ON NUMBERS, GERMS, AND TRANSSERIES

Matthias Aschenbrenner, Lou van den Dries and Joris van der Hoeven

Abstract

Germs of real-valued functions, surreal numbers, and transseries are three ways to enrich the real continuum by infinitesimal and infinite quantities. Each of these comes with naturally interacting notions of *ordering* and *derivative*. The category of H-fields provides a common framework for the relevant algebraic structures. We give an exposition of our results on the model theory of H-fields, and we report on recent progress in unifying germs, surreal numbers, and transseries from the point of view of asymptotic differential algebra.

Contemporaneous with Cantor's work in the 1870s but less well-known, P. du Bois-Reymond [1871, 1872, 1873, 1875, 1877, 1882] had original ideas concerning non-Cantorian infinitely large and small quantities (see Ehrlich [2006]). He developed a "calculus of infinities" to deal with the growth rates of functions of one real variable, representing their "potential infinity" by an "actual infinite" quantity. The reciprocal of a function tending to infinity is one which tends to zero, hence represents an "actual infinitesimal".

These ideas were unwelcome to Cantor (see Fisher [1981]) and misunderstood by him, but were made rigorous by F. Hausdorff [1906a,b, 1909] and G. H. Hardy [1910, 1912a,b, 1913]. Hausdorff firmly grounded du Bois-Reymond's "orders of infinity" in Cantor's set-theoretic universe (see Felgner [2002]), while Hardy focused on their differential aspects and introduced the *logarithmico-exponential functions* (short: *LE-functions*). This led to the concept of a *Hardy field* (Bourbaki [1951]), developed further mainly by Rosenlicht [1983a,b, 1984, 1987, 1995] and Boshernitzan [1981, 1982, 1986, 1987]. For the role of Hardy fields in *o-minimality* see Miller [2012].

Surreal numbers were discovered (or created?) in the 1970s by J. H. Conway [1976] and popularized by M. Gardner, and by D. E. Knuth [1974] who coined the term "surreal number". The surreal numbers form a proper class containing all reals as well as Cantor's ordinals, and come equipped with a natural ordering and arithmetic operations turning them into an ordered field. Thus with ω the first infinite ordinal, $\omega - \pi$, $1/\omega$, $\sqrt{\omega}$ make

sense as surreal numbers. In contrast to non-standard real numbers, their construction is completely canonical, naturally generalizing both Dedekind cuts and von Neumann's construction of the ordinals. (In the words of their creator Conway [1994, p. 102], the surreals are "the only correct extension of the notion of real number to the infinitely large and the infinitesimally small.") The surreal universe is very rich, yet shares many properties with the real world. For example, the ordered field of surreals is real closed and hence, by Tarski [1951], an elementary extension of its ordered subfield of real numbers. (In fact, every set-sized real closed field embeds into the field of surreal numbers.) M. Kruskal anticipated the use of surreal numbers in asymptotics, and based on his ideas Gonshor [1986] extended the exponential function on the reals to one on the surreals, with the same first-order logical properties; see van den Dries and Ehrlich [2001a,b]. Rudiments of analysis for functions on the surreal numbers have also been developed by Alling [1987], Costin, Ehrlich, and Friedman [2015], and Rubinstein-Salzedo and Swaminathan [2014].

Transseries generalize LE-functions in a similar way that surreals generalize reals and ordinals. Transseries have a precursor in the *generalized power series* of Levi-Civita [1892–93, 1898] and Hahn [1907], but were only systematically considered in the 1980s, independently by Écalle [1992] and Dahn and Göring [1987]. Écalle introduced transseries as formal counterparts to his "analyzable functions", which were central to his work on Dulac's Problem (related to Hilbert's 16th Problem on polynomial vector fields). Dahn and Göring were motivated by Tarski's Problem on the model theory of the real field with exponentiation. Transseries have since been used in various parts of mathematics and physics; their formal nature also makes them suitable for calculations in computer algebra systems. Key examples of transseries are the *logarithmic-exponential series* (*LE-series* for short), see van den Dries, Macintyre, and Marker [1997, 2001]; more general notions of transseries have been introduced by van der Hoeven [1997] and Schmeling [2001]. A transseries can represent a function of a real variable using exponential and logarithmic terms, going beyond the more prevalent asymptotic expansions in terms of powers of the independent variable. Transseries can be manipulated algebraically—added, subtracted, multiplied, divided—and like power series, can be differentiated term-wise: they comprise a differential field. However, they carry much more structure: for example, by virtue of its construction, the field of LE-series comes with an exponential function; there is a natural notion of composition for transseries; and differential-compositional equations in transseries are sometimes amenable to functional-analytic techniques van der Hoeven [2001].

The logical properties of the *exponential* field of LE-series have been well-understood since the 1990s: by Wilkie [1996] and van den Dries, Macintyre, and Marker [1997] it is model-complete and o-minimal. In our book Aschenbrenner, van den Dries, and van der Hoeven [2017a] we focused instead on the *differential* field of LE-series, denoted below by $\mathbb{T}$, and obtained some decisive results about its model theory. Following A. Robinson's general ideas we placed $\mathbb{T}$ into a suitable category of *H-fields* and, by developing the extension theory of H-fields, showed that $\mathbb{T}$ is existentially closed as an H-field: each system of algebraic differential equations and inequalities over $\mathbb{T}$ which has a solution in an H-field extension of $\mathbb{T}$ already has one in $\mathbb{T}$ itself. In Aschenbrenner, van den Dries, and van der Hoeven [ibid.] we also prove the related fact that $\mathbb{T}$ is model-complete; indeed, we obtain a quantifier elimination (in a natural language) for $\mathbb{T}$. As a consequence, the elementary theory of $\mathbb{T}$ is decidable, and model-theoretically "tame" in various ways: for example, it has Shelah's *non-independence property* (NIP).

Results from Aschenbrenner, van den Dries, and van der Hoeven [ibid.] about existential closedness, model completeness, and quantifier elimination substantiate the intuition, expressed already in Écalle [1992], that $\mathbb{T}$ plays the role of a *universal domain* for the part of asymptotic differential algebra that steers clear of oscillations. How far does this intuition lead us? Hardy's field of LE-functions embeds into $\mathbb{T}$, as an ordered differential field, but this fails for other Hardy fields. The natural question here is: *Are all maximal Hardy fields elementarily equivalent to $\mathbb{T}$?* It would mean that any maximal Hardy field instantiates Hardy's vision of a maximally inclusive and well-behaved algebra of oscillation-free real functions. Related is the issue of embedding Hardy fields into more general differential fields of transseries. Positive answers to these questions would tighten the link between germs of functions (living in Hardy fields) and their transseries expansions. We may also ask how surreal numbers fit into the picture: *Is there a natural isomorphism between the field of surreal numbers and some field of generalized transseries?* This would make it possible to differentiate and compose surreal numbers as if they were functions, and confirm Kruskal's premonition of a connection between surreals and the asymptotics of functions.

We believe that answers to these questions are within grasp due to advances in our understanding during the last decade as represented in our book Aschenbrenner, van den Dries, and van der Hoeven [2017a]. We discuss these questions with more details in Sections 3, 4, 5. In Section 1 we set the stage by describing Hardy fields and transseries as two competing approaches to the asymptotic behavior of non-oscillatory real-valued functions. (Section 5 includes a brief synopsis of the remarkable surreal number system.) In Section 2 we define H-fields and state the main results of Aschenbrenner, van den Dries, and van der Hoeven [ibid.].

We let m, n range over $\mathbb{N} = \{0, 1, 2, \dots\}$. Given an (additive) abelian group A we let $A^{\neq} := A \setminus \{0\}$. In some places below we assume familiarity with very basic model theory, for example, on the level of Aschenbrenner, van den Dries, and van der Hoeven [ibid., Appendix B]. "Definable" will mean "definable with parameters".

1 Orders of Infinity and Transseries

Germs of continuous functions. Consider continuous real-valued functions whose domain is a subset of $\mathbb{R}$ containing an interval $(a, +\infty)$, $a \in \mathbb{R}$. Two such functions *have the same germ* (at $+\infty$) if they agree on an interval $(a, +\infty)$, $a \in \mathbb{R}$, contained in both their domains; this defines an equivalence relation on the set of such functions, whose equivalence classes are called *germs*. Addition and multiplication of germs is defined pointwise, giving rise to a commutative ring $\mathcal{C}$. For a germ g of such a function we also let g denote that function if the resulting ambiguity is harmless. With this convention, given a property P of real numbers and $g \in \mathcal{C}$ we say that $P\big(g(t)\big)$ holds *eventually* if $P\big(g(t)\big)$ holds for all sufficiently large real t in the domain of g. We identify each real number r with the germ of the constant function $\mathbb{R} \to \mathbb{R}$ with value r. This makes the field $\mathbb{R}$ into a subring of $\mathcal{C}$.

Following Hardy we define for $f, g \in \mathcal{C}$,

$$f \preccurlyeq g \quad :\Longleftrightarrow \quad \text{for some } c \in \mathbb{R}^{>0} \text{ we have } |f(t)| \leqslant c|g(t)| \text{ eventually,}$$
$$f \prec g \quad :\Longleftrightarrow \quad \text{for every } c \in \mathbb{R}^{>0} \text{ we have } |f(t)| < c|g(t)| \text{ eventually.}$$

The reflexive and transitive relation $\preccurlyeq$ yields an equivalence relation $\asymp$ on $\mathcal{C}$ by setting $f \asymp g :\Longleftrightarrow f \preccurlyeq g$ and $g \preccurlyeq f$, and $\preccurlyeq$ induces a partial ordering on the set of equivalence classes of $\asymp$; these equivalence classes are essentially du Bois-Reymond's "orders of infinity". Thus with x the germ of the identity function on $\mathbb{R}$:

$$0 \prec 1 \prec \log\log x \prec \log x \prec \sqrt{x} \prec x \asymp -2x + x\sin x \prec x^2 \prec \mathrm{e}^x.$$

One way to create interesting subrings of $\mathcal{C}$ is via expansions of the field of real numbers: any such expansion $\tilde{\mathbb{R}}$ gives rise to the subring $H(\tilde{\mathbb{R}})$ of $\mathcal{C}$ consisting of the germs of the continuous functions $\mathbb{R} \to \mathbb{R}$ that are definable in $\tilde{\mathbb{R}}$.

Hausdorff fields. A *Hausdorff field* is by definition a subfield of $\mathcal{C}$. Simple examples are

(1) $$\mathbb{Q}, \quad \mathbb{R}, \quad \mathbb{R}(x), \quad \mathbb{R}(\sqrt{x}), \quad \mathbb{R}(x, \mathrm{e}^x, \log x).$$

That $\mathbb{R}(x, \mathrm{e}^x, \log x)$ is a Hausdorff field, for instance, follows from two easy facts: first, an element f of $\mathcal{C}$ is a unit iff $f(t) \neq 0$ eventually (and then either $f(t) > 0$ eventually or $f(t) < 0$ eventually), and if $f \neq 0$ is an element of the subring $\mathbb{R}[x, \mathrm{e}^x, \log x]$ of $\mathcal{C}$, then $f \asymp x^k\, \mathrm{e}^{lx}(\log x)^m$ for some $k, l, m \in \mathbb{N}$. Alternatively, one can use the fact that an expansion $\tilde{\mathbb{R}}$ of the field of reals is o-minimal iff $H(\tilde{\mathbb{R}})$ is a Hausdorff field, and note that the examples above are subfields of $H(\mathbb{R}_{\exp})$ where $\mathbb{R}_{\exp}$ is the exponential field of real numbers, which is well-known to be o-minimal by Wilkie [1996].

