1 \end{pmatrix}, h) \in G$.

The double quotient $H_1 \backslash G / H_2$ can be identified with $\mathrm{GL}_{n-1} \backslash \mathrm{S}_n$, where

$$\mathrm{S}_n = \{g \in \mathrm{Res}_{F'/F}\mathrm{GL}_n | \sigma(g) = g^{-1}\}$$

with GL_{n-1} acting by conjugation. The local orbital integral relevant to this relative trace formula is

(2-21)
$$J^{\mathrm{GL}}_{x,\gamma}(f) := \int_{\mathrm{GL}_{n-1}(F_x)} f(h^{-1}\gamma h)\eta_x(\det h)dh, \quad \gamma \in \mathrm{S}_n(F_x), f \in C_c^\infty(\mathrm{S}_n(F_x)).$$

Here η_x is the character $F_x^\times \to \{\pm 1\}$ attached to the quadratic extension F'_x/F_x.

The Lie algebra analogue of $\mathrm{GL}_{n-1}\backslash \mathrm{S}_n$ is $\mathrm{GL}_{n-1}\backslash(\mathfrak{gl}_n \otimes_F F'_-)$ where $F'_- = (F')^{\sigma=-1}$, and GL_{n-1} acts by conjugation. Let V_n be the standard representation of GL_n over F. It is more convenient to identify $\mathrm{GL}_{n-1}\backslash(\mathfrak{gl}_n \otimes_F F'_-)$ with

$$\mathrm{GL}_n \backslash \left(\mathrm{Hom}_F(V_n, V_n \otimes F'_-) \times (V_n \times V_n^*)^1\right),$$

where $(V_n \times V_n^*)^1$ consists of $(e, e^*) \in V_n \times V_n^*$ such that $e^*(e) = 1$, and GL_n is acting diagonally on all factors (conjugation on the first factor). The GIT quotient $\mathfrak{C}$ of $\mathrm{Hom}_F(V_n, V_n \otimes F'_-) \times (V_n \times V_n^*)^1$ by GL_n is an affine space of dimension $2n-1$. For $(\varphi, e, e^*) \in \mathrm{Hom}_F(V_n, V_n \otimes F'_-) \times (V_n \times V_n^*)^1$, we have invariants $a_i(\varphi) \in (F'_-)^{\otimes i}$ that records the i-th coefficient of the characteristic polynomial of φ ($1 \le i \le n$), and $b_i = e^*(\varphi^i e) \in (F'_-)^{\otimes i}$ for $1 \le i \le n-1$. The invariants $(a_1, \cdots, a_n, b_1, \cdots, b_{n-1})$ give coordinates for $\mathfrak{C}$.

We introduce the following moduli stack $\mathfrak{M}$ which serves as a global avatar for the Lie algebra version of the orbital integrals appearing in this relative trace formula. Fix line bundles $\mathfrak{L}$ and $\mathfrak{L}'$ on X. Let $\mathfrak{L}_- = \mathfrak{L} \otimes_{\mathcal{O}_X} \mathcal{O}_{X'}^{\sigma=-1}$. The stack $\mathfrak{M}$ classifies tuples $(\mathcal{E}, \varphi, s, s^*)$ where $\mathcal{E}$ is a vector bundle of rank n over X, $\varphi : \mathcal{E} \to \mathcal{E} \otimes \mathfrak{L}_-$, $s : \mathfrak{L}'^{-1} \to \mathcal{E}$ and $s^* : \mathcal{E} \to \mathfrak{L}'$ are $\mathcal{O}_X$-linear maps of coherent sheaves. The "Hitchin base" $\mathfrak{B}$ in this situation is the affine space $\prod_{i=1}^n \Gamma(X, \mathfrak{L}_-^{\otimes i}) \times \prod_{i=0}^{n-1} \Gamma(X, \mathfrak{L}'^{\otimes 2} \otimes \mathfrak{L}_-^{\otimes i})$. The Hitchin map $f : \mathfrak{M} \to \mathfrak{B}$ sends $(\mathcal{E}, \varphi, s, s^*)$ to the point of $\mathfrak{B}$ with coordinates $(a_1(\varphi), \cdots, a_n(\varphi), b_0, \cdots, b_{n-1})$, where $a_i(\varphi)$ are the coefficients of the characteristic polynomial of φ, and $b_i = s^* \circ \varphi^i \circ s : \mathfrak{L}'^{-1} \to \mathfrak{L}_-^{\otimes i} \otimes \mathfrak{L}'$.

2.3.4 Example. Let F'/F and $\nu : X' \to X$ be as in Example 2.3.3. Let W_{n-1} be a Hermitian vector space of dimension $n-1$ over F'. Let $W_n = W_{n-1} \oplus F'e_n$ with the

Hermitian form $(\cdot,\cdot)$ extending that on W_{n-1} and such that $W_{n-1} \perp e_n$, $(e_n, e_n) = 1$. Let U_n and U_{n-1} be the unitary groups over F attached to W_n and W_{n-1}. Consider $G' = \mathrm{U}_n \times \mathrm{U}_{n-1}$, and the subgroup $H'_1 = H'_2 = \mathrm{U}_{n-1}$ diagonally embedded into G'.

The double quotient $H'_1 \backslash G' / H'_2$ can be identified with the quotient $\mathrm{U}_{n-1} \backslash \mathrm{U}_n$ where U_{n-1} acts by conjugation. For $x \in |X|$, the local orbital integral relevant to this relative trace formula is

$$J^{\mathrm{U}}_{x,\delta}(f) = \int_{\mathrm{U}_{n-1}(F_x)} f(h^{-1}\delta h)dh, \quad \delta \in \mathrm{U}_n(F_x), f \in C_c^\infty(\mathrm{U}_n(F_x)).$$

The Lie algebra analogue of $\mathrm{U}_{n-1} \backslash \mathrm{U}_n$ is $\mathrm{U}_{n-1} \backslash \mathfrak{u}_n$, where $\mathfrak{u}_n$, the Lie algebra of U_n, consists of skew-self-adjoint endomorphisms of W_n. As in the case of Example 2.3.3, we identify $\mathrm{U}_{n-1} \backslash \mathfrak{u}_n$ with $\mathrm{U}_n \backslash \left(\mathfrak{u}_n \times W_n^1\right)$ where W_n^1 is the set of vectors $e \in W_n$ such that $(e, e) = 1$. The GIT quotient of $\mathfrak{u}_n \times W_n^1$ by U_n can be identified with the space $\mathfrak{C}$ introduced in Example 2.3.3. For $(\psi, e) \in \mathfrak{u}_n \times W_n^1$, its image in $\mathfrak{C}$ is $(a_1(\psi), \cdots, a_n(\psi), b_1, \cdots, b_{n-1})$ where $a_i(\psi) \in (F'_-)^{\otimes i}$ are the coefficients of the characteristic polynomial of ψ (as an endomorphism of W_n), and $b_i = (\psi^i e, e) \in (F'_-)^{\otimes i}$, since $\sigma(\psi^i e, e) = (e, \psi^i e) = (-1)^i(\psi^i e, e)$.

We introduce a moduli stack $\mathfrak{N}$ which serves as a global avatar for the Lie algebra version of the orbital integrals appearing in this relative trace formula. Fix line bundles $\mathfrak{L}$ and $\mathfrak{L}'$ on X. The stack $\mathfrak{N}$ classifies tuples $(\mathfrak{F}, h, \psi, t)$ where $\mathfrak{F}$ is a vector bundle of rank n on X', $h : \mathfrak{F} \xrightarrow{\sim} \sigma^*\mathfrak{F}^\vee$ is a Hermitian form on $\mathfrak{F}$, $\psi : \mathfrak{F} \to \mathfrak{F} \otimes \nu^*\mathfrak{L}$ is skew-self-adjoint with respect to h and $t : \nu^*\mathfrak{L}'^{-1} \to \mathfrak{F}$ is an $\mathcal{O}_{X'}$-linear map. When ν is unramified, the base $\mathfrak{B}$ introduced in Example 2.3.3 still serves as the Hitchin base for $\mathfrak{N}$. The Hitchin map $g : \mathfrak{N} \to \mathfrak{B}$ sends $(\mathfrak{F}, h, \psi, t)$ to $(a_1(\psi), \cdots, a_n(\psi), b_0, \cdots, b_{n-1})$, where $a_i(\psi)$ are the coefficients of the characteristic polynomial of ψ, and $b_i = t^\vee \circ h \circ \psi^i \circ t$ descends to an $\mathcal{O}_X$-linear map $\mathfrak{L}'^{-1} \to \mathfrak{L}_-^{\otimes i} \otimes \mathfrak{L}'$.

2.3.5 Theorem (Yun [2011b]). *Let x be a place of F such that F'/F is unramified over x and the Hermitian space $W_{n,x}$ has a self-dual lattices $\Lambda_{n,x}$. Then for strongly regular semisimple elements $\gamma \in \mathrm{S}_n(F_x)$ and $\delta \in \mathrm{U}_n(F_x)$ with the same invariants in $\mathfrak{C}(F_x)$, we have*

$$J^{\mathrm{GL}}_{x,\gamma}(\mathbf{1}_{\mathrm{S}_n(\mathcal{O}_x)}) = \pm J^{\mathrm{U}}_{x,\delta}(\mathbf{1}_{\mathrm{U}(\Lambda_{n,x})})$$

for some sign depending on the invariants of γ.

The main geometric observation in Yun [ibid.] is that both $f : \mathfrak{M} \to \mathfrak{B}$ and $g : \mathfrak{N} \to \mathfrak{B}$ are small maps when restricted to a certain open subset of $\mathfrak{B}$. This enables us to prove an isomorphism between the direct images complexes of f and g by checking over the generic point of $\mathfrak{B}$. Such an isomorphism of sheaves, after passing to the Frobenius traces on stalks, implies the identity above, which was the fundamental lemma conjectured by Jacquet and Rallis.