Let H be a Hausdorff field. Then H becomes an ordered field with (total) ordering given by: $f > 0$ iff $f(t) > 0$ eventually. Moreover, the set of orders of infinity in H is totally ordered by $\preccurlyeq$: for $f, g \in H$ we have $f \preccurlyeq g$ or $g \preccurlyeq f$. In his landmark paper, Hausdorff [1909] essentially proved that H has a unique algebraic Hausdorff field extension that is real closed. (Writing before Artin and Schreier [1927], of course he doesn't use this terminology.) He was particularly interested in "maximal" objects and their order type. By Hausdorff's Maximality Principle (a form of Zorn's Lemma) every Hausdorff field is contained in one that is maximal with respect to inclusion. By the above, maximal Hausdorff fields are real closed. Hausdorff also observed that maximal Hausdorff fields have uncountable cofinality; indeed, he proved the stronger result that the underlying ordered set of a maximal Hausdorff field H is η_1: *if A, B are countable subsets of H and $A < B$, then $A < h < B$ for some $h \in H$.* A real closed ordered field is $\aleph_1$-saturated iff its underlying ordered set is η_1. Standard facts from model theory (or Erdős, Gillman, and Henriksen [1955]) now yield an observation that could have been made by Hausdorff himself in the wake of Artin and Schreier [1927]:

Corollary 1.1. *Assuming* CH (*the Continuum Hypothesis*), *all maximal Hausdorff fields are isomorphic.*

This observation was in fact made by Ehrlich [2012] in the more specific form that under CH any maximal Hausdorff field is isomorphic to the field of surreal numbers of countable length; see Section 5 below for basic facts on surreals. We don't know whether here the assumption of CH can be omitted. (By Esterle [1977], the negation of CH implies the existence of non-isomorphic real closed η_1-fields of size $2^{\aleph_0}$.) It may also be worth mentioning that the intersection of all maximal Hausdorff fields is quite small: it is just the field of real algebraic numbers.

Hardy fields. A Hardy field is a Hausdorff field whose germs can be differentiated. This leads to a much richer theory. To define Hardy fields formally we introduce the subring

$$\mathcal{C}^n := \{f \in \mathcal{C} : f \text{ is eventually } n \text{ times continuously differentiable}\}$$

of $\mathcal{C}$, with $\mathcal{C}^0 = \mathcal{C}$. Then each $f \in \mathcal{C}^{n+1}$ has derivative $f' \in \mathcal{C}^n$. A *Hardy field* is a subfield of $\mathcal{C}^1$ that is closed under $f \mapsto f'$; Hardy fields are thus not only ordered fields but also differential fields. The Hausdorff fields listed in (1) are all Hardy fields; moreover, for each o-minimal expansion $\tilde{\mathbb{R}}$ of the field of reals, $H(\tilde{\mathbb{R}})$ is a Hardy field. As with Hausdorff fields, each Hardy field is contained in a maximal one. For an element f of a Hardy field we have either $f' > 0$, or $f' = 0$, or $f' < 0$, so f is either eventually strictly increasing, or eventually constant, or eventually strictly decreasing. (This may fail for f in a Hausdorff field.) Each element of a Hardy field is contained in the intersection

$\bigcap_n \mathcal{C}^n$, but not necessarily in its subring $\mathcal{C}^\infty$ consisting of those germs which are eventually infinitely differentiable. In a Hardy field H, the ordering and derivation interact in a pleasant way: if $f \in H$ and $f > \mathbb{R}$, then $f' > 0$. Asymptotic relations in H can be differentiated and integrated: for $0 \neq f, g \not\asymp 1$ in H, we have $f \preccurlyeq g$ iff $f' \preccurlyeq g'$.

Extending Hardy fields. Early work on Hardy fields focused on solving algebraic equations and simple first order differential equations: Borel [1899], Hardy [1912a,b], Bourbaki [1951], Marić [1972], Sjödin [1971], Robinson [1972], Rosenlicht [1983a]. As a consequence, every Hardy field H has a smallest real closed Hardy field extension $\operatorname{Li}(H) \supseteq \mathbb{R}$ that is also closed under integration and exponentiation; call $\operatorname{Li}(H)$ the *Hardy-Liouville closure* of H. (Hardy's field of LE-functions mentioned earlier is contained in $\operatorname{Li}(\mathbb{R})$.) Here is a rather general result of this kind, due to Singer [1975]:

Theorem 1.2. *If $y \in \mathcal{C}^1$ satisfies a differential equation $y'P(y) = Q(y)$ where $P(Y)$ and $Q(Y)$ are polynomials over a Hardy field H and $P(y)$ is a unit in $\mathcal{C}$, then y generates a Hardy field $H\langle y\rangle = H(y, y')$ over H.*

Singer's theorem clearly does not extend to second order differential equations: the nonzero solutions of $y'' + y = 0$ in $\mathcal{C}^2$ do not belong to any Hardy field. The solutions in $\mathcal{C}^2$ of the differential equation

$$y'' + y = \mathrm{e}^{x^2} \tag{2}$$

form a two-dimensional affine space $y_0 + \mathbb{R}\sin x + \mathbb{R}\cos x$ over $\mathbb{R}$, with y_0 any particular solution. Boshernitzan [1987] proved that any of these continuum many solutions generates a Hardy field. Since no Hardy field can contain more than one solution, there are at least continuum many different maximal Hardy fields. By the above, each of them contains $\mathbb{R}$, is real closed, and closed under integration and exponentiation. *What more can we say about maximal Hardy fields?* To give an answer to this question, consider the following conjectures about Hardy fields H:

A. *For any differential polynomial $P(Y) \in H\{Y\} = H[Y, Y', Y'', \dots]$ and $f < g$ in H with $P(f) < 0 < P(g)$ there exists y in a Hardy field extension of H such that $f < y < g$ and $P(y) = 0$.*

B. *For any countable subsets $A < B$ in H there exists y in a Hardy field extension of H such that $A < y < B$.*

Conjecture A for $P \in H[Y, Y']$ holds by van den Dries [2000]. Conjecture A implies that *all maximal Hardy fields are elementarily equivalent* as we shall see in Section 2. Conjecture B was first raised as a question by Ehrlich [2012]. The conjectures together imply that, under CH, *all maximal Hardy fields are isomorphic* (the analogue of Corollary 1.1). We sketch a program to prove A and B in Section 3.

Transseries. Hardy [1910, p. 35] made the point that the LE-functions seem to cover all orders of infinity that occur naturally in mathematics. But he also suspected that the order of infinity of the compositional inverse of $(\log x)(\log\log x)$ differs from that of any LE-function (see Hardy [1912a]); this suspicion is correct. For a more revealing view of orders of infinity and a more comprehensive theory we need transseries. For example, transseries lead to an easy argument to confirm Hardy's suspicion (see van den Dries, Macintyre, and Marker [1997] and van der Hoeven [1997]). Here we focus on the field $\mathbb{T}$ of LE-series and in accordance with Aschenbrenner, van den Dries, and van der Hoeven [2017a], simply call its elements *transseries,* bearing in mind that many variants of formal series, such as those appearing in Schmeling [2001] (see Section 4 below), can also rightfully be called "transseries".

Transseries are formal series $f = \sum_{\mathfrak{m}} f_{\mathfrak{m}}\mathfrak{m}$ where the $f_{\mathfrak{m}}$ are real coefficients and the $\mathfrak{m}$ are "transmonomials" such as

$$x^r\ (r \in \mathbb{R}), \quad x^{-\log x}, \quad \mathrm{e}^{x^2\,\mathrm{e}^x}, \quad \mathrm{e}^{\mathrm{e}^x}.$$

One can get a sense by considering an example like

$$7\,\mathrm{e}^{\mathrm{e}^x+\mathrm{e}^{x/2}+\mathrm{e}^{x/4}+\cdots} - 3\,\mathrm{e}^{x^2} + 5x^{\sqrt{2}} - (\log x)^{\pi} + 42 + x^{-1} + x^{-2} + \cdots + \mathrm{e}^{-x}.$$

Here think of x as positive infinite: $x > \mathbb{R}$. The transmonomials in this series are arranged from left to right in decreasing order. The reversed order type of the set of transmonomials that occur in a given transseries can be any countable ordinal. (In the example above it is $\omega + 1$ because of the term e^{-x} at the end.) Formally, $\mathbb{T}$ is an ordered subfield of a Hahn field $\mathbb{R}[[G^{\mathrm{LE}}]]$ where G^{LE} is the ordered group of transmonomials (or LE-monomials). More generally, let $\mathfrak{M}$ be any (totally) ordered commutative group, multiplicatively written, the $\mathfrak{m} \in \mathfrak{M}$ being thought of as monomials, with the ordering denoted by $\preccurlyeq$. The Hahn field $\mathbb{R}[[\mathfrak{M}]]$ consists of the formal series $f = \sum_{\mathfrak{m}} f_{\mathfrak{m}}\mathfrak{m}$ with real coefficients $f_{\mathfrak{m}}$ whose support $\operatorname{supp} f := \{\mathfrak{m} \in \mathfrak{M} : f_{\mathfrak{m}} \neq 0\}$ is *well-based*, that is, well-ordered in the reversed ordering $\succcurlyeq$ of $\mathfrak{M}$. Addition and multiplication of these Hahn series works just as for ordinary power series, and the ordering of $\mathbb{R}[[\mathfrak{M}]]$ is determined by declaring a nonzero Hahn series to be positive if its leading coefficient is positive (so the series above, with leading coefficient 7, is positive). Both $\mathbb{R}[[G^{\mathrm{LE}}]]$ and its ordered subfield $\mathbb{T}$ are real closed. Informally, each transseries is obtained, starting with the powers x^r $(r \in \mathbb{R})$, by applying the following operations finitely many times:

1. multiplication with real numbers;
2. infinite summation in $\mathbb{R}[[G^{\mathrm{LE}}]]$;
3. exponentiation and taking logarithms of positive transseries.

To elaborate on (2), a family $(f_i)_{i\in I}$ in $\mathbb{R}[[\mathfrak{M}]]$ is said to be *summable* if for each $\mathfrak{m}$ there are only finitely many $i \in I$ with $\mathfrak{m} \in \operatorname{supp} f_i$, and $\bigcup_{i\in I} \operatorname{supp} f_i$ is well-based; in this case we define the *sum* $f = \sum_{i\in I} f_i \in \mathbb{R}[[\mathfrak{M}]]$ of this family by $f_{\mathfrak{m}} = \sum_{i\in I}(f_i)_{\mathfrak{m}}$ for each $\mathfrak{m}$. One can develop a "strong" linear algebra for this notion of "strong" (infinite) summation (see van der Hoeven [2006] and Schmeling [2001]). As to (3), it may be instructive to see how to exponentiate a transseries f: decompose f as $f = g + c + \varepsilon$ where $g := \sum_{\mathfrak{m}\succ 1} f_{\mathfrak{m}}\mathfrak{m}$ is the infinite part of f, $c := f_1$ is its constant term, and ε its infinitesimal part (in our example $c = 42$ and $\varepsilon = x^{-1} + x^{-2} + \cdots + e^{-x}$); then

$$e^f = e^g \cdot e^c \cdot \sum_n \frac{\varepsilon^n}{n!}$$

where $e^g \in \mathfrak{M}$ is a transmonomial, and $e^c \in \mathbb{R}$, $\sum_n \frac{\varepsilon^n}{n!} \in \mathbb{R}[[G^{\mathrm{LE}}]]$ have their usual meaning. The story with logarithms is a bit different: taking logarithms may also create transmonomials, such as $\log x$, $\log\log x$, etc.

The formal definition of $\mathbb{T}$ is inductive and somewhat lengthy; see van den Dries, Macintyre, and Marker [2001], Edgar [2010], and van der Hoeven [2006] for detailed expositions, or Aschenbrenner, van den Dries, and van der Hoeven [2017a, Appendix A] for a summary. We only note here that by virtue of the construction of $\mathbb{T}$, series like $\frac{1}{x} + \frac{1}{e^x} + \frac{1}{e^{e^x}} + \cdots$ or $\frac{1}{x} + \frac{1}{x\log x} + \frac{1}{x\log x\log\log x} + \cdots$ (involving "nested" exponentials or logarithms of unbounded depth), though they are legitimate elements of $\mathbb{R}[[G^{\mathrm{LE}}]]$, do not appear in $\mathbb{T}$; moreover, the sequence $x, e^x, e^{e^x}, \dots$ is cofinal in $\mathbb{T}$, and the sequence $x, \log x, \log\log x, \dots$ is coinitial in the set $\{f \in \mathbb{T} : f > \mathbb{R}\}$. The map $f \mapsto e^f$ is an isomorphism of the ordered additive group of $\mathbb{T}$ onto its multiplicative group of positive elements, with inverse $g \mapsto \log g$. As an ordered exponential field, $\mathbb{T}$ turns out to be an elementary extension of $\mathbb{R}_{\exp}$ (see van den Dries, Macintyre, and Marker [1997]).

Transseries can be differentiated termwise; for instance, $\left(\sum_n n!\frac{e^x}{x^{n+1}}\right)' = \frac{e^x}{x}$. We obtain a derivation $f \mapsto f'$ on the field $\mathbb{T}$ with constant field $\{f \in \mathbb{T} : f' = 0\} = \mathbb{R}$ and satisfying $(\exp f)' = f'\exp f$ and $(\log g)' = g'/g$ for $f, g \in \mathbb{T}$, $g > 0$. Moreover, each $f \in \mathbb{T}$ has an antiderivative in $\mathbb{T}$, that is, $f = g'$ for some $g \in \mathbb{T}$. As in Hardy fields, $f > \mathbb{R} \Rightarrow f' > 0$, for transseries f. We also have a dominance relation on $\mathbb{T}$: for $f, g \in \mathbb{T}$ we set

$$\begin{aligned} f \preccurlyeq g \ &:\Longleftrightarrow\ |f| \leqslant c|g| \text{ for some } c \in \mathbb{R}^{>0} \\ &\Longleftrightarrow\ (\text{leading transmonomial of } f) \preccurlyeq (\text{leading transmonomial of } g), \end{aligned}$$

and as in Hardy fields we declare $f \asymp g :\Longleftrightarrow f \preccurlyeq g$ and $g \preccurlyeq f$, as well as $f \prec g :\Longleftrightarrow f \preccurlyeq g$ and $g \not\preccurlyeq f$. As in Hardy fields we can also differentiate and integrate asymptotic relations: for $0 \neq f, g \not\asymp 1$ in $\mathbb{T}$ we have $f \preccurlyeq g$ iff $f' \preccurlyeq g'$.

Hardy's ordered exponential field of (germs of) logarithmic-exponential functions embeds uniquely into $\mathbb{T}$ so as to preserve real constants and to send the germ x to the transseries x; this embedding also preserves the derivation. However, the field of LE-series enjoys many closure properties that the field of LE-functions lacks. For instance, $\mathbb{T}$ is not only closed under exponentiation and integration, but also comes with a natural operation of composition: for $f, g \in \mathbb{T}$ with $g > \mathbb{R}$ we can substitute g for x in $f = f(x)$ to obtain $f \circ g = f(g(x))$. The Chain Rule holds: $(f \circ g)' = (f' \circ g) \cdot g'$. Every $g > \mathbb{R}$ has a compositional inverse in $\mathbb{T}$: a transseries $f > \mathbb{R}$ with $f \circ g = g \circ f = x$. As shown in van der Hoeven [2006], a Newton diagram method can be used to solve any "feasible" algebraic differential equation in $\mathbb{T}$ (where the meaning of feasible can be made explicit).

Thus it is not surprising that soon after the introduction of $\mathbb{T}$ the idea emerged that it should play the role of a *universal domain* (akin to Weil's use of this term in algebraic geometry) for asymptotic differential algebra: that it *is truly the algebra-from-which-one-can-never-exit and that it marks an almost impassable horizon for "ordered analysis"*, as Écalle [1992, p. 148] put it. Model theory provides a language to make such an intuition precise, as we explain in our survey Aschenbrenner, van den Dries, and van der Hoeven [2013] where we sketched a program to establish the basic model-theoretic properties of $\mathbb{T}$, carried out in Aschenbrenner, van den Dries, and van der Hoeven [2017a]. Next we briefly discuss our main results from Aschenbrenner, van den Dries, and van der Hoeven [ibid.].

2 H-Fields

We shall consider $\mathbb{T}$ as an $\mathcal{L}$-structure where the language $\mathcal{L}$ has the primitives 0, 1, $+$, $-$, $\cdot$, ∂ (derivation), $\leqslant$ (ordering), $\preccurlyeq$ (dominance). More generally, let K be any ordered differential field with constant field $C = \{f \in K : f' = 0\}$. This yields a dominance relation $\preccurlyeq$ on K by

$$f \preccurlyeq g \quad :\Longleftrightarrow \quad |f| \leqslant c|g| \text{ for some positive } c \in C$$

and we view K accordingly as an $\mathcal{L}$-structure. The convex hull of C in K is the valuation ring $\mathcal{O} = \{f \in K : f \preccurlyeq 1\}$ of K, with its maximal ideal $\scriptstyle\mathcal{O} := \{f \in K : f \prec 1\}$ of infinitesimals.

Definition 2.1. *An* H-field *is an ordered differential field* K *such that* (*with the notations above*), $\mathcal{O} = C + \scriptstyle\mathcal{O}$, *and for all* $f \in K$ *we have:* $f > C \Rightarrow f' > 0$.

Examples include all Hardy fields that contain $\mathbb{R}$, and all ordered differential subfields of $\mathbb{T}$ that contain $\mathbb{R}$. In particular, $\mathbb{T}$ is an H-field, but $\mathbb{T}$ has further basic elementary properties that do not follow from this: its derivation is small, and it is Liouville closed.

An H-field K is said to have *small derivation* if it satisfies $f \prec 1 \Rightarrow f' \prec 1$, and to be *Liouville closed* if it is real closed and for every $f \in K$ there are $g, h \in K$, $h \neq 0$, such that $g' = f$ and $h' = hf$. Each Hardy field H has small derivation, and $\operatorname{Li}(H)$ is Liouville closed.

Inspired by the familiar characterization of real closed ordered fields via the intermediate value property for one-variable polynomial functions, we say that an H-field K has the *Intermediate Value Property* (IVP) if for all differential polynomials $P(Y) \in K\{Y\}$ and all $f < g$ in K with $P(f) < 0 < P(g)$ there is some $y \in K$ with $f < y < g$ and $P(y) = 0$. van der Hoeven showed that a certain variant of $\mathbb{T}$, namely its H-subfield of gridbased transseries, has IVP; see van der Hoeven [2002].

Theorem 2.2. *The $\mathfrak{L}$-theory of $\mathbb{T}$ is completely axiomatized by the requirements: being an H-field with small derivation; being Liouville closed; and having IVP.*

Actually, IVP is a bit of an afterthought: in Aschenbrenner, van den Dries, and van der Hoeven [2017a] we use other (but equivalent) axioms that will be detailed below. We mention the above variant for expository reasons and since it explains why Conjecture A from Section 1 yields that all maximal Hardy fields are elementarily equivalent. Let us define an *H-closed field* to be an H-field that is Liouville closed and has the IVP. All H-fields embed into H-closed fields, and the latter are exactly the existentially closed H-fields. Thus:

Theorem 2.3. *The theory of H-closed fields is model complete.*

Here is an unexpected byproduct of our proof of this theorem:

Corollary 2.4. *H-closed fields have no proper differentially algebraic H-field extensions with the same constant field.*

IVP refers to the ordering, but the valuation given by $\preccurlyeq$ is more robust and more useful. IVP comes from two more fundamental properties: ω-*freeness* and *newtonianity* (a differential version of henselianity). These concepts make sense for any differential field with a suitable dominance relation $\preccurlyeq$ in which the equivalence $f \preccurlyeq g \iff f' \preccurlyeq g'$ holds for $0 \neq f, g \prec 1$.

To give an inkling of these somewhat technical notions, let K be an H-field and assume that for every $\phi \in K^\times$ for which the derivation $\phi\partial$ is small (that is, $\phi\partial\mathcal{O} \subseteq \mathcal{O}$), there exists $\phi_1 \prec \phi$ in $K^\times$ such that $\phi_1\partial$ is small. (This assumption is satisfied for Liouville closed H-fields.) Let $P(Y) \in K\{Y\}^{\neq}$. We wish to understand how the function $y \mapsto P(y)$ behaves for $y \preccurlyeq 1$. It turns out that this function only reveals its true colors after rewriting P in terms of a derivation $\phi\partial$ with suitable $\phi \in K^\times$.

Indeed, this rewritten P has the form $a \cdot (N + R)$ with $a \in K^\times$ and where $N(Y) \in C\{Y\}^{\neq}$ is independent of ϕ for sufficiently small $\phi \in K^\times$ with respect to $\preccurlyeq$, subject to $\phi\partial$

being small, and where the coefficients of $R(Y)$ are infinitesimal. We call N the *Newton polynomial* of P. Now K is said to be ω*-free* if for all P as above its Newton polynomial has the form $A(Y)\cdot(Y')^n$ for some $A \in C[Y]$ and some n. We say that K is *newtonian* if for all P as above with $N(P)$ of degree 1 we have $P(y) = 0$ for some $y \in \mathcal{O}$. For H-fields, IVP $\Longrightarrow$ ω-free and newtonian; for Liouville closed H-fields, the converse also holds.

Our main result in Aschenbrenner, van den Dries, and van der Hoeven [ibid.] refines Theorem 2.3 by giving quantifier elimination for the theory of H-closed fields in the language $\mathfrak{L}$ above augmented by an additional unary function symbol ι and two extra unary predicates Λ and Ω. These have defining axioms in terms of the other primitives. Their interpretations in $\mathbb{T}$ are as follows: $\iota(f) = 1/f$ if $f \neq 0$, $\iota(0) = 0$, and with $\ell_0 := x$, $\ell_{n+1} := \log \ell_n$,

$$\Lambda(f) \iff f < \lambda_n := \tfrac{1}{\ell_0} + \tfrac{1}{\ell_0\ell_1} + \cdots + \tfrac{1}{\ell_0\cdots\ell_n} \text{ for some } n,$$

$$\Omega(f) \iff f < \omega_n := \tfrac{1}{(\ell_0)^2} + \tfrac{1}{(\ell_0\ell_1)^2} + \cdots + \tfrac{1}{(\ell_0\cdots\ell_n)^2} \text{ for some } n.$$

Thus Λ and Ω define downward closed subsets of $\mathbb{T}$. The sequence (ω_n) also appears in classical non-oscillation theorems for second-order linear differential equations. The ω-freeness of $\mathbb{T}$ reflects the fact that (ω_n) has no pseudolimit in the valued field $\mathbb{T}$. Here are some applications of this quantifier elimination:

Corollary 2.5.

(1) *"O-minimality at infinity": if $S \subseteq \mathbb{T}$ is definable, then for some $f \in \mathbb{T}$ we either have $g \in S$ for all $g > f$ in $\mathbb{T}$ or $g \notin S$ for all $g > f$ in $\mathbb{T}$.*

(2) *All subsets of $\mathbb{R}^n$ definable in $\mathbb{T}$ are semialgebraic.*

Corollaries 2.4 and 2.5 are the departure point for developing a notion of (differential-algebraic) dimension for definable sets in $\mathbb{T}$; see Aschenbrenner, van den Dries, and van der Hoeven [2017b].

The results reported on above make us confident that the category of H-fields is the right setting for asymptotic differential algebra. To solidify this impression we return to the motivating examples—Hardy fields, ordered differential fields of transseries, and surreal numbers—and consider how they are related. We start with Hardy fields, which historically came first.

3 H-Field Elements as Germs

After Theorem 1.2 and Boshernitzan [1982, 1987], the first substantial "Hardy field" result on more general differential equations was obtained by van der Hoeven [2009]. In what follows we use "d-algebraic" to mean "differentially algebraic" and "d-transcendental" to mean "differentially transcendental".

Theorem 3.1. *The differential subfield* $\mathbb{T}^{\mathrm{da}}$ *of* $\mathbb{T}$ *whose elements are the* d-*algebraic transseries is isomorphic over* $\mathbb{R}$ *to a Hardy field.*

The proof of this theorem is in the spirit of model theory, iteratively extending by a single d-algebraic transseries. The most difficult case (immediate extensions) is handled through careful construction of suitable solutions as convergent series of iterated integrals. We are currently trying to generalize Theorem 3.1 to d-algebraic extensions of arbitrary Hardy fields. Here is our plan:

Theorem 3.2. *Every Hardy field has an* ω*-free Hardy field extension.*

Theorem 3.3 (in progress)**.** *Every* ω*-free Hardy field has a newtonian* d-*algebraic Hardy field extension.*

These two theorems, when established, imply that all maximal Hardy fields are H-closed. Hence (by Theorem 2.2) they will all be elementarily equivalent to $\mathbb{T}$, and since H-closed fields have the IVP, Conjecture A from Section 1 will follow.