3 Hitchin moduli stack and Shtukas

In this section we consider automorphic objects that arise as cohomology classes of moduli stacks of Shtukas, which are the function-field counterpart of Shimura varieties. These cohomology classes generalize the notion of automorphic forms. The periods and relative traces have their natural analogues in this more general setting. Hitchin-type moduli stacks continue to play an important role in the study of such relative trace formulae. We give a survey of our recent work Yun and Zhang [2017],Yun and Zhang [n.d.] on higher Waldspurger-Gross-Zagier formulae and Yun [n.d.] on the arithmetic fundamental lemma, which fit into the framework to be discussed in this section.

3.1 Moduli of Shtukas. In his seminal paper, Drinfeld [1974] introduced the moduli of elliptic modules as a function field analogue of modular curves. Later, Drinfeld [1987] defined more general geometric object called Shtukas, and used them to prove the Langlands conjecture for GL_2 over function fields. Since then it became clear that the moduli stack of Shtukas should play the role of Shimura varieties for function fields, and its cohomology should realize the Langlands correspondence for global function fields. This idea was realized for GL_n by L. Lafforgue [2002] who proved the full Langlands conjecture in this case. For an arbitrary reductive group G, V. Lafforgue [2012] proved the automorphic to Galois direction of the Langlands conjecture using moduli stacks of Shtukas.

3.1.1 The moduli of Shtukas. The general definition of G-Shtukas was given by Varshavsky [2004]. For simplicity of presentation we assume G is split. Again we fix an open subgroup $K \subset K_0$, and let $N \subset |X|$ be the finite set of places where $K_x \neq G(\mathcal{O}_x)$. Choosing a maximal split torus T and a Borel subgroup B containing T, we may therefore talk about dominant coweights of T with respect to B. Let $r \geq 0$ be an integer. Let $\mu = (\mu_1, \cdots, \mu_r)$ be a sequence of dominant coweights of T. Recall dominant coweights of T are in bijection with relative positions of two G-bundles over the formal disk with the same generic fiber.

Let $\mathrm{Hk}^{\mu}_{G,K}$ be the Hecke stack classifying points $x_1, \cdots, x_r \in X - N$ together with a diagram of the form

$$\mathcal{E}_0 \overset{f_1}{\dashrightarrow} \mathcal{E}_1 \overset{f_2}{\dashrightarrow} \cdots \overset{f_r}{\dashrightarrow} \mathcal{E}_r$$

where $\mathcal{E}_i$ are G-bundles over X with K-level structures, and $f_i : \mathcal{E}_{i-1}|_{X-x_i} \xrightarrow{\sim} \mathcal{E}_i|_{X-x_i}$ is an isomorphism compatible with the level structures whose relative position at x_i is in the closure of that given by μ_i.

A *G-Shtuka of type μ with level K* is the same data as those classified by $\mathrm{Hk}^{\mu}_{G,K}$, together with an isomorphism of G-bundles compatible with K-level structures

$$\iota : \mathcal{E}_r \xrightarrow{\sim} {}^{\tau}\mathcal{E}_0. \tag{3-1}$$

Here, ${}^{\tau}\mathcal{E}_0$ is the image of $\mathcal{E}_0$ under the Frobenius morphism $\mathrm{Fr} : \mathrm{Bun}_{G,K} \to \mathrm{Bun}_{G,K}$. If we are talking about an S-family of G-Shtukas for some k-scheme S, $\mathcal{E}_0$ is a G-torsor over $X \times S$, then ${}^{\tau}\mathcal{E}_0 := (\mathrm{id}_X \times \mathrm{Fr}_S)^*\mathcal{E}_0$. There is a moduli stack $\mathrm{Sht}^{\mu}_{G,K}$ of G-Shtuka of type μ, which fits into a Cartesian diagram

$$\begin{array}{ccc} \mathrm{Sht}^{\mu}_{G,K} & \longrightarrow & \mathrm{Hk}^{\mu}_{G,K} \\ \downarrow & & \downarrow{\scriptstyle (p_0,p_r)} \\ \mathrm{Bun}_{G,K} & \xrightarrow{(\mathrm{id},\mathrm{Fr})} & \mathrm{Bun}_{G,K} \times \mathrm{Bun}_{G,K} \end{array} \tag{3-2}$$

Let us observe the similarity with the definition of the (group version of) Hitchin stack in diagram (2-8): the main difference is that we are replacing the diagonal map of $\mathrm{Bun}_{G,K}$ by the graph of the Frobenius.

Recording only the points $x_1, \cdots, x_r$ gives a morphism

$$\pi^{\mu}_{G,K} : \mathrm{Sht}^{\mu}_{G,K} \to (X - N)^r$$

The datum μ is called *admissible* if $\sum_i \mu_i$ lies in the coroot lattice. The existence of an isomorphism (3-1) forces μ to be admissible. Therefore $\mathrm{Sht}^{\mu}_{G,K}$ is nonempty only when μ is admissible. When $r = 0$, $\mathrm{Sht}^{\mu}_{G,K}$ is the discrete stack given by the double coset $\mathrm{Bun}_{G,K}(k) = G(F)\backslash G(\mathbb{A})/K$. For μ admissible, we have

$$d_G(\mu) := \dim \mathrm{Sht}^{\mu}_{G,K} = \sum_i (\langle 2\rho_G, \mu_i\rangle + 1).$$

3.1.2 Hecke symmetry. Let $g \in G(\mathbb{A})$ and let S be the finite set of $x \in |X| - N$ such that $g_x \notin G(\mathcal{O}_x)$. There is a self-correspondence $\mathrm{Sht}^{\mu}_{G,KgK}$ (the dependence on g is only through the double coset KgK) of $\mathrm{Sht}^{\mu}_{G,K}|_{(X-N-S)^r}$ such that both maps to $\mathrm{Sht}^{\mu}_{G,K}|_{(X-N-S)^r}$ are finite étale. It then induces an endomorphism of the direct image complex $\mathbf{R}\pi^{\mu}_{G,K,!}\mathrm{IC}(\mathrm{Sht}^{\mu}_{G,K})|_{(X-N-S)^r}$. V. Lafforgue [2012] used his construction of excursion operators to extend this endomorphism to the whole complex $\mathbf{R}\pi^{\mu}_{G,K,!}\mathrm{IC}(\mathrm{Sht}^{\mu}_{G,K})$ over $(X - N)^r$. If we assign this endomorphism to the function $\mathbf{1}_{KgK}$, it extends by linearity to an action of the Hecke algebra $C_c(K\backslash G(\mathbb{A})/K)$ on the complex $\mathbf{R}\pi^{\mu}_{G,K,!}\mathrm{IC}(\mathrm{Sht}^{\mu}_{G,K})$, and hence on its geometric stalks and on its cohomology groups.

3.1.3 Intersection cohomology of $\mathrm{Sht}^{\mu}_{G,K}$. The singularities of the map $\pi^{\mu}_{G,K}$ are exactly the same as the product of the Schubert varieties $\mathrm{Gr}_{G,\leq\mu_i}$ in the affine Grassmannian Gr_G. It is expected that the complex $\mathbf{R}\pi^{\mu}_{G,K,!}\mathrm{IC}(\mathrm{Sht}^{\mu}_{G,K})$ should realize the global Langlands correspondence for G in a way similar to the Eichler-Shimura correspondence for modular curves. The phenomenon of endoscopy makes stating a precise conjecture quite subtle, but a rough form of the expectation is a $C_c(K\backslash G(\mathbb{A})/K)$-equivariant decomposition over $(X-N)^r$

$$\mathbf{R}\pi^{\mu}_{G,K,!}\mathrm{IC}(\mathrm{Sht}^{\mu}_{G,K})'' ='' \left(\bigoplus_{\pi \text{ cuspidal}} \pi^K \otimes (\boxtimes_{i=1}^{r}\rho_{\pi}^{\mu_i}[1])\right)\bigoplus(\text{Eisenstein part}). \tag{3-3}$$

Here π runs over cuspidal automorphic representations of $G(\mathbb{A})$ such that $\pi^K \neq 0$, ρ_π is the $\widehat{G}$-local system on $X-N$ attached to π by the Langlands correspondence, and $\rho_\pi^{\mu_i}$ is the local system obtained by the composition

$$\pi_1(X-N,*) \xrightarrow{\rho_\pi} \widehat{G}(\overline{\mathbb{Q}}_\ell) \to \mathrm{GL}(V(\mu_i))$$

where $V(\mu_i)$ is the irreducible representation of the dual group $\widehat{G}$ with highest weight μ_i.

One approach to prove (3-3) is to use trace formulae. One the one hand, consider the action of a Hecke operator composed with a power of Frobenius at some $x \in |X|-N$ acting on the geometric stalk at x of the left side of (3-3), which is $\mathrm{IH}^*_c(\mathrm{Sht}^{\mu}_{G,K,\overline{x}})$. The trace of this action can be calculated by the Lefschetz trace formula, and can be expressed as a sum of twisted orbital integrals. On the other hand, the trace of the same operator on the right side of (3-3) can be calculated by the Arthur-Selberg trace formula, and be expressed using orbital integrals. The identity (3-3) would then follow from an identity between the twisted orbital integrals and the usual orbital integrals that appear in both trace formulae, known as the base-change fundamental lemma.

The difficulty in implementing this strategy is that $\mathrm{Sht}^{\mu}_{G,K}$ is not of finite type, and both the Lefschetz trace and the Arthur-Selberg trace would be divergent. L. Lafforgue [2002] treated the case $G=\mathrm{GL}_n$ and $\mu=((1,0,\cdots,0),(0,\cdots,0,-1))$ by difficult analysis of the compactification of truncations of $\mathrm{Sht}^{\mu}_{G,K}$, generalizing the work of Drinfeld on GL_2.