In order to get an even better grasp on the structure of maximal Hardy fields, we also need to understand how to adjoin d-transcendental germs to Hardy fields. An example of this situation is given by d-transcendental series such as $\sum_n n!!x^{-n}$. By an old result by É. Borel [1895] every formal power series $\sum_n a_n t^n$ over $\mathbb{R}$ is the Taylor series at 0 of a $\mathcal{C}^\infty$-function f on $\mathbb{R}$; then $\sum_n a_n x^{-n}$ is an asymptotic expansion of the function $f(x^{-1})$ at $+\infty$, and it is easy to show that if this series is d-transcendental, then the germ at $+\infty$ of this function does generate a Hardy field. Here is a far-reaching generalization:

Theorem 3.4 (in progress)**.** *Every pseudocauchy sequence* (y_n) *in a Hardy field* H *has a pseudolimit in some Hardy field extension of* H.

The proof of this for H-closed $H \supseteq \mathbb{R}$ relies heavily on results from Aschenbrenner, van den Dries, and van der Hoeven [2017a], using also intricate glueing techniques. For extensions that increase the value group, we need very different constructions. If succesful, these constructions in combination with Theorem 3.4 will lead to a proof of Conjecture B from Section 1:

Theorem 3.5 (in progress)**.** *For any countable subsets* $A < B$ *of a Hardy field* H *there exists an element* y *in a Hardy field extension of* H *with* $A < y < B$.

The case $H \subseteq \mathcal{C}^\infty$, $B = \emptyset$ was already dealt with by Sjödin [1971]. The various "theorems in progress" together with results from Aschenbrenner, van den Dries, and van der Hoeven [2017a] imply that any maximal Hardy fields H_1 and H_2 are back-and-forth equivalent, which is considerably stronger than H_1 and H_2 being elementarily equivalent. It implies for example

> *Under* CH *all maximal Hardy fields are isomorphic.*

This would be the Hardy field analogue of Corollary 1.1. (In contrast to maximal Hausdorff fields, however, maximal Hardy fields cannot be $\aleph_1$-saturated, since their constant field is $\mathbb{R}$.) When we submitted this manuscript, we had finished the proof of Theorem 3.2, and also the proof of Theorem 3.4 in the relevant H-closed case.

Related problems. Some authors (such as Sjödin [1971]) prefer to consider only Hardy fields contained in $\mathcal{C}^\infty$. Theorem 3.2 and our partial result for Theorem 3.4 go through in the $\mathcal{C}^\infty$-setting. All the above "theorems in progress" are plausible in that setting.

What about real analytic Hardy fields (Hardy fields contained in the subring $\mathcal{C}^\omega$ of $\mathcal{C}$ consisting of all real analytic germs)? In that setting Theorem 3.2 goes through. Any d-algebraic Hardy field extension of a real analytic Hardy field is itself real analytic, and so Theorem 3.3 (in progress) will hold in that setting as well. However, our glueing technique employed in the proof of Theorem 3.4 doesn't work there.

Kneser [1949] obtained a real analytic solution E at infinity to the functional equation $E(x+1) = \exp E(x)$. It grows faster than any finite iteration of the exponential function, and generates a Hardy field. See Boshernitzan [1986] for results of this kind, and a proof that Theorem 3.5 holds for $B = \varnothing$ in the real analytic setting. So in this context we also have an abundant supply of Hardy fields.

Similar issues arise for germs of quasi-analytic and "cohesive" functions of Écalle [1992]. These classes of functions are somewhat more flexible than the class of real analytic functions. For instance, the series $x^{-1} + \mathrm{e}^{-x} + \mathrm{e}^{-\mathrm{e}^x} + \cdots$ converges uniformly for $x > 1$ to a cohesive function that is not real analytic.

Accelero-summation. The definition of a Hardy field ensures that the differential field operations never introduce oscillatory behavior. Does this behavior persist for operations such as composition or various integral transforms? In this connection we note that the Hardy field $H(\tilde{\mathbb{R}})$ associated to an o-minimal expansion $\tilde{\mathbb{R}}$ of the field of reals is always closed under composition (see Miller [2012]).

To illustrate the problem with composition, let α be a real number > 1 and let $y_0 \in \mathcal{C}^2$ be a solution to (2). Then $z_0 := y_0(\alpha x)$ satisfies the equation

$$\alpha^{-2} z'' + z \;=\; \mathrm{e}^{\alpha^2 x^2}. \tag{3}$$

It can be shown that $\{y_0 + \sin x, z_0\}$ generates a Hardy field, but it is clear that no Hardy field containing both $y_0 + \sin x$ and z_0 can be closed under composition.

Adjoining solutions to (2) and (3) "one by one" as in the proof of Theorem 3.1 will not prevent the resulting Hardy fields to contain both $y_0 + \sin x$ and z_0. In order to obtain closure under composition we therefore need an alternative device. Écalle's theory of *accelero-summation* (Écalle [1992]) is much more than that. Vastly extending Borel's summation method for divergent series (Borel [1899]), it associates to each *accelero-summable* transseries an *analyzable* function. In this way many non-oscillating real-valued functions that arise naturally (e.g., as solutions of algebraic differential equations) can be represented faithfully by transseries. This leads us to conjecture an improvement on Theorem 3.1:

Conjecture 3.6. *Consider the real accelero-summation process where we systematically use the organic average whenever we encounter singularities on the positive real axis. This yields a composition-preserving H-field isomorphism from $\mathbb{T}^{\mathrm{da}}$ onto a Hardy field contained in $\mathcal{C}^{\omega}$.*

There is little doubt that this holds. The main difficulty here is that a full proof will involve many tools forged by Écalle in connection with accelero-summation, such as resurgent functions, well-behaved averages, cohesive functions, etc., with some of these tools requiring further elaboration; see also Costin [2009] and Menous [1999].

The current theory of accelero-summation only sums transseries with coefficients in $\mathbb{R}$. Thus it is not clear how to generalize Conjecture 3.6 in the direction of Theorem 3.3. Such a generalization might require introducing transseries over a Hardy field H with suitable additional structure, as well as a corresponding theory of accelero-summation over H for such transseries. In particular, elements of H should be accelero-summable over H in this theory, by construction.

4 H-Field Elements as Generalized Transseries

Next we discuss when H-fields embed into differential fields of formal series. A classical embedding theorem of this type is due to Krull [1932]: any valued field has a spherically complete immediate extension. As a consequence, any real closed field containing $\mathbb{R}$ is isomorphic over $\mathbb{R}$ to a subfield of a Hahn field $\mathbb{R}[[\mathfrak{M}]]$ with divisible monomial group $\mathfrak{M}$, such that the subfield contains $\mathbb{R}(\mathfrak{M})$. We recently proved an analogue of this theorem for valued differential fields; see Aschenbrenner, van den Dries, and van der Hoeven [2017c]. Here a *valued differential field* is a valued field of equicharacteristic zero equipped with a derivation that is continuous with respect to the valuation topology.

Theorem 4.1. *Every valued differential field has a spherically complete immediate extension.*

For a real closed H-field K with constant field C this theorem gives a Hahn field $\widehat{K} = C[[\mathfrak{M}]]$ with a derivation ∂ on $\widehat{K}$ making it an H-field with constant field C such that K is isomorphic over C to an H-subfield of $\hat{K}$ that contains $C(\mathfrak{M})$. A shortcoming of this result is that there is no guarantee that ∂ preserves infinite summation. In contrast, the derivation of $\mathbb{T}$ is *strong* (does preserve infinite summation). An abstract framework for even more general notions of transseries is due to van der Hoeven and his former student Schmeling [2001].

Fields of transseries. To explain this, consider an (ordered) Hahn field $\mathbb{R}[[\mathfrak{M}]]$ with a partially defined function exp obeying the usual rules of exponentiation; see van der Hoeven [2006, Section 4.1] for details. In particular, exp has a partially defined inverse function log. We say that $\mathbb{R}[[\mathfrak{M}]]$ is a *field of transseries* if the following conditions hold:

(T1) the domain of the function log is $\mathbb{R}[[\mathfrak{M}]]^{>0}$;

(T2) for each $\mathfrak{m} \in \mathfrak{M}$ and $\mathfrak{n} \in \operatorname{supp} \log \mathfrak{m}$ we have $\mathfrak{n} \succ 1$;

(T3) $\log(1+\varepsilon) = \varepsilon - \frac{1}{2}\varepsilon^2 + \frac{1}{3}\varepsilon^3 + \cdots$ for all $\varepsilon \prec 1$ in $\mathbb{R}[[\mathfrak{M}]]$; and

(T4) for every sequence $(\mathfrak{m}_n)$ in $\mathfrak{M}$ with $\mathfrak{m}_{n+1} \in \operatorname{supp} \log \mathfrak{m}_n$ for all n, there exists an index n_0 such that for all $n \geqslant n_0$ and all $\mathfrak{n} \in \operatorname{supp} \log \mathfrak{m}_n$, we have $\mathfrak{n} \succcurlyeq \mathfrak{m}_{n+1}$ and $(\log \mathfrak{m}_n)_{\mathfrak{m}_{n+1}} = \pm 1$.

The first three axioms record basic facts from the standard construction of transseries. The fourth axiom is more intricate and puts limits on the kind of “nested transseries” that are allowed. Nested transseries such as

$$y = \sqrt{x} + \mathrm{e}^{\sqrt{\log x} + \mathrm{e}^{\sqrt{\log\log x} + \mathrm{e}^{\cdots}}} \tag{4}$$

are naturally encountered as solutions of functional equations, in this case

$$y(x) = \sqrt{x} + \mathrm{e}^{y(\log x)}. \tag{5}$$

Axiom (T4) does allow nested transseries as in (4), but excludes series like

$$u = \sqrt{x} + \mathrm{e}^{\sqrt{\log x} + \mathrm{e}^{\sqrt{\log\log x} + \mathrm{e}^{\cdots} + \log\log\log x} + \log\log x} + \log x,$$

which solves the functional equation $u(x) = \sqrt{x} + \mathrm{e}^{u(\log x)} + \log x$; in some sense, u is a perturbation of the solution y in (4) to the equation (5).

In his thesis Schmeling [2001] shows how to extend a given field of transseries $K = \mathbb{R}[[\mathfrak{M}]]$ with new exponentials and nested transseries like (4), and if K also comes with a strong derivation, how to extend this derivation as well. Again, (T4) is crucial for this task: naive termwise differentiation leads to a huge infinite sum that turns out to be summable by (T4). A *transserial derivation* is a strong derivation on K such that nested transseries are differentiated in this way. Such a transserial derivation is uniquely determined by its values on the *log-atomic* elements: those $\lambda \in K$ for which $\lambda, \log\lambda, \log\log\lambda, \ldots$ are all transmonomials in $\mathfrak{M}$.

We can now state a transserial analogue of Krull's theorem. This analogue is a consequence of Theorem 5.3 below, proved in Aschenbrenner, van den Dries, and van der Hoeven [2015].

Theorem 4.2. *Every H-field with small derivation and constant field $\mathbb{R}$ can be embedded over $\mathbb{R}$ into a field of transseries with transserial derivation.*

For simplicity, we restricted ourselves to transseries over $\mathbb{R}$. The theory naturally generalizes to transseries over ordered exponential fields (see van der Hoeven [2006] and Schmeling [2001]) and it should be possible to extend Theorem 4.2 likewise.