3.1.4 Cohomological spectral decomposition. We discuss a weaker version of the spectral decomposition (3-3). As mentioned above, $\mathrm{Sht}^{\mu}_{G,K}$ is not of finite type, so its intersection cohomology is not necessarily finite-dimensional. One can present $\mathrm{Sht}^{\mu}_{G,K}$ as an increasing union of finite-type open substacks, but these substacks are not preserved by the Hecke correspondences. Despite all that, we expect nice finiteness properties of $\mathrm{IH}^*_c(\mathrm{Sht}^{\mu}_{G,K}\otimes\overline{k})$ as a Hecke module. More precisely, the spherical Hecke algebra $C_c(K_0^N\backslash G(\mathbb{A}^N)/K_0^N,\overline{\mathbb{Q}}_\ell)$ (superscript N means removing places in N) should act through a quotient $\overline{\mathcal{H}}^N$ (possibly depending on μ) which is a finitely generated algebra over $\overline{\mathbb{Q}}_\ell$, and that $\mathrm{IH}^*_c(\mathrm{Sht}^\mu_{G,K}\otimes\overline{k})$ should be a finitely generated module over $\overline{\mathcal{H}}^N$. Now viewing $\mathrm{IH}^*_c(\mathrm{Sht}^\mu_{G,K}\otimes\overline{k})$ as a coherent sheaf on $\overline{\mathcal{H}}^N$, we should get a canonical decomposition of it in terms of connected components of $\overline{\mathcal{H}}^N$. A coarser decomposition should take the following form

$$\mathrm{IH}^*_c(\mathrm{Sht}^\mu_{G,K}\otimes\overline{k})=\bigoplus_{[P]}\mathrm{IH}^*_c(\mathrm{Sht}^\mu_{G,K}\otimes\overline{k})_{[P]} \tag{3-4}$$

where $[P]$ runs over associated classes of parabolic subgroups of G. The support of $\mathrm{IH}^*_c(\mathrm{Sht}^\mu_{G,K}\otimes\overline{k})_{[P]}$ should be described using the analogous quotient of the Hecke algebra $\overline{\mathcal{H}}^N_L$ for the Levi factor L of P, via the Satake transform from the spherical Hecke algebra for G to the one for L. If G is semisimple, the part $\mathrm{IH}^*_c(\mathrm{Sht}^\mu_{G,K}\otimes\overline{k},\overline{\mathbb{Q}}_\ell)_{[G]}$ should be finite-dimensional over $\overline{\mathbb{Q}}_\ell$.

In the simplest nontrivial case $G=\mathrm{PGL}_2$ we have proved the coarse decomposition.

3.1.5 Theorem (Yun and Zhang [2017],Yun and Zhang [n.d.]). *For $G=\mathrm{PGL}_2$, consider the moduli of Shtukas Sht^r_G without level structures of type $\mu=(\mu_1,\cdots,\mu_r)$ where each μ_i is the minuscule coweight. Then there is a decomposition of Hecke modules*

$$\mathrm{H}^{2r}_c(\mathrm{Sht}^r_G\otimes\overline{k})=(\oplus_\chi\mathrm{H}^{2r}_c(\mathrm{Sht}^r_G\otimes\overline{k})[\chi])\oplus\mathrm{H}^{2r}_c(\mathrm{Sht}^r_G\otimes\overline{k})_{\mathrm{Eis}}$$

where χ runs over a finite set of characters of the Hecke algebra $C_c(K_0\backslash G(\mathbb{A})/K_0)$, and the support of $\mathrm{H}^{2r}_c(\mathrm{Sht}^r_G\otimes\overline{k})_{\mathrm{Eis}}$ is defined by the Eisenstein ideal.

For $i\neq 2r$, $\mathrm{H}^i_c(\mathrm{Sht}^r_G\otimes\overline{k})$ is finite-dimensional.

Similar result holds for a version of Sht^r_G with Iwahori level structures.

We expect the similar techniques to work for general split G and general type μ.

Assume we have an analogue of the above theorem for G. Let π be a cuspidal automorphic representation of $G(\mathbb{A})$ such that $\pi^K\neq 0$, then $C_c(K^N_0\backslash G(\mathbb{A}^N)/K^N_0,\overline{\mathbb{Q}}_\ell)$ acts on π^K by a character χ_π up to semisimplification. Suppose χ_π does not appear in the support of $\mathrm{IH}^*_c(\mathrm{Sht}^\mu_G\otimes\overline{k})_{[P]}$ for any proper parabolic P (in which case we say χ_π is non-Eisenstein), then the generalized eigenspace $\mathrm{IH}^*_c(\mathrm{Sht}^\mu_{G,K}\otimes\overline{k})[\chi_\pi]$ is a finite-dimensional direct summand of $\mathrm{IH}^*_c(\mathrm{Sht}^\mu_{G,K}\otimes\overline{k})$ containing the contribution of π but possibly also companions of π with the same Hecke character χ_π away from N.

3.2 Heegner-Drinfeld cycles and periods. When $r=0$, the left side of (3-3) is simply the function space $C_c(G(F)\backslash G(\mathbb{A})/K)$ where cuspidal automorphic forms live. In general, we should think of cohomology classes in $\mathrm{IH}^*_c(\mathrm{Sht}^\mu_{G,K,\overline{x}})$ or $\mathrm{IH}^*_c(\mathrm{Sht}^\mu_{G,K}\otimes\overline{k})$

as generalizations of automorphic forms. We shall use this viewpoint to generalize some constructions in Section 2 from classical automorphic forms to cohomology classes of $\mathrm{Sht}^{\mu}_{G,K}$.

3.2.1 Heegner-Drinfeld cycles. Let $H \subset G$ be a subgroup defined over k with level group $K_H = K \cap H(\mathbb{A})$. It induces a map $\theta_{\mathrm{Bun}} : \mathrm{Bun}_{H,K_H} \to \mathrm{Bun}_{G,K}$.

Fix an integer $r \geq 0$. Let $\lambda = (\lambda_1, \cdots, \lambda_r)$ be an admissible sequence of dominant coweights of H; let $\mu = (\mu_1, \cdots, \mu_r)$ be an admissible sequence of dominant coweights of G. To relate $\mathrm{Sht}^{\lambda}_{H}$ to Sht^{μ}_{G}, we need to impose more restrictions on λ and μ. For two coweights μ, μ' of G we write $\mu \leq_G \mu'$ if for some (equivalently all) choices of a Borel $B' \subset G_{\overline{k}}$ and a maximal torus $T' \subset B'$, $\mu'_{B',T'} - \mu_{B',T'}$ is a sum of positive roots. Here $\mu_{B',T'}$ (resp. $\mu'_{B',T'}$) is the unique dominant coweight of T' conjugate to μ (resp. μ').

We assume that $\lambda_i \leq_G \mu_i$ for $0 \leq i \leq r$. In this case there is a natural morphism of Hecke stacks

$$\theta_{\mathrm{Hk}} : \mathrm{Hk}^{\lambda}_{H,K_H} \to \mathrm{Hk}^{\mu}_{G,K}$$

compatible with θ_{Bun}. The Cartesian diagram (3-2) and its counterpart for $\mathrm{Sht}^{\lambda}_{H}$ then induce a map over $(X-N)^r$

$$\theta : \mathrm{Sht}^{\lambda}_{H,K_H} \to \mathrm{Sht}^{\mu}_{G,K}.$$

If θ is proper, the image of the fundamental class of $\mathrm{Sht}^{\lambda}_{H,K_H}$ defines an algebraic cycle $\mathrm{Sht}^{\mu}_{G,K}$ which we call a *Heegner-Drinfeld cycle*.

3.2.2 Example. Consider the case $G = \mathrm{PGL}_2$, and $H = T$ is a non-split torus of the form $T = (\mathrm{Res}_{F'/F}\mathbb{G}_m)/\mathbb{G}_m$ for some quadratic extension F'/F. Since T is not a constant group scheme over X, our previous discussion does not directly apply, but we can easily define what a T-Shtuka is. The quadratic extension F' is the function field of a smooth projective curve X' with a degree two map $\nu : X' \to X$. Let $\lambda = (\lambda_1, \cdots, \lambda_r) \in \mathbb{Z}^r$ with $\sum_i \lambda_i = 0$, we may consider the moduli of rank one Shtukas $\mathrm{Sht}^{\lambda}_{\mathrm{GL}_1,X'}$ over X' of type λ. We define $\mathrm{Sht}^{\lambda}_{T}$ to be the quotient $\mathrm{Sht}^{\lambda}_{\mathrm{GL}_1,X'}/\mathrm{Pic}_X(k)$, where the discrete groupoid $\mathrm{Pic}_X(k)$ is acting by pulling back to X' and tensoring with rank one Shtukas. It can be shown that the projection $\mathrm{Sht}^{\lambda}_{T} \to X'^r$ is a finite étale Galois cover with Galois group $\mathrm{Pic}_{X'}(k)/\mathrm{Pic}_X(k)$. In particular, $\mathrm{Sht}^{\lambda}_{T}$ is a smooth and proper DM stack over k of dimension r.

Now let $\mu = (\mu_1, \cdots, \mu_r)$ be a sequence of dominant coweights of G. Then each μ_i can be identified with an element in $\mathbb{Z}_{\geq 0}$, with the positive coroot corresponding to 1. Admissibility of μ means that $\sum_i \mu_i$ is even. The condition $\lambda_i \leq_G \mu_i$ is saying that $|\lambda_i| \leq \mu_i$ and that $\mu_i - \lambda_i$ is even. When $\lambda_i \leq_G \mu_i$ for all i, the map $\theta : \mathrm{Sht}^{\lambda}_{T} \to$

Sht_G^μ simply takes a rank one Shtuka $(\{\mathcal{E}_i\};\{x'_i\})$ on X' and sends it to the direct image $(\{\nu_*\mathcal{E}_i\};\{\nu(x'_i)\})$, which is a rank two Shtuka on X.

3.2.3 Periods. Fix a Haar measure μ_H on $H(\mathbb{A})$. Under a purely root-theoretic condition on λ and μ, θ^* induces a map

$$\theta^* : \mathrm{IH}_c^{2d_H(\lambda)}(\mathrm{Sht}^\mu_{G,K}\otimes\overline{k}) \to \mathrm{H}_c^{2d_H(\lambda)}(\mathrm{Sht}^\lambda_{H,K_H}\otimes\overline{k}),$$

and therefore defines a period map

$$\mathcal{P}^{G,\mu}_{H,\lambda} : \mathrm{IH}_c^{2d_H(\lambda)}(\mathrm{Sht}^\mu_{G,K}\otimes\overline{k}) \xrightarrow{\theta^*} \mathrm{H}_c^{2d_H(\lambda)}(\mathrm{Sht}^\lambda_{H,K_H}\otimes\overline{k}) \xrightarrow{\cap[\mathrm{Sht}^\lambda_{H,K_H}]\cdot\mathrm{vol}(K_H,\mu_H)} \overline{\mathbb{Q}}_\ell.$$

The last map above is the cap product with the fundamental class of Sht^λ_H followed by multiplication by $\mathrm{vol}(K_H,\mu_H)$.

Now assume $\mathrm{Sht}^\lambda_{H,K_H}$ has half the dimension of $\mathrm{Sht}^\mu_{G,K}$,

$$d_G(\mu) = 2d_H(\lambda). \tag{3-5}$$

Let π be a cuspidal automorphic representation of $G(\mathbb{A})$. To make sense of periods on π, we assume for the moment that the contribution of π to the intersection cohomology of $\mathrm{Sht}^\mu_{G,K}$ is as predicted in (3-3). Restricting $\mathcal{P}^{G,\mu}_{H,\lambda}$ to the π-part we get

$$\pi^K\otimes(\otimes_{i=1}^r \mathrm{H}_c^1((X-N)\otimes\overline{k},\rho_\pi^{\mu_i})) \xrightarrow{\theta^*} \mathrm{H}_c^{2d_H(\lambda)}(\mathrm{Sht}^\lambda_{H,K_H}\otimes\overline{k}) \to \overline{\mathbb{Q}}_\ell.$$

As we expect $\rho_\pi^{\mu_i}$ to be pure, the above map should factor through the pure quotient of $\mathrm{H}_c^1((X-N)\otimes\overline{k},\rho_\pi^{\mu_i})$, which is $\mathrm{H}_c^1(X\otimes\overline{k}, j_{!*}\rho_\pi^{\mu_i})$ (the cohomology of the middle extension of $\rho_\pi^{\mu_i}$), and which does not change after enlarging N. Now shrinking K and passing to the direct limit, we get

$$\mathcal{P}^{G,\mu}_{H,\lambda,\pi} : \pi\otimes(\otimes_{i=1}^r \mathrm{H}^1(X\otimes\overline{k}, j_{!*}\rho_\pi^{\mu_i})) \to \overline{\mathbb{Q}}_\ell$$

which is the analogue of the classical period (2-12). Again $\mathcal{P}^{G,\mu}_{H,\lambda,\pi}$ should factor through the coinvariants $\pi_{H(\mathbb{A})}\otimes(\cdots)$.

3.3 Shtuka version of relative trace formula.

3.3.1 The setup. Let H_1 and H_2 be reductive subgroups of G over k. Fix an integer $r\geq 0$. Let $\lambda=(\lambda_1,\cdots,\lambda_r)$ (resp. κ and μ) be an admissible sequence of dominant coweights of H_1 (resp. H_2 and G). Assume that $\lambda_i \leq_G \mu_i$ and $\kappa_i \leq_G \mu_i$. In this case there are natural morphisms

$$\mathrm{Sht}^{\lambda}_{H_1} \xrightarrow{\theta_1} \mathrm{Sht}^{\mu}_{G} \xleftarrow{\theta_2} \mathrm{Sht}^{\kappa}_{H_2}$$

Suppose

$$\dim \mathrm{Sht}^{\lambda}_{H_1} = \dim \mathrm{Sht}^{\kappa}_{H_2} = \frac{1}{2} \dim \mathrm{Sht}^{\mu}_{G}.$$

With the same extra assumptions as in Section 3.2.3, we may define the periods $\mathcal{P}^{G,\mu}_{H_1,\lambda,\pi}$ and $\mathcal{P}^{G,\mu}_{H_2,\kappa,\widetilde{\pi}}$ (where $\widetilde{\pi}$ is the contragradient of π). We expect the tensor product

$$\mathcal{P}^{G,\mu}_{H_1,\lambda,\pi} \otimes \mathcal{P}^{G,\mu}_{H_2,\kappa,\widetilde{\pi}} : \pi \otimes \widetilde{\pi} \otimes \Big(\otimes_{i=1}^{r} \Big(\mathrm{H}^1(X \otimes \overline{k}, j_{!*}\rho^{\mu_i}_{\pi}) \otimes \mathrm{H}^1(X \otimes \overline{k}, j_{!*}\rho^{\mu_i}_{\widetilde{\pi}})\Big)\Big) \to \overline{\mathbb{Q}}_{\ell}$$

to factor through the pairing between $\mathrm{H}^1(X \otimes \overline{k}, j_{!*}\rho^{\mu_i}_{\pi})$ and $\mathrm{H}^1(X \otimes \overline{k}, j_{!*}\rho^{\mu_i}_{\widetilde{\pi}})$ given by the cup product (the local systems $\rho^{\mu_i}_{\widetilde{\pi}}$ and $\rho^{\mu_i}_{\pi}$ are dual to each other up to a Tate twist). Assuming this, we get a pairing

$$\mathcal{P}^{G,\mu}_{H_1,\lambda,\pi} \otimes \mathcal{P}^{G,\mu}_{H_2,\kappa,\widetilde{\pi}} : \pi_{H_1(\mathbb{A})} \otimes \widetilde{\pi}_{H_2(\mathbb{A})} \to \overline{\mathbb{Q}}_{\ell}.$$

When $\dim \pi_{H_1(\mathbb{A})} = \dim \widetilde{\pi}_{H_2(\mathbb{A})} = 1$, we expect the ratio between the above pairing and the Petersson inner product to be related to *derivatives* of L-functions of π, though I do not know how to formulate a precise conjecture in general.

3.3.2 The relative trace. One way to access $\mathcal{P}^{G,\mu}_{H_1,\lambda,\pi} \otimes \mathcal{P}^{G,\mu}_{H_2,\kappa,\widetilde{\pi}}$ is to develop a relative trace formula whose spectral expansion gives these periods. Fix a compact open subgroup $K \subset G(\mathbb{A})$ and let $K_i = H_i(\mathbb{A}) \cap K$. Assume θ_i are proper, we have Heegner-Drinfeld cycles

$$\mathcal{Z}^{\lambda}_{H_1} = \theta_{1*}[\mathrm{Sht}^{\lambda}_{H_1,K_1}], \quad \mathcal{Z}^{\kappa}_{H_2} = \theta_{2*}[\mathrm{Sht}^{\kappa}_{H_2,K_2}]$$

both of half dimension in $\mathrm{Sht}^{\mu}_{G,K}$. Intuitively we would like to form the intersection number

(3-6) $$I^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa)}(f) = \langle \mathcal{Z}^{\lambda}_{H_1}, f * \mathcal{Z}^{\kappa}_{H_2} \rangle_{\mathrm{Sht}^{\mu}_{G,K}}, \quad f \in C_c(K \backslash G(\mathbb{A})/K)$$

as the "relative trace" of f in this context. Here $f * (-)$ denotes the action of the Hecke algebra on the Chow group of $\mathrm{Sht}^{\mu}_{G,K}$, defined similarly as in Section 3.1.2. However, there are several technical issues before we can make sense of this intersection number.

1. $\mathrm{Sht}^{\mu}_{G,K}$ may not be smooth so the intersection product of cycles may not be defined.

2. Suppose the intersection of $\mathcal{Z}^{\lambda}_{H_1}$ and $\mathcal{Z}^{\kappa}_{H_2}$ is defined as a 0-cycle on $\mathrm{Sht}^{\mu}_{G,K}$, if we want to get a number out of this 0-cycle, we need it to be a proper cycle, i.e., it should lie in the Chow group of cycles with proper support (over k).

The first issue goes away if we assume each μ_i to be a minuscule coweight of G, which guarantees that $\mathrm{Sht}^{\mu}_{G,K}$ is smooth over $(X-N)^r$. The second issue is more serious and is analogous to the divergence issue for the usual relative trace. In results that we will present later, it won't be an issue because there $\mathcal{Z}^{\lambda}_{H_1,K_1}$ is itself a proper cycle. In the sequel we will proceed with heuristic arguments as we did in Section 2.2, and ignore these issues.

When λ, κ, μ are all zero, the linear functional $I^{(G,0)}_{(H_1,0),(H_2,0)}$ becomes the relative trace $\mathrm{RTr}^{G}_{H_1,H_2}$ defined in (2-14). Therefore the functional $I^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa)}$ is a generalization of the relative trace.