Hyperseries. Besides derivations, one can also define a notion of composition for generalized transseries (see van der Hoeven [1997] and Schmeling [2001]). Whereas certain functional equations such as (5) can still be solved using nested transseries, solving the equation $E(x+1) = \exp E(x)$ where $E(x)$ is the unknown, requires extending $\mathbb{T}$ to a field of transseries with composition containing an element $E(x) = \exp_\omega x > \mathbb{T}$, called the *iterator* of $\exp x$. Its compositional inverse $\log_\omega x$ should then satisfy $\log_\omega \log x = (\log_\omega x) - 1$, providing us with a primitive for $(x \log x \log_2 x \cdots)^{-1}$:

$$\log_\omega x = \int \frac{\mathrm{d}x}{x \log x \log_2 x \cdots}.$$

It is convenient to start with iterated logarithms rather than iterated exponentials, and to introduce transfinite iterators $\log_\alpha x$ recursively using

$$\log_\alpha x = \int \frac{\mathrm{d}x}{\prod_{\beta<\alpha} \log_\beta x} \qquad (\alpha \text{ any ordinal}).$$

By Écalle [1992] the iterators $\log_\alpha x$ with $\alpha < \omega^\omega$ and their compositional inverses $\exp_\alpha x$ suffice to resolve all pure composition equations of the form

$$f^{\circ k_1} \circ \phi_1 \circ \cdots \circ f^{\circ k_n} \circ \phi_n = x \quad \text{where } \phi_1, \ldots, \phi_n \in \mathbb{T} \text{ and } k_1, \ldots, k_n \in \mathbb{N}.$$

The resolution of more complicated functional equations involving differentiation and composition requires the introduction of fields of *hyperseries*: besides exponentials and logarithms, hyperseries are allowed to contain iterators $\exp_\alpha x$ and $\log_\alpha x$ of any strength α.

For $\alpha < \omega^\omega$, the necessary constructions were carried out in Schmeling [2001]. The ultimate objective is to construct a field **Hy** of hyperseries as a proper class, similar to the field of surreal numbers, endow it with its canonical derivation and composition, and establish the following:

Conjecture 4.3. *Let Φ be any partial function from* **Hy** *into itself, constructed from elements in* **Hy**, *using the field operations, differentiation and composition. Let $f < g$ be hyperseries in* **Hy** *such that Φ is defined on the closed interval $[f, g]$ and $\Phi(f)\Phi(g) < 0$. Then for some $y \in$* **Hy** *we have $\Phi(y) = 0$ and $f < y < g$.*

One might then also consider H-fields with an additional composition operator and try to prove that these structures can always be embedded into **Hy**.

5 Growth Rates as Numbers

Turning to surreal numbers, how do they fit into asymptotic differential algebra?

The H-field of surreal numbers. The totality **No** of surreal numbers is not a set but a proper class: a surreal $a \in$ **No** is uniquely represented by a transfinite sign sequence $(a_\lambda)_{\lambda<\ell(a)} \in \{-,+\}^{\ell(a)}$ where $\ell(a)$ is an ordinal, called the *length* of a; a surreal b is said to be *simpler than* a (notation: $b <_s a$) if the sign sequence of b is a proper initial segment of that of a. Besides the (partial) ordering $<_s$, **No** also carries a natural (total) lexicographic ordering $<$. For any *sets* $L < R$ of surreals there is a unique simplest surreal a with $L < a < R$; this a is denoted by $\{L \mid R\}$ and called the *simplest* or *earliest* surreal between L and R. In particular, $a = \{L_a \mid R_a\}$ for any $a \in$ **No**, where $L_a := \{b <_s a : b < a\}$ and $R_a = \{b <_s a : b > a\}$. We let a^L range over elements of L_a, and a^R over elements of R_a.

A rather magical property of surreal numbers is that various operations have natural inductive definitions. For instance, we have ring operations given by

$$\begin{aligned} a+b &:= \{a^L+b, a+b^L \mid a^R+b, a+b^R\} \\ ab &:= \{a^Lb+ab^L-a^Lb^L, a^Rb+ab^R-a^Rb^R \mid \\ &\qquad a^Lb+ab^R-a^Lb^R, a^Rb+ab^L-a^Rb^L\}. \end{aligned}$$

Remarkably, these operations make **No** into a real closed field with $<$ as its field ordering and with $\mathbb{R}$ uniquely embedded as an initial subfield. (A set $A \subseteq$ **No** is said to be *initial* if for all $a \in A$ all $b <_s a$ are also in A.)

Can we use such magical recursions to introduce other reasonable operations? Exponentiation was dealt with by Gonshor [1986]. But it remained long open how to define a "good" derivation ∂ on **No** such that $\partial(\omega) = 1$. (An ordinal α is identified with the surreal of length α whose sign sequence has just plus signs.) A positive answer was given recently by Berarducci and Mantova [2018]. Their construction goes in two parts. They first analyze **No** as an exponential field, and show that it is basically a field of transseries in the sense of Section 4. A transserial derivation on **No** is determined by its values at log-atomic elements. There is some flexibility here, but Berarducci and Mantova [ibid.] present a "simplest" way to choose these derivatives. Most important, that choice indeed leads to a derivation ∂_{BM} on **No**. In addition:

Theorem 5.1 (Berarducci and Mantova [ibid.]). *The derivation ∂_{BM} is transserial and makes* **No** *a Liouville closed H-field with constant field $\mathbb{R}$.*

This result was further strengthened in Aschenbrenner, van den Dries, and van der Hoeven [2015], using key results from Aschenbrenner, van den Dries, and van der Hoeven [2017a]:

Theorem 5.2. **No** *with the derivation ∂_{BM} is an H-closed field.*

Embedding H-fields into No. In the remainder of this section we consider **No** as equipped with the derivation ∂_{BM}, although Theorems 5.1 and 5.2 and much of what follows hold for other transserial derivations. Returning to our main topic of embedding H-fields into specific H-fields such as **No**, we also proved the following in Aschenbrenner, van den Dries, and van der Hoeven [2015]:

Theorem 5.3. *Every H-field with small derivation and constant field $\mathbb{R}$ can be embedded as an ordered differential field into* **No**.

How "nice" can we take the embeddings in Theorem 5.3? For instance, when can we arrange the image of the embedding to be initial? The image of the natural embedding $\mathbb{T} \to \mathbf{No}$ is indeed initial, as has been shown by Elliot Kaplan.

For further discussion it is convenient to introduce, given an ordinal α, the *set*

$$\mathbf{No}(\alpha) := \{a \in \mathbf{No} : \ell(a) < \alpha\}.$$

It turns out that for uncountable cardinals κ, $\mathbf{No}(\kappa)$ is closed under the differential field operations, and in Aschenbrenner, van den Dries, and van der Hoeven [ibid.] we also show:

Theorem 5.4. *The H-subfield $\mathbf{No}(\kappa)$ of* **No** *is an elementary submodel of* **No**.

In particular, the H-field $\mathbf{No}(\omega_1)$ of surreal numbers of countable length is an elementary submodel of **No**. It has the η_1-property: for any countable subsets $A < B$ of $\mathbf{No}(\omega_1)$ there exists $y \in \mathbf{No}(\omega_1)$ with $A < y < B$. This fact and the various "theorems in progress" from Section 3 imply:

Under CH *all maximal Hardy fields are isomorphic to* $\mathbf{No}(\omega_1)$.

This would be an analogue of Ehrlich's observation about maximal Hausdorff fields.

Hyperseries as numbers and *vice versa*. The similarities in the constructions of the field of hyperseries **Hy** and the field of surreal numbers **No** led van der Hoeven [2006, p. 6] to the following:

Conjecture 5.5. *There is a natural isomorphism between* **Hy** *and* **No** *that associates to any hyperseries* $f(x) \in \mathbf{Hy}$ *its value* $f(\omega) \in \mathbf{No}$.

The problem is to make sense of the value of a hyperseries at ω. Thanks to Gonshor's exponential function, it is clear how to evaluate ordinary transseries at ω. The difficulties start as soon as we wish to represent surreal numbers that are not of the form $f(\omega)$ with $f(x)$ an ordinary transseries. That is where the iterators $\exp_\omega$ and $\log_\omega$ come into play:

$$\begin{aligned}
\exp_\omega \omega &:= \{\omega, \exp \omega, \exp_2 \omega, \ldots \mid \} \\
\log_\omega \omega &:= \{ \mathbb{R} \mid \ldots, \log_2 \omega, \log \omega, \omega\} \\
\exp_{1/2} \omega &:= \exp_\omega \left(\log_\omega \left(\omega + \tfrac{1}{2}\right)\right) \\
&:= \left\{ \omega^2, \exp \log^2 \omega, \exp_2 \log_2^2 \omega, \ldots \,\middle|\, \ldots, \exp_2 \sqrt{\log \omega}, \exp \sqrt{\omega} \right\}
\end{aligned}$$

The intuition behind Conjecture 5.5 is that all "holes in **No** can be filled" using suitable nested hyperseries and suitable iterators of exp and log. It reconciles two *a priori* very different types of infinities: on the one hand, we have growth orders corresponding to smooth functional behavior; on the other side, we have numbers. Being able to switch between functions (more precisely: formal series acting as functions) and numbers, we may also transport any available structure in both directions: we immediately obtain a canonical derivation ∂_c (with constant field $\mathbb{R}$) and composition $\circ_c$ on **No**, as well as a notion of simplicity on **Hy**.

Does the derivation ∂_{BM} coincide with the canonical derivation ∂_c induced by the conjectured isomorphism? A key observation is that any derivation ∂ on **No** with a distinguished right inverse ∂^{-1} naturally gives rise to a definition of $\log_\omega$:

$$\log_\omega a := \partial^{-1}(\partial a \log'_\omega a) \quad \text{where}$$
$$\log'_\omega a := 1 \Big/ \prod_n \log_n a \qquad (a \in \mathbf{No},\ a > \mathbb{R}).$$

(For a family (a_i) of positive surreals, $\prod_i a_i := \exp \sum_i \log a_i$ if $\sum_i \log a_i$ is defined.) Since ∂_{BM} is transserial, it does admit a distinguished right inverse ∂_{BM}^{-1}. According to

Berarducci and Mantova [2018, Remark 6.8], $\partial_{\mathrm{BM}}\lambda = 1/\log'_\omega \lambda$ for log-atomic λ with $\lambda > \exp_n \omega$ for all n. For $\lambda = \exp_\omega \omega$ and setting $\exp'_\omega(a) := \prod_n \log_n \exp_\omega a$ for $a \in \mathbf{No}^{>0}$, this yields $\partial_{\mathrm{BM}}\lambda = \exp'_\omega \omega$, which is also the value we expect for $\partial_{\mathrm{c}}\lambda$. However, for $\lambda = \exp_\omega(\exp_\omega \omega)$ we get $\partial_{\mathrm{BM}}\lambda = \exp'_\omega(\exp_\omega \omega)$ whereas we expect $\partial_{\mathrm{c}}\lambda = (\exp'_\omega \omega)\cdot \exp'_\omega(\exp_\omega \omega)$. Thus the "simplest" derivation ∂_{BM} making $\mathbf{No}$ an H-field probably does *not* coincide with the ultimately "correct" derivation ∂_{c} on $\mathbf{No}$. Berarducci and Mantova [2017] use similar considerations to conclude that ∂_{BM} is incompatible with any reasonable notion of composition for surreal numbers.

The surreal numbers from a model theoretic perspective. We conclude with speculations motivated by the fact that various operations defined by "surreal" recursions have a nice model theory. Examples: $(\mathbf{No}; \leqslant, +, \cdot)$ is a model of the theory of real closed fields; $(\mathbf{No}; \leqslant, +, \cdot, \exp)$ is a model of the theory of $\mathbb{R}_{\exp}$; and $(\mathbf{No}; \leqslant, +, \cdot, \partial_{\mathrm{BM}})$ is a model of the theory of H-closed fields. Each of these theories is model complete in a natural language. Is there a model theoretic reason that explains why this works so well?

Let us look at this in connection with the last example. Our aim is to define a derivation ∂ on $\mathbf{No}$ making it an H-field. Let $a \in \mathbf{No}$ be given for which we wish to define ∂a, and assume that ∂b has been defined for all $b \in L_a \cup R_a$. Let Δ_a be the class of all surreals b for which there exists a derivation ∂ on $\mathbf{No}$ with $\partial a = b$ and taking the prescribed values on $L_a \cup R_a$. Assembling all conditions that should be satisfied by ∂a, it is not hard to see that there exist sets $L, R \subseteq \mathbf{No}$ such that $\Delta_a = \{b \in \mathbf{No} : L < b < R\}$. We are left with two main questions: *When do we have $L < R$, thereby allowing us to define $\partial a = \{L \mid R\}$? Does this lead to a global definition of ∂ on* $\mathbf{No}$ *making it an H-closed field?* It might be of interest to isolate reasonable model theoretic conditions that imply the success of this type of construction. If the above construction does work, yet another question is whether the resulting derivation coincides with ∂_{BM}.