3.3.3 Intersection number in terms of Hitchin-like moduli stacks. In the case of the usual relative trace for $f = \mathbf{1}_{KgK}$, we introduced a Hitchin-like moduli stack $\mathfrak{M}^{G}_{H_1,H_2,KgK}$ whose point-counting is essentially the relative trace of f. We now try to do the same for $I^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa)}$. To simplify notations we assume $K = K_0 = \prod_x G(\mathcal{O}_x)$, hence $K_i = \prod H_i(\mathcal{O}_x)$, and suppress them from the notation for Shtukas.

To calculate the intersection number (3-6), a natural starting point is to form the stack-theoretic intersection of the cycles $\mathcal{Z}^{\lambda}_{H_1}$ and $f * \mathcal{Z}^{\kappa}_{H_2}$, i.e., consider the Cartesian diagram

$$\begin{array}{ccc} \mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0} & \longrightarrow & \mathrm{Sht}^{\mu}_{G,K_0gK_0} \\ \downarrow & & \downarrow \\ \mathrm{Sht}^{\lambda}_{H_1} \times \mathrm{Sht}^{\kappa}_{H_2} & \xrightarrow{\theta_1\times\theta_2} & \mathrm{Sht}^{\mu}_{G} \times \mathrm{Sht}^{\mu}_{G} \end{array} \tag{3-7}$$

The expected dimension of $\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0}$ is zero. If $\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0}$ indeed was zero-dimensional and moreover was proper over k, then $I^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa)}(\mathbf{1}_{K_0gK_0})$ would be equal to the length of $\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0}$. However, neither the zero-dimensionality nor the properness is true in general. Putting these issues aside, we proceed to rewrite $\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0}$ in Hitchin-like terms.

Recall we have Hecke correspondences Hk^{μ}_{G}, $\mathrm{Hk}^{\lambda}_{H_1}$ and $\mathrm{Hk}^{\kappa}_{H_2}$ for Bun_G, Bun_{H_1} and Bun_{H_2} related by the maps $\theta_{1,\mathrm{Hk}}$ and $\theta_{2,\mathrm{Hk}}$. We can also define a Hecke correspondence for Hk_{G,K_0gK_0} as the moduli stack classifying $x_1, \cdots, x_r \in X$ and a commutative diagram of rational isomorphisms of G-bundles over X

(3-8)
$$\begin{array}{ccccccc} \mathcal{E}_0 & \dashrightarrow & \mathcal{E}_1 & \dashrightarrow & \cdots & \dashrightarrow & \mathcal{E}_r \\ \downarrow{\scriptstyle \varphi_0} & & \downarrow{\scriptstyle \varphi_1} & & & & \downarrow{\scriptstyle \varphi_r} \\ \mathcal{E}'_0 & \dashrightarrow & \mathcal{E}'_1 & \dashrightarrow & \cdots & \dashrightarrow & \mathcal{E}'_r \end{array}$$

such that

1. The top and bottom rows of the diagram give objects in Hk^{μ}_{G} over $(x_1, \cdots, x_r) \in X^r$;
2. Each column of the diagram gives an object in Hk_{G,K_0gK_0}, i.e., the relative position of φ_i is given by K_0gK_0 for $0 \leq i \leq r$.

We denote the resulting moduli stack by $\mathrm{Hk}^{\mu}_{\mathrm{Hk},K_0gK_0}$. We have maps $\mathfrak{p}, \mathfrak{q} : \mathrm{Hk}^{\mu}_{\mathrm{Hk},K_0gK_0} \to \mathrm{Hk}^{\mu}_{G}$ by taking the top and the bottom rows; we also have maps $\mathfrak{p}_i : \mathrm{Hk}^{\mu}_{\mathrm{Hk},K_0gK_0} \to \mathrm{Hk}_{G,K_0gK_0}$ by taking the ith column. The Hecke correspondence $\mathrm{Sht}^{\mu}_{G,K_0gK_0}$ in Section 3.1.2 is defined as the pullback of $(\mathfrak{p}_0, \mathfrak{p}_r) : \mathrm{Hk}^{\mu}_{\mathrm{Hk},K_0gK_0} \to \mathrm{Hk}_{G,K_0gK_0} \times \mathrm{Hk}_{G,K_0gK_0}$ along the graph of the Frobenius morphism for Hk_{G,K_0gK_0}.

We then define $\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}$ using the Cartesian diagram

$$\begin{array}{ccc} \mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0} & \longrightarrow & \mathrm{Hk}^{\mu}_{\mathrm{Hk},K_0gK_0} \\ \downarrow & & \downarrow{\scriptstyle (\mathfrak{p},\mathfrak{q})} \\ \mathrm{Hk}^{\lambda}_{H_1} \times \mathrm{Hk}^{\kappa}_{H_2} & \xrightarrow{\theta_{1,\mathrm{Hk}} \times \theta_{2,Hk}} & \mathrm{Hk}^{\mu}_{G} \times \mathrm{Hk}^{\mu}_{G} \end{array}$$

Now $\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}$ can be viewed as an r-step Hecke correspondence for $\mathfrak{M}^{G}_{H_1,H_2,K_0gK_0}$. Indeed, $\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}$ classifies a diagram similar to (3-8), except that $\mathcal{E}_i$ (resp. $\mathcal{E}'_i$) are now induced from H_1-bundles $\mathcal{F}_i$ (resp. H_2-bundles $\mathcal{F}'_i$), and the top row (resp. bottom row) are induced from an object in $\mathrm{Hk}^{\lambda}_{H_1}$ (resp. $\mathrm{Hk}^{\kappa}_{H_2}$). Now each column in such a diagram gives an object in $\mathfrak{M}^{G}_{H_1,H_2,K_0gK_0}$. Recording the i-th column gives a map m_i : $\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0} \to \mathfrak{M}^{G}_{H_1,H_2,K_0gK_0}$. We claim that there is a Cartesian diagram expressing $\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0}$ as the "moduli of Shtukas for $\mathfrak{M}^{G}_{H_1,H_2,K_0gK_0}$ with modification type (λ,κ)":

(3-9)
$$\begin{array}{ccc} \mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0} & \longrightarrow & \mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0} \\ \downarrow & & \downarrow{\scriptstyle (m_0,m_r)} \\ \mathfrak{M}^G_{H_1,H_2,K_0gK_0} & \xrightarrow{(\mathrm{id},\mathrm{Fr})} & \mathfrak{M}^G_{H_1,H_2,K_0gK_0}\times\mathfrak{M}^G_{H_1,H_2,K_0gK_0} \end{array}$$

Indeed, this diagram is obtained by unfolding each corner of (3-7) as a fiber product of an r-step Hecke correspondence with the graph of Frobenius, and re-arranging the order of taking fiber products.

Continuing with the heuristics, the intersection number $I^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa)}(\mathbf{1}_{K_0gK_0})$, which "is" the length of $\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0}$, should also be the intersection number of $\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}$ with the graph of Frobenius for $\mathfrak{M}^G_{H_1,H_2,K_0gK_0}$. In other words, we are changing the order of intersection and leaving the "Shtuka-like" construction to the very last step. It is often true that $\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}$ has the same dimension as $\mathfrak{M}^G_{H_1,H_2,K_0gK_0}$, and the fundamental class of $\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}$ induces an endomorphism of the cohomology of $\mathfrak{M}^G_{H_1,H_2,K_0gK_0}$ which we denote by $[\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}]$. The Lefschetz trace formula then gives the following heuristic identity

(3-10)
$$I^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa)}(\mathbf{1}_{K_0gK_0})'' ='' \mathrm{Tr}([\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}]\circ\mathrm{Frob}, \mathrm{H}^*_c(\mathfrak{M}^G_{H_1,H_2,K_0gK_0}\otimes\overline{k},\mathbb{Q}_\ell)).$$

The equal sign above is in quotation marks for at least two reasons: both sides may diverge; change of the order of intersection needs to be justified.

Let $\mathfrak{B}^G_{H_1,H_2,K_0gK_0}$ be the Hitchin base and $h^G_{H_1,H_2}$ be the Hitchin map as in (2-18). Observe that for various $0\le i\le r$, the compositions $h^G_{H_1,H_2}\circ m_i : \mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}\to \mathfrak{B}^G_{H_1,H_2,K_0gK_0}$ are all the same. On the other hand, the Frobenius of $\mathfrak{M}^G_{H_1,H_2,K_0gK_0}$ covers the Frobenius of $\mathfrak{B}^G_{H_1,H_2,K_0gK_0}$. Therefore diagram (3-9) induces a map

$$\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0}\to\mathfrak{B}^G_{H_1,H_2,K_0gK_0}(k)$$

which simply says that $\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0}$ decomposes into a disjoint union

(3-11)
$$\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0}=\coprod_{a\in\mathfrak{B}^G_{H_1,H_2,K_0gK_0}(k)}\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa),K_0gK_0}(a).$$

The action of $[\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}]$ on the cohomology of $\mathfrak{M}^G_{H_1,H_2,K_0gK_0}$ can be localized to an action on the complex $\mathbf{R}h^G_{H_1,H_2,!}\mathbb{Q}_\ell$ using the formalism of cohomological correspondences. Then we may rewrite (3-10) as

$$I^{(G,\mu)}_{(H_1,\lambda),(H_2,\kappa)}(\mathbf{1}_{K_0gK_0})'' ='' \sum_a \mathrm{Tr}([\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}]_a \circ \mathrm{Frob}_a, (\mathbf{R}h^G_{H_1,H_2,!}\mathbb{Q}_\ell)_a), \tag{3-12}$$

where a runs over $\mathfrak{B}^G_{H_1,H_2,K_0gK_0}(k)$.

Comparing (3-12) with (2-20), we see the only difference is the insertion of the operator $[\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}]_a$ acting on the stalk $(\mathbf{R}h^G_{H_1,H_2,!}\mathbb{Q}_\ell)_a$.

3.3.4 Example. Suppose $G = \mathrm{PGL}_2$ and $H_1 = H_2 = T$ as in Example 3.2.2. Let $r \geq 0$ be even. We pick $\lambda, \kappa \in \{\pm 1\}^r$ with total sum zero, and form Sht^λ_T and Sht^κ_T. Let $\mu = (\mu_1, \cdots, \mu_r)$ consist of minuscule coweights of G. In this situation we have $\dim \mathrm{Sht}^\lambda_T = \dim \mathrm{Sht}^\kappa_T = r = \frac{1}{2}\dim \mathrm{Sht}^\mu_G$. Below we give more explicit descriptions of $\mathfrak{M}^G_{T,T,K_0gK_0}$ and $\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},K_0gK_0}$. For simplicity, we assume that the double cover $\nu : X' \to X$ is étale.

As in Example 2.2.6, it is more convenient to work with the test function h_D rather than $\mathbf{1}_{K_0gK_0}$, where D is an effective divisor on X. We denote the corresponding version of $\mathfrak{M}^G_{T,T,K_0gK_0}$ by $\mathfrak{M}^G_{T,T,D}$. To describe $\mathfrak{M}^G_{T,T,D}$, we first consider the moduli stack $\widetilde{\mathfrak{M}}^G_{T,T,D}$ classifying $(\mathcal{L}, \mathcal{L}', \varphi)$ where $\mathcal{L}$ and $\mathcal{L}'$ are line bundles over X', and $\varphi : \nu_*\mathcal{L} \to \nu_*\mathcal{L}'$ is an injective map of coherent sheaves such that $\det(\varphi)$ has divisor D. We then have $\mathfrak{M}^G_{T,T,D} = \widetilde{\mathfrak{M}}^G_{T,T,D}/\mathrm{Pic}_X$, where Pic_X acts by pulling back to X' and simultaneously tensoring with $\mathcal{L}$ and $\mathcal{L}'$.

It is more convenient to work with another description of $\mathfrak{M}^G_{T,T,D}$. The map $\varphi : \nu_*\mathcal{L} \to \nu_*\mathcal{L}'$ is equivalent to the data of two maps

$$\alpha : \mathcal{L} \to \mathcal{L}', \quad \beta : \sigma^*\mathcal{L} \to \mathcal{L}'$$

where σ is the nontrivial involution of X' over X. The determinant $\det(\varphi) = \mathrm{Nm}(\alpha) - \mathrm{Nm}(\beta)$, as sections of $\mathrm{Nm}(\mathcal{L})^{-1} \otimes \mathrm{Nm}(\mathcal{L}')$. Let $\mathfrak{M}^{G,\diamond}_{T,T,D} \subset \mathfrak{M}^G_{T,T,D}$ be the open subset where α and β are nonzero. By recording the divisors of α and β, we may alternatively describe $\mathfrak{M}^{G,\diamond}_{T,T,D}$ as the moduli of pairs (D_α, D_β) of effective divisors on X' of degree $d = \deg D$, such that there exists a rational function f on X (necessarily unique) satisfying $\mathrm{div}(f) = \nu(D_\alpha) - \nu(D_\beta)$ and $\mathrm{div}(1-f) = D - \nu(D_\beta)$.

The Hecke correspondence $\mathrm{Hk}^{\lambda,\kappa}_{\mathfrak{M},D}$ is the composition of r correspondences each of which is either $\mathcal{H}_+$ or $\mathcal{H}_-$ depending on whether $\lambda_i = \kappa_i$ or not. Over the open subset $\mathfrak{M}^{G,\diamond}_{T,T,D}$, $\mathcal{H}_+$ can be described as follows: it classifies triples of effective divisors $(D_\alpha, D_\beta, D'_\beta)$ on X' such that $(D_\alpha, D_\beta) \in \mathfrak{M}^{G,\diamond}_{T,T,D}$, and D'_β is obtained by changing one point of D_β by its image under σ. The two maps $p_+, q_+ : \mathcal{H}_+ \to \mathfrak{M}^{G,\diamond}_{T,T,D}$ send $(D_\alpha, D_\beta, D'_\beta)$ to (D_α, D_β) and (D_α, D'_β). Similarly, over $\mathfrak{M}^{G,\diamond}_{T,T,D}$, $\mathcal{H}_-$ classifies triples of effective divisors $(D_\alpha, D'_\alpha, D_\beta)$ on X' such that D'_α is obtained by changing one point of D_α by its image under σ.

3.4 Application to L-functions. In the work Yun and Zhang [2017], we considered the case $G = \mathrm{PGL}_2$ and the moduli of Shtukas Sht^r_G without level structures, where r stands for the r-tuple $\mu = (\mu_1, \cdots, \mu_r)$ consisting of minuscule coweights of G (so r is even). Let $\nu : X' \to X$ be an unramified double cover. The Heegner-Drinfeld cycle we considered was the one introduced in Example 3.2.2, i.e., Sht^λ_T for $\lambda \in \{\pm 1\}^r$. We consider the lifting of the natural map $\theta : \mathrm{Sht}^\lambda_T \to \mathrm{Sht}^r_G$

$$\theta' : \mathrm{Sht}^\lambda_T \to \mathrm{Sht}'^r_G := \mathrm{Sht}^r_G \times_{X^r} X'^r.$$

Since Sht^λ_T is proper of dimension r, the Heegner-Drinfeld cycle $\mathcal{Z}^\lambda_T := \theta'_*[\mathrm{Sht}^\lambda_T]$ is an r-dimensional proper cycle in the $2r$-dimensional Sht'^r_G. Therefore $\mathcal{Z}^\lambda_T$ defines a class $Z^\lambda_T \in \mathrm{H}^{2r}_c(\mathrm{Sht}'^r_G \otimes \overline{k}, \overline{\mathbb{Q}}_\ell)(r)$.

Now let π be an everywhere unramified cuspidal automorphic representation of $G(\mathbb{A})$ with coefficients in $\overline{\mathbb{Q}}_\ell$. By the coarse cohomological spectral decomposition for $\mathrm{H}^{2r}_c(\mathrm{Sht}'^r_G \otimes \overline{k}, \overline{\mathbb{Q}}$ (see Theorem 3.1.5), we may project Z^λ_T to the χ_π-isotypical summand, and denote the resulting class by $Z^\lambda_{T,\pi} \in \mathrm{H}^{2r}_c(\mathrm{Sht}'^r_G \otimes \overline{k}, \overline{\mathbb{Q}}_\ell)[\chi_\pi]$.

3.4.1 Theorem (Yun and Zhang [ibid.]). *We have*

$$\langle Z^\lambda_{T,\pi}, Z^\lambda_{T,\pi}\rangle_{\mathrm{Sht}'^r_G} = \frac{q^{2-2g}}{2(\log q)^r}\frac{\mathcal{L}^{(r)}(\pi_{F'}, 1/2)}{L(\pi, \mathrm{Ad}, 1)}$$

where

- $\langle Z^\lambda_{T,\pi}, Z^\lambda_{T,\pi}\rangle_{\mathrm{Sht}'^r_G}$ *is the self-intersection number of the cycle class* $Z^\lambda_{T,\pi}$.
- $\pi_{F'}$ *is the base change of* π *to* $F' = k(X')$.
- $\mathcal{L}(\pi_{F'}, s) = q^{4(g-1)(s-1/2)} L(\pi_{F'}, s)$ *is the normalized* L*-function of* $\pi_{F'}$ *such that* $\mathcal{L}(\pi_{F'}, s) = \mathcal{L}(\pi_{F'}, 1-s)$.

In Yun and Zhang [n.d.], we extended the above theorem to allow the automorphic representation π to have square-free level structures (which means the local representations π_v are either unramified or an unramified twist of the Steinberg representation), and to allow ramifications for the double cover $\nu : X' \to X$. We consider the moduli stack $\mathrm{Sht}^r_G(\Sigma; \Sigma_\infty)$ where Σ is a finite set of places where we add Iwahori level structures to the G-Shtukas; $\Sigma_\infty \subset \Sigma$ is a subset of places where we impose supersingular conditions. The admissibility condition forces r to have the same parity as $\#\Sigma_\infty$.

3.4.2 Theorem (Yun and Zhang [ibid.]). *Let π be a cuspidal automorphic representation of $G(\mathbb{A})$ with square-free level Σ. Assume the double cover $\nu : X' \to X$ is unramified over Σ. Let $\Sigma_\infty \subset \Sigma$ be the places that are inert in F'. Let $r \in \mathbb{Z}_{\geq 0}$ be of the same parity as $\#\Sigma_\infty$. Then for any $r_1, r_2 \in \mathbb{Z}_{\geq 0}$ such that $r_1 + r_2 = r$, there is an explicit linear combination $Z_T^{r_1,r_2}$ of the cycles $\{Z_T^\lambda; \lambda \in \{\pm 1\}^r\}$ such that*

$$\langle Z_{T,\pi}^{r_1,r_2}, Z_{T,\pi}^{r_1,r_2} \rangle_{\mathrm{Sht}_G'^r(\Sigma;\Sigma_\infty)} = \frac{q^{2-2g+\rho/2-N}}{2(-\log q)^r} \frac{\mathcal{L}^{(r_1)}(\pi, 1/2)\mathcal{L}^{(r_2)}(\pi \otimes \eta_{F'/F}, 1/2)}{L(\pi, \mathrm{Ad}, 1)}.$$

where

- $N = \deg \Sigma$*, and ρ is the degree of the ramification locus of ν.*
- $\mathcal{L}(\pi, s) = q^{(2g-2+N/2)(s-1/2)} L(\pi, s)$ *is the normalized L-function of π such that* $\mathcal{L}(\pi, s) = \mathcal{L}(\pi, 1-s)$.
- $\eta_{F'/F}$ *is the character of $F^\times \backslash \mathbb{A}^\times$ corresponding to the quadratic extension F'/F.*
- $\mathcal{L}(\pi \otimes \eta_{F'/F}, s) = q^{(2g-2+\rho+N/2)(s-1/2)} L(\pi \otimes \eta_{F'/F}, s)$ *is the normalized L-function of $\pi \otimes \eta_{F'/F}$ such that $\mathcal{L}(\pi \otimes \eta_{F'/F}, s) = \mathcal{L}(\pi \otimes \eta_{F'/F}, 1-s)$.*

When $r = 0$, the above theorem is a special case of the Waldspurger formula Waldspurger [1985], and our proof in this case is very close to the one in Jacquet [1986]. When $r = 1$ and $\#\Sigma_\infty = 1$, the above theorem is an analogue of the Gross-Zagier formula (see Gross and Zagier [1986]) which expresses the first derivative of the base-change L-function of a cuspidal Hecke eigenform in terms of the height of Heegner points on the modular curve. However our proof is very different from the original proof of the Gross-Zagier formula in that we do not need to explicitly compute either side of the formula.