TOWARDS A THEORY OF DEFINABLE SETS

Stephen Jackson

Abstract

The subject of descriptive set theory is traditionally concerned with the theory of definable subsets of Polish spaces. By introducing large cardinal/determinacy axioms, a theory of definable subsets of Polish spaces and their associated ordinals has been developed over the last several decades which extends far up in the definability hierarchy. Recently, much interest has been focused on trying to extend the theory of definable objects to more general types of sets, not necessarily subsets of a Polish space or an ordinal. A large class of these objects are represented by equivalence relations on Polish spaces. Even for some of the simpler of these relations, an interesting combinatorial theory is emerging. We consider both problems of extending further the theory of definable subsets of Polish spaces, and that of determining the structure of these new types of definable sets.

1 Introduction and background

The field of descriptive set theory traditionally in concerned with the theory of definable sets in Polish spaces (complete, separable, metric spaces). As all uncountable Polish spaces are isomorphic by a Borel function, it is customary to refer to the elements of any of several standard Polish spaces as “reals.” Aside from $\mathbb{R}$, familiar examples include the Baire space ω^ω (homeomorphic to the space of irrationals in $\mathbb{R}$; here ω denotes the set of natural numbers), and 2^ω (homeomorphic to the Cantor set in $\mathbb{R}$; here $2 = \{0, 1\}$). In the latter two cases, ω is endowed with the discrete topology, and ω^ω or 2^ω with the product topology. Note that if G is any countable discrete group, then 2^G is likewise homeomorphic to the Cantor set, so it is naturally a compact Polish space.

Using the axiom of choice, AC, “pathological” sets with a variety of properties can be constructed. Examples include Vitali sets (non-measurable sets), Bernstein sets (a set such that neither the set nor its complement contains a closed uncountable set), Lusin sets (a set of reals which meets every meager set in a countable set), and Sierpinski sets (a set

MSC2010: primary 03E15; secondary 03E60.

which meets every measure 0 set in a countable set). A theme of descriptive set theory is that if we restrict out attention to "definable" sets, then these pathologies disappear and a reasonable structure theory emerges. The notion of definable is made precise through hierarchies of collections of sets of increasing complexity. A *pointclass* $\boldsymbol{\Gamma}$ is a collection of subsets of Polish spaces which is closed under inverse images by continuous functions, that is, if $f: X \to Y$ is continuous and $A \subseteq Y$ is in $\boldsymbol{\Gamma}$, then $f^{-1}(A)$ is also in $\boldsymbol{\Gamma}$. A basic example is the pointclass of Borel sets, the smallest collection containing the open and closed sets and closed under countable unions and intersections. The Borel sets are stratified into the *Borel hierarchy*, the pointclasses $\boldsymbol{\Sigma}^0_\alpha$, $\boldsymbol{\Pi}^0_\alpha$, and $\boldsymbol{\Delta}^0_\alpha$, for $\alpha < \omega_1$. Here $\boldsymbol{\Sigma}^0_1 \upharpoonright X$ is the collection of open sets in the Polish space X, $\boldsymbol{\Pi}^0_1 \upharpoonright X$ the closed sets in X, $\boldsymbol{\Delta}^0_1 \upharpoonright X = \boldsymbol{\Sigma}^0_1 \upharpoonright X \cap \boldsymbol{\Pi}^0_1 \upharpoonright X$, and in general $A \in \boldsymbol{\Sigma}^0_\alpha$ if $A = \bigcup_n A_n$ where each $A_n \in \boldsymbol{\Pi}^0_{\beta_n}$ for some $\beta_n < \alpha$. Likewise, $A \in \boldsymbol{\Pi}^0_\alpha$ if $A = \bigcap_n A_n$ with each $A_n \in \boldsymbol{\Sigma}^0_{\beta_n}$ for some $\beta_n < \alpha$. Also, we define $\boldsymbol{\Delta}^0_\alpha = \boldsymbol{\Sigma}^0_\alpha \cap \boldsymbol{\Pi}^0_\alpha$. It is a classical fact that the Borel sets in any Polish space have the perfect set property (if they are uncountable then they contain a perfect set, or equivalently an uncountable closed set), and are Lebesgue measurable and have the Baire property. Thus, they cannot be any of the above types of pathological sets. Another example of a "regularity property" for sets is the *Ramsey property* for the set $A \subseteq [\omega]^\omega$ (here $[H]^\omega$ denotes the set of infinite subsets of H, which we can identify with the set of increasing functions from ω to ω) which asserts that there is an infinite set $H \subseteq \omega$ such that either $[H]^\omega \subseteq A$ or $[H]^\omega \subseteq \omega^\omega - A$. Again, all Borel sets have this regularity property, this being a theorem of Galvin and Prikry (in fact the Borel sets are *completely Ramsey*, a somewhat stronger version of the Ramsey property).

The hierarchy of definable sets extends far beyond the Borel sets. The next hierarchy after the Borel sets is the *projective hierarchy*, so called because the main operation used in generating the hierarchy is projection from a product $X \times Y$ of Polish spaces to X. The *analytic*, or $\boldsymbol{\Sigma}^1_1$ sets, are defined by projecting closed (or equivalently Borel) sets: $A \subseteq X$ is $\boldsymbol{\Sigma}^1_1$ iff there is a closed set $F \subseteq X \times \omega^\omega$ such that $x \in A$ iff $\exists y\ (x, y) \in F$. In more succinct notation, we write $\boldsymbol{\Sigma}^1_1 \upharpoonright X = \exists^{\omega^\omega} \boldsymbol{\Pi}^0_1 \upharpoonright (X \times \omega^\omega)$, where $\exists^Y$ denotes the operation of applying existential quantification over Y. A set $A \subseteq X$ is *co-analytic*, or $\boldsymbol{\Pi}^1_1$, if it is the complement of an analytic set. That is, $\boldsymbol{\Pi}^1_1$ is the *dual pointclass* of $\boldsymbol{\Sigma}^1_1$, which we write as $\boldsymbol{\Pi}^1_1 = \check{\boldsymbol{\Sigma}}^1_1$. We set $\boldsymbol{\Delta}^1_1 = \boldsymbol{\Sigma}^1_1 \cap \boldsymbol{\Pi}^1_1$ to be the sets that are both $\boldsymbol{\Sigma}^1_1$ and $\boldsymbol{\Pi}^1_1$. A classical theorem of Suslin states that $\boldsymbol{\Delta}^1_1$ is the collection of Borel sets, so the projective hierarchy begins where the Borel hierarchy ends. We continue to define the $\boldsymbol{\Sigma}^1_n$, $\boldsymbol{\Pi}^1_n$, and $\boldsymbol{\Delta}^1_n$ sets for all $n \in \omega$ by setting $\boldsymbol{\Sigma}^1_{n+1} = \exists^{\omega^\omega} \boldsymbol{\Pi}^1_n$, $\boldsymbol{\Pi}^1_{n+1} = \check{\boldsymbol{\Sigma}}^1_{n+1}$ (or equivalently, $\boldsymbol{\Pi}^1_{n+1} = \forall^{\omega^\omega} \boldsymbol{\Sigma}^1_n$), and $\boldsymbol{\Delta}^1_{n+1} = \boldsymbol{\Sigma}^1_{n+1} \cap \boldsymbol{\Pi}^1_{n+1}$. The projective hierarchy is important because it includes all of the sets of conventional analysis. In fact, the sets of analysis generally occur at the first or second levels of this hierarchy. In any uncountable Polish space, all of the levels of the Borel and projective hierarchies are distinct, that is,

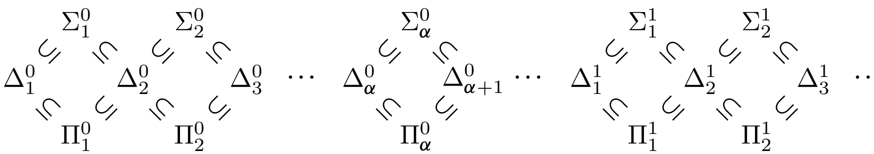

Figure 1: The Borel and projective hierarchies.

there is no collapsing in either of these hierarchies. The inclusions of pointclasses within these hierarchies is shown in Figure 1.

Beginning with the fundamental work of Gödel, it was realized that there were strong limits to how much further far one could extend the regularity results for Borel sets working just in ZFC set theory (the set theory of "ordinary mathematics"). For example, the $\boldsymbol{\Sigma}^1_1$ sets have the perfect set property, but it is consistent with ZFC that the $\boldsymbol{\Pi}^1_1$ sets do not. Likewise, while the $\boldsymbol{\Sigma}^1_1$ and $\boldsymbol{\Pi}^1_1$ sets are all Lebesgue measurable and have the Baire property, it is consistent with ZFC that the collection of $\boldsymbol{\Delta}^1_2$ sets does not. A theorem of Silver asserts that the $\boldsymbol{\Sigma}^1_1$ and $\boldsymbol{\Pi}^1_1$ sets are all (completely) Ramsey, but it is again consistent that there are $\boldsymbol{\Delta}^1_2$ sets which are not. Thus, in order to extend the theory further, one must assume additional axioms which go beyond the ZFC axioms. There are currently two main axiom schemes for doing this: large cardinal axioms and determinacy axioms. Large cardinal axioms, which are generally meant to be added to the ZFC axioms, assert that cardinals κ with certain properties exist which cannot be shown to exist just from ZFC. Determinacy axioms, on the other hand, assert that certain two-player games are determined. If $A \subseteq \omega^\omega$, then we associate a two-player integer game $G(A)$ to A in a natural way: the players I and II alternate picking integers $x(n) \in \omega$ as shown in Figure 2. They thereby jointly build an $x = (x(0), x(1), \dots) \in \omega^\omega$. Player I wins the game iff $x \in A$.

	I	$x(0)$		$x(2)$			
$G(A)$						$\cdots$	$x \in \omega^\omega$
	II		$x(1)$		$x(3)$		

Figure 2: The basic game $G(A)$.

The notions of a winning strategy for one of the players, and of the game being determined (i.e., one of the players has a winning strategy) are defined in the natural manner. The axiom of determinacy, AD, is the assertion that $G(A)$ is determined for all $A \subseteq \omega^\omega$.

This axiom contradicts the axiom of choice, AC, but is meant to be an axiom for certain inner models of the full universe of sets V for which the sets are, in some sense, definable. If $\mathbf{\Gamma}$ is a pointclass, then $\det(\mathbf{\Gamma})$ is the statement that $G(A)$ is determined for all $A \subseteq \omega^\omega$ in $\mathbf{\Gamma}$. A celebrated theorem of Martin says all Borel games are determined. More generally, if X is any set and $A \subseteq X^\omega$ is Borel in the product topology on X^ω, where X is given the discrete topology, then (in ZFC) the game $G(A)$ is determined. In fact, a version of this result holds in ZF (without choice), where now every every Borel game $G(A)$ for $A \subseteq X^\omega$ is *quasi-determined* (see Moschovakis [1980]). Here a quasi-strategy is like a strategy except it is multi-valued. Results of Martin and Harrington show that $\mathsf{ZFC} + \det(\mathbf{\Sigma}^1_1)$ is strictly stronger than ZFC. The assertions $\det(\mathbf{\Sigma}^1_n)$ are strictly increasing in strength, and projective determinacy, PD, is the statement that all projective games are determined. The model $L(\mathbb{R})$ is the smallest model of set theory containing all of the reals and ordinals. Every set of reals in this model is definable in this model by a formula using only ordinal and real parameters. Because of this, the axiom $\mathsf{AD}^{L(\mathbb{R})}$ that all $A \in L(\mathbb{R})$ are determined is a plausible axiom. Since strategies in integer games are essentially reals, if $\mathsf{AD}^{L(\mathbb{R})}$ holds then in fact $L(\mathbb{R})$ satisfies the axiom AD. The model $L(\mathbb{R})$ is thus the smallest candidate inner model (containing all the ordinals) which satisfies AD. More generally, if M is any inner model satisfying AD, then we may consider the sets in M as being, in some abstract sense, definable.

Work of Martin, Steel, and Woodin in the 80's established the precise connection between determinacy axioms and large cardinal axioms. It was shown, for example, that $\mathsf{ZFC} + \exists n$ Woodin cardinals $+\exists$ a larger measurable cardinal implies $\det(\mathbf{\Sigma}^1_{n+1})$. Also, AD is equiconsistent with the existence of ω many Woodin cardinals, and $\mathsf{AD}^{L(\mathbb{R})}$ is implied by the existence of ω many Woodin cardinals and a measurable cardinal above them. These fundamental results lend respectability to the determinacy axioms and show that not only is $\mathsf{AD}^{L(\mathbb{R})}$ an intuitively appealing axiom, but that it is actually implied by large cardinal axioms out in the ZFC universe.

Moving past AD, we many consider the axiom AD_X which asserts that every game played on the set X, that is, where $A \subseteq X^\omega$, is determined. This axiom is inconsistent for $X = \omega_1$ or $X = \mathcal{P}(\mathbb{R})$, but for $X = \mathbb{R}$ the axiom of real game determinacy $\mathsf{AD}_{\mathbb{R}}$ is reasonable. This axiom is significantly stronger than AD, and cannot hold in the minimal model $L(\mathbb{R})$ of AD, or in any model of the form $L(T, \mathbb{R})$, for $T \subseteq \mathrm{On}$. Woodin has identified the exact consistency strength of $\mathsf{AD}_{\mathbb{R}}$ in the large cardinal hierarchy as well. Thus we have a progression of the determinacy axioms starting with $\det(\mathbf{\Delta}^1_1)$, which is a theorem of ZFC, to $\det(\mathbf{\Sigma}^1_1)$, $\det(\mathbf{\Sigma}^1_n)$, PD, AD, and $\mathsf{AD}_{\mathbb{R}}$. There are also stronger determinacy axioms than $\mathsf{AD}_{\mathbb{R}}$ involving "long games," but we will not need to consider these here. We note that in any model of AD the sets of reals fall into a single hierarchy, called the Wadge hierarchy, which gives a far-reaching generalization of the Borel and projective hierarchies. In particular, in these models we can define the $\boldsymbol{\Sigma}^1_\alpha$, $\boldsymbol{\Pi}^1_\alpha$ classes for all $\alpha < \Theta$, where Θ is the length of the Wadge hierarchy in the model. Thus, these higher level analogs of the projective sets are defined and extend throughout the entire Wadge hierarchy of sets of reals.

Beginning in the 60's, and continuing to the present, it was realized that determinacy axioms were a powerful tool which allowed the classical results for Borel and analytic sets to be extended to larger classes of sets. Work of Kechris, Martin, Moschovakis, Solovay, Steel, Woodin, and others showed that assuming determinacy axioms, and in particular assuming AD, one could propagate a structural theory similar to the ZFC theory of Borel and analytic sets. This theory is largely presented in terms of *scales* and *Suslin cardinals*, and gives a tight connection between the theory of the sets of reals in a pointclass $\boldsymbol{\Gamma}$ and the properties of an ordinal $\delta(\boldsymbol{\Gamma})$ associated to the pointclass. The notion of a scale was isolated by Moschovakis, and has origins in the Novikov-Kondo proof of $\boldsymbol{\Pi}^1_1$ uniformization. We recall the following definition. By a tree T on a set X we mean a $T \subseteq X^{<\omega}$ which is closed under subsequence, that is, if $s \in T$ and m is less than the length of s, then $s \restriction m \in T$. We let $[T] = \{x \in X^\omega : \forall n\ x \restriction n \in T\}$ be the set of infinite branches (or body) of T.

Definition 1. We say a set $A \subseteq \omega^\omega$ is κ-Suslin, for $\kappa \in \mathrm{On}$, if there is a tree $T \subseteq (\omega \times \kappa)^{<\omega}$ such that $A = p[T] = \{x \in \omega^\omega : \exists f \in \kappa^\omega\ (x, f) \in [T]\}$.

We say κ is a Suslin cardinal if there is a set A which is κ-Suslin but not λ-Suslin for any $\lambda < \kappa$. The notions of semi-scale and scale are a more algebraic reformulation of having Suslin representations, presented in terms of norms $\varphi_n : A \to \kappa$. In fact, being κ-Suslin is equivalent to having a semi-scale with norms to κ, and also equivalent to having a scale with norms to κ. We refer the reader to Moschovakis [ibid.] for the precise definitions of semi-scales, scales, and the scale property for a pointclass.

Assuming AD, we can propagate the scale/Suslin cardinal analysis past the $\boldsymbol{\Sigma}^1_1$, $\boldsymbol{\Pi}^1_1$ levels to the entire projective hierarchy and beyond. In Jackson [2010] one can find a presentation of the complete scale and Suslin cardinal analysis from AD. This analysis, though it extends throughout the full extent of the Suslin cardinals, presents the theory in terms of the ordinals $\delta(\boldsymbol{\Gamma})$. A much more detailed inductive analysis is necessary to analyze these ordinals and describe the cardinal structure below them. In Jackson [1999] and Jackson [1988] this analysis is described through the projective hierarchy. The extent of this analysis is currently far short of the extent of scales, and so much about the general cardinal structure of determinacy models remains unknown.

To give one example of the consequences of this analysis, we first recall that it is classical fact (proved in ZFC) that every $\boldsymbol{\Sigma}^1_1$ or $\boldsymbol{\Pi}^1_1$ set is ω_2-Borel, that is, is in the smallest collection containing the open and closed sets and closed under unions and intersections of length $< \omega_2$. In fact, every $\boldsymbol{\Sigma}^1_1$ or $\boldsymbol{\Pi}^1_1$ set is an ω_1 union of Borel sets (a proof can be found in Moschovakis [1980], A. S. Kechris [1978], or Jackson [2010]). From the above mentioned inductive analysis we get the following extension of this result, assuming determinacy holds for the sets in $L(\mathbb{R})$ (see Jackson [1989]).

Theorem 2. *Assume* $\mathsf{ZFC} + \mathsf{AD}^{L(\mathbb{R})}$. *Then every projective set is* ω_ω*-Borel.*

Moving forward, in trying to develop the theory of definable objects from stronger set-theoretic axioms, there are two main directions to pursue. The first is to extend this theory of sets of reals and their associated ordinals further, and to to attempt to describe the entire cardinal structure of determinacy models. We might refer to this as extending the theory of "reals and ordinals." A second direction is to study more general types of objects, moving past those that be identified with sets in a Polish space or wellordered sets. Of course, the study of these more general definable objects encompasses the first direction, but the point is that we can advance the study of these more general objects without having the complete theory of the cardinals structure in hand.

In Section 2 we describe in a little more detail some of the progress in developing the theory of "reals and ordinals" and problems that are reasonably aligned with this program. We describe some of the recent progress various researchers have made, in particular using new techniques from inner model theory. This emerging area of "descriptive inner model theory" holds much promise for future progress in this area. We also mention some of the old questions and conjectures which are still around and which may serve as a benchmark for further progress. In Section 3 we consider some questions related to more general types of objects. Here we see an interesting and fascinating combinatorial structure beginning to emerge. The focus here is not so much on extending the theory to higher and higher pointclasses, but to understand how the new nature of these objects affects their combinatorial structure. Thus, we frequently consider problems at the Borel level, where the sets and functions used in the definitions of the objects are Borel, or even continuous/clopen. Recent years have seen a growing interest in this study of "Borel combinatorics" and its connections with other areas such as ergodic theory, geometric group theory, and descriptive set theory.

2 The theory of reals and ordinals

A well-known consequence of AD is that all sets of reals have the perfect set property, are measurable (with respect to any Borel measure), and have the Baire property. It follows that we have the Fubini theorem and its analog for category, the Kuratowski-Ulam theorem, for arbitrary sets $A \subseteq X \times Y$ in products of Polish spaces. We then also have full additivity of measure and category, that is, an arbitrary well-ordered union of meager (or measure 0) sets is meager (measure 0). In particular, from the perfect set property we have that there are only two possibilities for the cardinality of a set in reals in a determinacy model: countable and the size of the continuum. We note that one must be careful with the term "cardinality" in a model without AC as, for example a map from a set X onto a set Y does not necessarily yield a map from Y into X (in a model of AD there are maps from $\mathbb{R}$ onto any ordinal $\alpha < \Theta$, which is very large in the $\aleph_\beta$ hierarchy, but there is only an injection from α to $\mathbb{R}$ if α is countable). Nevertheless, if a set of reals contains a perfect set, then it is in bijection with $\mathbb{R}$.

The cardinal structure inside a model of determinacy is interesting and non-trivial. As we indicated before, the cardinal structure is closely connected with certain associated pointclasses. At the projective level, the ordinals associated to these classes are called the *projective ordinals*. More precisely, let

$$\delta^1_n = \delta(\mathbf{\Pi}^1_n) = \sup\{|\preceq| \colon \preceq \text{ is a prewellordering of } \omega^\omega \text{ in } \mathbf{\Delta}^1_n\}$$

where a prewellordering $\preceq$ is a reflexive, transitive, connected relation whose strict part $(x \prec y \leftrightarrow (x \preceq y) \wedge \neg(y \preceq x))$ is wellfounded and $|\preceq|$ denotes its length. The work of Kechris, Kunen, Martin, Moschovakis, and Solovay established the basic properties of the $\boldsymbol{\delta}^1_n$, and computed their values for $n \leq 4$ (these results can be found in A. S. Kechris [1978] of Jackson [2010]). The author computed their values for all n and described the structure of the cardinals below their supremeum (c.f. Jackson [1999] and Jackson [1988]). The Suslin cardinals below their supremum are the odd projective ordinals $\boldsymbol{\delta}^1_{2n+1}$ and their cardinal predecessors $\lambda^1_{2n+1} = (\boldsymbol{\delta}^1_{2n+1})^-$. The $\boldsymbol{\delta}^1_{2n+1}$-Suslin sets are the $\mathbf{\Sigma}^1_{2n+2}$ sets, and the λ^1_{2n+1}-Suslin sets are the $\mathbf{\Sigma}^1_{2n+1}$ sets. The cardinal structure below the supremum of the projective ordinals reveals some interesting and delicate patterns. The projective ordinals are all regular cardinals and the even ones are the successors of the odd ones, $\boldsymbol{\delta}^1_{2n+2} = (\boldsymbol{\delta}^1_{2n+1})^+$ (this was known from early work), and there are exactly $2^{n+1}-1$ many regular cardinals strictly between $\boldsymbol{\delta}^1_{2n+1}$ and $\boldsymbol{\delta}^1_{2n+3}$. The other cardinals between these two odd projective ordinals are all singular of cofinality one of these $2^{n+1} - 1$ cardinals. The values of the $\boldsymbol{\delta}^1_n$ can be computed exactly. The result is that $\boldsymbol{\delta}^1_{2n+1} = \omega_{e(2n-1)+1}$, where $e(0) = 1$ and $e(n+1) = \omega^{e(n)}$ (ordinal exponentiation). Also, the exact cofinalities of the cardinals below the projective ordinals can be computed (see Jackson and Khafizov [2016] and Jackson and Löwe [2013]). Figure 3 shows some of the cardinal structure below the projective ordinals. Note that the three regular cardinals between $\boldsymbol{\delta}^1_3$ and $\boldsymbol{\delta}^1_5$ are $\boldsymbol{\delta}^1_4 = \omega_{\omega+2}$, $\omega_{\omega\cdot 2+1}$, and $\omega_{\omega^\omega+1}$.