3.4.3 Relation with the B-SD conjecture. Theorem 3.4.2 is applicable to those π coming from semistable elliptic curves E over the function field F. The relation of our result and the Birch–Swinnerton-Dyer conjecture for E can be roughly stated as follows. Take r to be the vanishing order of $L(E_{F'}, s) = L(\pi_{F'}, s-1/2)$ at $s = 1$. According to the expectation (3-3), $Z_{T,\pi}^\lambda$ is an element in $\pi^K \otimes \mathrm{H}^1(X' \otimes \overline{k}, j_{!*}\nu^*\rho_\pi)^{\otimes r}$. The 2-dimensional ℓ-adic Galois representation ρ_π attached to π is the Tate module of E, therefore $L(E_{F'}, s) = \det(1 - q^{-s}\mathrm{Frob}|\mathrm{H}^1(X' \otimes \overline{k}, j_{!*}\nu^*\rho_\pi))$. The standard conjecture predicts that the Frobenius acts semisimply on $\mathrm{H}^1(X' \otimes \overline{k}, j_{!*}\nu^*\rho_\pi)$, hence the multiplicity of the Frobenius eigenvalue q should be r. We expect $Z_{T,\pi}^\lambda$ to lie in $\pi^K \otimes \wedge^r(\mathrm{H}^1(X' \otimes \overline{k}, j_{!*}\nu^*\rho_\pi)^{\mathrm{Fr}=q})$, and giving a basis for this hypothetically 1-dimensional space. However, currently we do not have a way to construct rational points on E from the Heegner-Drinfeld cycle Sht_T^λ.

3.4.4 . The method to prove Theorems 3.4.1 is by comparing the Shtuka version of the relative trace $I^G_{T,T}(f) = \langle \mathcal{Z}^\lambda_T, f * \mathcal{Z}^\lambda_T \rangle_{\mathrm{Sht}'^r_G}$ as in (3-6) with the usual relative trace of the kind in Example 2.2.6. More precisely, for the triple (G, A, A) considered in Example 2.2.6, we consider the relative trace involving a complex variable s

$$\mathrm{RTr}^G_{A,(A,\eta)}(f,s) = \langle \varphi_! |\cdot|^s_{A(F)\backslash A(\mathbb{A})}, \varphi_!(\eta|\cdot|^s)_{A(F)\backslash A(\mathbb{A})} \rangle_{L^2(G(F)\backslash G(\mathbb{A}),\mu_G)}.$$

Here $|\cdot| : A(F)\backslash A(\mathbb{A}) = F^\times\backslash\mathbb{A}^\times \to q^{\mathbb{Z}}$ is the global absolute value function, and $\eta = \eta_{F'/F}$. Let $J_r(f)$ be the rth derivative of $\mathrm{RTr}^G_{A,(A,\eta)}(f,s)$ at $s = 0$. The key to the proof is to establish the following identity of relative traces for all spherical Hecke functions f

$$I^G_{T,T}(f) = (\log q)^{-r} J_r(f). \tag{3-13}$$

To prove this identity, it suffices to consider $f = h_D$ for effective divisors D on X (see Example 2.2.6). The moduli stacks $\mathfrak{M}^G_{A,A,D}$ in Example 2.2.6 and $\mathfrak{M}^G_{T,T,D}$ in Example 3.3.4 share the same Hitchin base $\mathcal{B}_D = \mathrm{H}^0(X, \mathcal{O}_X(D))$. We may fix a degree d and let D vary over effective divisors of degree d and get Hitchin maps $f_d : \mathfrak{M}^G_{A,A,d} \to \mathcal{B}_d$ and $g_d : \mathfrak{M}^G_{T,T,d} \to \mathcal{B}_d$. Formulae (2-20) and (3-12) suggest that we should try to prove an identity between the direct image complexes of f_d and g_d. The new geometric input here is the action of the Hecke correspondences $[\mathrm{Hk}^{\lambda,\lambda}_{\mathfrak{M}_d}]$ on the complex $\mathbf{R}g_{d!}\mathbb{Q}_\ell$, which is the r-th iteration of the action of the correspondence $[\mathcal{H}_+]$ defined in Example 3.3.4. It turns out that the eigenvalues of the action of $[\mathcal{H}_+]$ on $\mathbf{R}g_{d!}\mathbb{Q}_\ell$ match exactly with the factors coming from taking the derivative of the relative trace $\mathrm{RTr}^G_{A,(A,\eta)}(f,s)$, which explains why derivatives of automorphic quantities are indeed geometric.

3.5 Arithmetic fundamental lemma. Generalizing Theorems 3.4.1 and 3.4.2 to higher rank groups would involve intersecting non-proper cycles in an ambient stack which is not of finite type. This is the same issue as the non-convergence of the naive relative trace (2-14), therefore a certain truncation and regularization procedure is needed. There is, however, a local version of such results that can be proved for higher rank groups. One example of such a local version is the Arithmetic Fundamental Lemma formulated by W. Zhang [2012] originally for Rapoport-Zink spaces. In Yun [n.d.], we stated a higher derivative extension of W.Zhang's conjecture in the function field case, and sketched a proof. This was the first time higher derivatives of automorphic quantities were related to geometry, and it partially motivated the later work Yun and Zhang [2017].

3.5.1 Local Shtukas. The moduli of Shtukas has a local version. Fix a local function field F_x with ring of integers $\mathcal{O}_x$. In the diagram (3-2) defining the moduli of Shtukas, we may replace Bun_G by the affine Grassmannian Gr_G, and replace Hk_G^μ by an iterated Hecke correspondence for Gr_G over a formal disk $\Delta_r = \mathrm{Spf}(\mathcal{O}_x \widehat{\otimes} \cdots \widehat{\otimes} \mathcal{O}_x)$ of dimension r. We also have the freedom of changing the Frobenius morphism on Gr_G by the composition $b \circ \mathrm{Fr} : \mathrm{Gr}_G \to \mathrm{Gr}_G$, where b is an element of the loop group of G giving the datum of a G-isocrystal. The resulting object ${}^b\mathrm{Sht}_G^{\mu,\mathrm{loc}}$ by forming the Cartesian square as (3-2) is called the moduli space of local Shtukas, and it is a formal scheme over Δ_r. The special fiber of ${}^b\mathrm{Sht}_G^{\mu,\mathrm{loc}}$ is an iterated version of the affine Deligne-Lusztig variety. The twisted centralizer G_b of b is an inner form of a Levi subgroup of G, and $G_b(F_x)$ acts on ${}^b\mathrm{Sht}_G^{\mu,\mathrm{loc}}$.

For a subgroup $H \subset G$ with a sequence of coweights $\lambda = (\lambda_1, \cdots, \lambda_r)$ such that $\lambda_i \leq_G \mu_i$ for all i and an H-isocrystal b_H compatible with b, we have a morphism $\theta^{\mathrm{loc}} : {}^{b_H}\mathrm{Sht}_H^{\lambda,\mathrm{loc}} \to {}^b\mathrm{Sht}_G^{\mu,\mathrm{loc}}$ over Δ_r. This morphism is a closed embedding because $\mathrm{Gr}_H \to \mathrm{Gr}_G$ is. We define the local Heegner-Drinfeld cycle ${}^{b_H}\mathcal{Z}_H^{\lambda,\mathrm{loc}}$ as the image of θ^{loc}.

If we have two local Heegner-Drinfeld cycles ${}^{b_1}\mathcal{Z}_{H_1}^{\lambda,\mathrm{loc}}$ and ${}^{b_2}\mathcal{Z}_{H_2}^{\kappa,\mathrm{loc}}$ in ${}^b\mathrm{Sht}_G^{\mu,\mathrm{loc}}$ with complementary dimensions, and if μ_i are minuscule and the reduced structure of their intersection is proper over k, we may ask for their intersection number in ${}^b\mathrm{Sht}_G^{\mu,\mathrm{loc}}$. More generally, if $\delta \in G_b(F_x)$, we may consider the intersection number

$$I_\delta = \langle {}^{b_1}\mathcal{Z}_{H_1}^{\lambda,\mathrm{loc}}, \delta \cdot {}^{b_2}\mathcal{Z}_{H_2}^{\kappa,\mathrm{loc}} \rangle_{{}^b\mathrm{Sht}_G^{\mu,\mathrm{loc}}}$$

using the action of $G_b(F_x)$ on ${}^b\mathrm{Sht}_G^{\mu,\mathrm{loc}}$. When $\mu = 0$, this is the same as the local orbital integral $J^G_{H_1,H_2,\delta}(\mathbf{1}_{G(\mathcal{O}_x)})$ (see (2-15)) for the relative trace formula of the triple (G, H_1, H_2).

3.5.2 Example. Let F'_x/F_x be an unramified quadratic extension, with ring of integers $\mathcal{O}'_x$ and residue field k'_x. Fix a Hermitian vector space $W_{n,x}$ of dimension n over x, and let U_n be the unitary group of $W_{n,x}$. We define the moduli of local Shtukas $\mathrm{Sht}_{\mathrm{U}_n}^{r,\mathrm{loc}}$ over $\Delta'_r = \mathrm{Spf}(\mathcal{O}'_x \widehat{\otimes}_{k'_x} \cdots \widehat{\otimes}_{k'_x} \mathcal{O}'_x)$ in the following way. Let $\mathrm{Gr}_{\mathrm{U}_n}$ be the affine Grassmannian classifying self-dual lattices in $W_{n,x}$. Since U_n is split over F'_x, the base change $\mathrm{Gr}_{\mathrm{U}_n} \otimes_{k_x} k'_x$ can be identified with the affine Grassmannian $\mathrm{Gr}_{\mathrm{GL}_n} \otimes_{k_x} k'_x$ classifying $\mathcal{O}'_x$-lattices in $W_{n,x}$. We have the local Hecke correspondence $\mathrm{Hk}_{\mathrm{U}_n}^{\mathrm{loc}}$ over Δ'_1 which, after identifying $\mathrm{Gr}_{\mathrm{U}_n} \otimes_{k_x} k'_x$ with $\mathrm{Gr}_{\mathrm{GL}_n} \otimes_{k_x} k'_x$, corresponds to the upper modification of lattices in $W_{n,x}$ of colength one. Let $\mathrm{Hk}_{\mathrm{U}_n}^{r,\mathrm{loc}}$ be the r-fold composition of $\mathrm{Hk}_{\mathrm{U}_n}^{\mathrm{loc}}$ as a correspondence, so $\mathrm{Hk}_{\mathrm{U}_n}^{r,\mathrm{loc}} \to \Delta'_r$. Then $\mathrm{Sht}_{\mathrm{U}_n}^{r,\mathrm{loc}}$ is defined using the Cartesian diagram

$$\begin{array}{ccc} \mathrm{Sht}_{\mathrm{U}_n}^{r,\mathrm{loc}} & \longrightarrow & \mathrm{Hk}_{\mathrm{U}_n}^{r,\mathrm{loc}} \\ \downarrow & & \downarrow \\ \mathrm{Gr}_{\mathrm{U}_n} & \xrightarrow{(\mathrm{id},\mathrm{Fr})} & \mathrm{Gr}_{\mathrm{U}_n} \times \mathrm{Gr}_{\mathrm{U}_n} \end{array}$$

The group $\mathrm{U}_n(F_x)$ acts on $\mathrm{Sht}^{r,\mathrm{loc}}_{\mathrm{U}_n}$. We remark that $\mathrm{Sht}^{r,\mathrm{loc}}_{\mathrm{U}_n}$ is formally smooth over Δ'_r of relative dimension $r(n-1)$.

Now suppose we are in the situation of Example 2.3.4 so we have an orthogonal decomposition $W_{n,x} = W_{n-1,x} \oplus F'_x e_n$ and $(e_n, e_n) = 1$. Adding a standard lattice $\mathcal{O}'_x e_n$ gives an embedding $\mathrm{Gr}_{\mathrm{U}_{n-1}} \hookrightarrow \mathrm{Gr}_{\mathrm{U}_n}$ compatible with the Hecke modifications, hence induces an embedding $\mathrm{Sht}^{r,\mathrm{loc}}_{\mathrm{U}_{n-1}} \hookrightarrow \mathrm{Sht}^{r,\mathrm{loc}}_{\mathrm{U}_n}$. Consider the diagonal map

$$\Delta : \mathrm{Sht}^{r,\mathrm{loc}}_{\mathrm{U}_{n-1}} \to \mathrm{Sht}^{r,\mathrm{loc}}_{\mathrm{U}_{n-1}} \times_{\Delta'_r} \mathrm{Sht}^{r,\mathrm{loc}}_{\mathrm{U}_n}.$$

The image of Δ gives an $r(n-1)$-dimensional cycle $\mathcal{Z}^{r,\mathrm{loc}}_x$ in the $2r(n-1)$-dimensional ambient space $\mathrm{Sht}^{r,\mathrm{loc}}_{\mathrm{U}_{n-1}} \times_{\Delta'_r} \mathrm{Sht}^{r,\mathrm{loc}}_{\mathrm{U}_n}$. For strongly regular semisimple $\delta \in \mathrm{U}_n(F_x)$ (with respect to the conjugation action by U_{n-1}) we form the intersection number

$$I^{\mathrm{U},r}_{x,\delta} = \langle \mathcal{Z}^{r,\mathrm{loc}}_x, (\mathrm{id} \times \delta)\mathcal{Z}^{r,\mathrm{loc}}_x \rangle_{\mathrm{Sht}^{r,\mathrm{loc}}_{\mathrm{U}_{n-1}} \times_{\Delta'_r} \mathrm{Sht}^{r,\mathrm{loc}}_{\mathrm{U}_n}}.$$

This makes sense because the support of the intersection of the two cycles $\mathcal{Z}^{r,\mathrm{loc}}_x$ and $(\mathrm{id} \times \delta)\mathcal{Z}^{r,\mathrm{loc}}_x$ is proper. When $r = 0$, we have $I^{\mathrm{U},r}_{x,\delta}$ is either equal to $J^{\mathrm{U}}_{x,\delta}(\mathbf{1}_{\mathrm{U}(\Lambda_{n,x})})$ as in Example 2.3.4 if a self-dual lattice $\Lambda_{n,x} \subset W_{n,x}$ exists, or 0 otherwise.

To state the higher arithmetic fundamental lemma, we introduce a variant of the orbital integral (2-21) with a complex variable s

$$J^{\mathrm{GL}}_{x,\gamma}(f, s) = \int_{\mathrm{GL}_{n-1}(F_x)} f(h^{-1}\gamma h)\eta_x(\det h)|\det h|^s dh, \; \gamma \in \mathrm{S}_n(F_x), f \in C^\infty_c(\mathrm{S}_n(F_x)).$$

For γ strongly regular semisimple, $J^{\mathrm{GL}}_{x,\gamma}(f, s)$ is a Laurent polynomial in q_x^s, where $q_x = \#k_x$. Let

$$J^{\mathrm{GL},r}_{x,\gamma}(f) = \left(\frac{d}{ds}\right)^r |_{s=0} J^{\mathrm{GL}}_{x,\gamma}(f, s).$$

3.5.3 Theorem (Yun [n.d.]). *Let $\gamma \in \mathrm{GL}_n(F_x)$ and $\delta \in \mathrm{U}_n(F_x)$ be strongly regular semisimple with the same invariants in the sense of Example 2.3.3 and Example 2.3.4. Then*

$$I^{\mathrm{U},r}_{x,\delta} = c(\log q_x)^{-r} J^{\mathrm{GL},r}_{x,\gamma}(\mathbf{1}_{\mathrm{S}_n(\mathcal{O}_x)}) \tag{3-14}$$

with an explicit constant c depending on r and the invariants of γ.

The proof consists of the following main steps.

1. Prove a global analogue of (3-14). Consider the triple (G, H_1, H_2) as in Example 2.3.4 with coweights μ for G and λ for $H_1 = H_2$ being the first fundamental coweights. Let the triple (G', H'_1, H'_2) be as in Example 2.3.3. Recall that for

the global situation, the intersection number $I^{(G,\mu)}_{(H_1,\lambda),(H_2,\lambda)}(\mathbf{1}_{K_0 g K_0})$ is the degree of a certain 0-cycle on $\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\lambda),K_0 g K_0}$ introduced in the diagram (3-7). On the other hand, we have a decomposition (3-11) of $\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\lambda),K_0 g K_0}$ into a disjoint union of $\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\lambda),K_0 g K_0}(a)$ indexed by k-points of the base $\mathcal{B}^G_{H_1,H_2,K_0 g K_0}$. For strongly regular semisimple a, $\mathrm{Sht}^{(G,\mu)}_{(H_1,\lambda),(H_2,\lambda),K_0 g K_0}(a)$ is proper for any g, so we can talk about the degree of the a-component of the zero cycle $\mathcal{Z}^\lambda_{H_1}\cdot(f * \mathcal{Z}^\lambda_{H_2})$, denoted $\langle \mathcal{Z}^\lambda_{H_1}, f * \mathcal{Z}^\lambda_{H_2}\rangle_a$. The global analogue of (3-14) means proving an identity of the form (3-13), but with both sides replaced by their a-components. One can prove such a global identity by analyzing the direct image complexes of the Hitchin maps $h^G_{H_1,H_2}$ and $h^{G'}_{H'_1,H'_2}$ using sheaf-theoretic methods, as we did in Yun [2011b] and Yun and Zhang [2017].

2. Deduce the arithmetic fundamental lemma from the global identity. The moduli $\mathrm{Sht}^{\mu,\mathrm{loc}}_G$ of local Shtukas for G is related to a formal completion of the global moduli stack Sht^μ_G by a uniformization diagram, analogous to the one relating Rapoport-Zink spaces and Shimura varieties. Using the uniformization, one can express $\langle \mathcal{Z}^\lambda_{H_1}, f * \mathcal{Z}^\lambda_{H_2}\rangle_a$ as a finite sum, where each summand is a product of usual orbital integrals and intersection numbers of the form $I^{\mathrm{U},r_i}_{x_i,\delta}$ (with $\sum r_i = r$). There is a similar product formula for the global orbital integral for (G', H'_1, H'_2). By choosing a appropriately we may deduce the local identity (3-14) from the global one using the product expansions and the known fundamental lemma (Theorem 2.3.5).