The detailed inductive analysis which provides the above mentioned analysis of cardinal cofinalities does not currently generalize to arbitrary levels of the Wadge hierarchy. While it does extend past the projective sets, likely to the first weakly inaccessible cardinal, it is known that the methods do not extend to the first "inductive like" pointclass (a non-selfdual pointclass closed under real quantification). Thus, some questions about cardinal cofinalities are still open past the projective hierarchy. To take an example, within

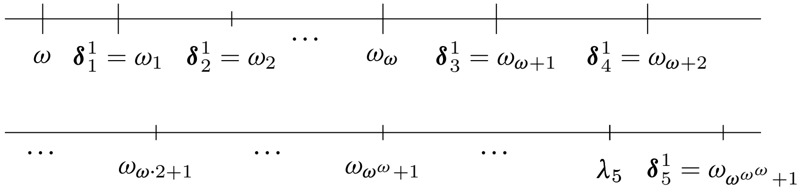

Figure 3: The cardinal structure below the projective ordinals.

the projective hierarchy there are never more than two regular cardinals in a row. Past the projective hierarchy, it is known that there can be three regular cardinals in a row (in Apter, Jackson, and B. Löwe [2013] this and stronger results are shown), however the evidence seems to suggest that there cannot be four in a row. This seems like a reasonable benchmark for understanding the cardinal structure, so we state:

Conjecture 3. Assuming AD, there does not exists a cardinal $\kappa < \Theta$ such that κ, κ^+, κ^{++}, and κ^{+++} are all regular.

Aside from the cofinalities of the cardinals, there are other interesting combinatorial properties of the cardinals which we may consider. One class of these concerns partition properties. In the Erdös-Rado partition notation we write $\kappa \to (\kappa)^\lambda$ if for all partitions $\mathcal{P} \colon \kappa^\lambda \to \{0,1\}$ of the increasing functions from λ to κ into two pieces, there is a set $H \subseteq \kappa$ of size κ and an $i \in \{0,1\}$ such that $\mathcal{P} \restriction H^\lambda = i$. The statement that all sets $A \subseteq \omega^\omega$ are Ramsey is the strong partition property for $\kappa = \omega$. This follows from AD^+, a technical strengthening of AD introduced by Woodin which has found many applications in determinacy theory (it is not known whether AD suffices for this result). Assuming AD, the cardinal analysis shows that all regular Suslin cardinals below the projective ordinals, which are just the $\boldsymbol{\delta}^1_{2n+1}$, have the strong partition property. This is also not known to extend to arbitrary levels, so we ask:

Conjecture 4. Assuming AD, every regular Suslin cardinal has the strong partition property.

It is shown in Jackson [2011] that for the (finitely many) regular cardinals κ between $\boldsymbol{\delta}^1_{2n+1}$ and $\boldsymbol{\delta}^1_{2n+3}$ we have $\kappa \to (\kappa)^{\boldsymbol{\delta}^1_{2n+1}}$, but $\kappa \not\to (\kappa)^{\boldsymbol{\delta}^1_{2n+2}}$. This leads to the following general problem.

Problem 5. Assume AD. Determine for each regular $\kappa < \Theta$ the λ such that $\kappa \to (\kappa)^\lambda$.

We close this section by results concerning three large cardinal notions interpreted in models of determinacy. Namely, we consider the notions of Jónsson cardinal, measurable cardinal, and supercompact cardinal. For $\kappa < \lambda < \theta$, we say that κ is λ-supercompact if there is a fine, normal measure ν on $\wp_\kappa(\lambda)$ (the subsets of λ of size less than κ). Here fine means that if $A \in \wp_\kappa(\lambda)$ then $\{B : B \supseteq A\}$ has ν measure one. Normal means that if $f : \wp_\kappa(\lambda) \to \lambda$ is such that $f(A) \in A$ for ν almost all A, then f is constant ν almost everywhere. Building on H. S. Becker and Jackson [2001] it is shown in Jackson [2001] that assuming AD^+ that every regular cardinal κ which is either a Suslin cardinal or the successor of a Suslin cardinal is λ-supercompact for all $\lambda < \Theta$. Again, this leads to a general problem:

Problem 6. Assume AD. For which regular κ and $\lambda > \kappa$ is κ λ-supercompact?

We say a cardinal κ is measurable if there is a non-principal, κ-complete ultrafilter μ of κ. We recall that assuming AD, every ultrafilter on a set is countably additive, that is, is a measure. It is not difficult to show that the regular Suslin cardinals are measurable, but for general regular cardinals the problem seems to require new methods. Specifically, methods of inner model theory have begun to play an important role in determinacy theory. In Steel [1995] Steel made an important breakthrough by using progress in inner model theory to analyze the inner model $\mathrm{HOD}^{L(\mathbb{R})}$ of $L(\mathbb{R})$ assuming a large cardinal/determinacy hypothesis, which Woodin improved to just assuming $\mathsf{AD}^{L(\mathbb{R})}$. A consequence of this analysis is:

Theorem 7 (Steel)**.** *Assume $\mathsf{AD} + V = L(\mathbb{R})$. Then every regular cardinal $\kappa < \Theta$ is measurable.*

As part of the HOD analysis, it is also shown that $\mathrm{HOD}^{L(\mathbb{R})}$ satisfies the GCH. Although this is a result about the model HOD, by "relativizing" it (i.e., using the fact that every set in $L(\mathbb{R})$ is definable from an ordinal and a real) we get:

Theorem 8 (Steel)**.** *Assume $\mathsf{AD} + V = L(\mathbb{R})$. Then for any $\kappa < \Theta$, any wellordered sequence of subsets of κ has length $< \kappa^+$.*

Again, the previous result was known to hold previously for Suslin cardinals κ. It is not known how to obtain either of the two previous theorems by direct determinacy arguments.

In a similar vein one can use the HOD analysis to prove a result concerning Jónsson cardinals. A cardinal κ is said to be Jonsson if for all $f : \kappa^{<\omega} \to \kappa$ there an $A \subseteq \kappa$ with $|A| = \kappa$ such that $f(A^{<\omega}) \neq \kappa$. Thus, the Jonsson property is a weak form of the partition property, weaker than being measurable. From the HOD analysis we get Jackson, Ketchersid, Schlutzenberg, and Woodin [2014]:

Theorem 9 (J, Ketchersid, Schlutzenberg, Woodin)**.** *Assume $\mathsf{AD}^{L(\mathbb{R})}$. Then every cardinal $\kappa < \Theta$ is Jónsson.*

Using additional arguments, Woodin has extended the last two theorems to models of AD^+. It remains open if these techniques can be extended to answer Conjectures 3, 4.

3 More general sets

In Section 2 we considered the problem of developing the theory of definable sets of reals and ordinals. The theory at the lower levels of the definability hierarchy seems fairly well established, though many interesting problems remain in extending this theory to higher levels. As we described, this theory is developed assuming stronger axioms than ZFC. In this section we consider the problem of developing the theory of more general types of sets. To motivate some of the basic objects of study, consider the model $L(\mathbb{R})$. In this model, every set $A \subseteq L_\Theta(\mathbb{R})$ is the surjective image of $\mathbb{R}$. Say $\pi : \mathbb{R} \to A$ is an onto map. This defines naturally an equivalence relation E on ω^ω, namely, $x\ E\ y$ iff $\pi(x) = \pi(y)$. It follows that A is in bijection with the quotient space $\mathbb{R}/\sim$. So, all of the sets in this model, at least those of rank $< \Theta$, can be identified with the set of equivalence classes (quotient space) of an equivalence relation on the Polish space $\mathbb{R}$. Thus, the collection of sets which can be represented as quotient spaces by equivalence relations on Polish spaces is a quite large collection, greatly extending the collection of sets which can be identified with a subset of a Polish space, or which can be wellordered (identified with an ordinal).

The simplest equivalence relations on Polish spaces are the *smooth* ones. We say (X, E) is smooth if there is a Borel map $f : X \to Y$, for some Polish space Y such that $x\ E\ y$ iff $f(x) = f(y)$. We can, of course, replace "Borel" with more liberal notions of definable, but in most cases this is a good stand-in for the more general case. In this case, the quotient space X/E can be identified with a subset of Y, namely the range of f. Conversely, any subset A of a Polish space X can be identified with the quotient space of a smooth equivalence relation on X. So, if (X, E) is smooth, or if the classes can be wellordered, then we are in the case of Section 2. So, from the point of view of introducing new types of definable objects, we consider these to be "trivial" equivalence relations.

One of the simplest non-trivial equivalence relations is the equivalence relation of eventual agreement on 2^ω known as E_0: $x\ E_0\ y$ iff $\exists n\ \forall m \geq n\ (x(m) = y(m))$. Note that the E_0 relation is a simple ($\mathbf{\Sigma}^0_2$) Borel equivalence relation. There is a natural action of the group $\mathbb{Z}$ on 2^ω called the odometer action which is defined by $1 \cdot x$ (1 being the generator $\mathbb{Z}$) is obtained by adding 1 to x viewed as an infinite binary expansion (with $x(0)$ being the least significant digit). This $\mathbb{Z}$ action is defined on all classes except $[\bar{0}]$ and $[\bar{1}]$, which are the constant 0 and 1 reals. The natural definition of the odometer map on the classes $[\bar{0}]$ and $[\bar{1}]$ amalgamates these two classes, but we can redefine the map on these two classes so that the $\mathbb{Z}$ action generates the E_0 equivalence relation, that is, $x\ E_0\ y$ iff $\exists n \in \mathbb{Z}\ (n \cdot x = y)$. The natural Bernoulli measure on 2^ω is invariant under this action (the redefinition on the two distinguished classes doesn't affect anything). It follows that there cannot be a Borel, or even measurable, *selector* for E_0, that is, a set S which meets every E_0 class in exactly one point. So, E_0 is not smooth. Of course, with AC one can form a selector by simply picking an element for each E_0 class, but this does not result in a definable set. This simple argument is just the standard Vitali argument for the construction of (non-definable) non-measurable set. From our current point of view, focusing on definable objects, the quotient space of E_0 is a new type of object, not given by a subset of a Polish space or an ordinal. This immediately raises a general question: what can we say about the structure of these definable equivalence relations on Polish spaces? As the above example shows, restricting the notion of definable to Borel still captures the main essence of the new phenomenon, and thus we led to the study of Borel equivalence relations on Polish spaces.

The motivation expressed in the above arguments for studying Borel equivalence relations is only one of many such possible. For example, classical dynamic can be viewed as the study of Borel actions of the group $\mathbb{Z}$ on Polish spaces, frequently equipped with other structure such an an invariant probability measure on X. From the point of view of "descriptive dynamics" however (a term likely coined by Kechris), we are not just interested in the structure up to measure zero sets, but rather what can be done everywhere in a definable (say Borel) manner. It is also of interest to restrict from Borel to continuous in many questions, that is, asking what can be done in continuous manner leads to interesting questions as well.

In the rest of this section we first give a brief (and selective) background on some results concerning Borel equivalence relations, and then describe some recent work on some problems in this area. We are particularly interested in problems concerning the combinatorial structure of these quotient spaces. We also mention some questions which arise when going past Borel equivalence relations to consider general equivalence relations in determinacy models.

If G is a group acting on the Polish space X, then there is an equivalence relation E_G, the *orbit equivalence relation*, associated to the action: $x \; E_G \; y$ iff $\exists g \in G \; (g \cdot x = y)$. The case of interest is when G is a Polish group (a topological group which is a Polish space in the group topology), and G acts in a Borel way on X (that is, the relation $R(g, x, y) \leftrightarrow g \cdot x = y$ is Borel). An important special of this is when G is a countable discrete group, in which case E_G is a *countable* Borel equivalence relation, that is, all of the E_G classes are countable. In the case of a general Polish group, the relation E_G need only be $\boldsymbol{\Sigma}^1_1$, though it is a fact that all of the individual orbits $[x]_{E_G}$ are Borel. When G is countable, E_G is Borel. Given any countable group G, a natural action is the (left) *shift action* of G on 2^G defined by $g \cdot x(h) = x(g^{-1}h)$. The is a natural action and is also important as it is essentially a universal action of G (we refer the reader to Dougherty, Jackson, and A. S. Kechris [1994] for details).

The theory largely splits in two directions: the case of general (uncountable) Polish groups, and the case where G is countable. Both directions are interesting. For example, the Polish group S_∞ of permutation of ω has a natural action, the *logic action* on the space of countable models of first-order theories (which can viewed as a Polish space). Various important questions in model theory/logic can be phrased as question about this Polish group action. One such question is the well-known Vaught conjecture on the number of models of a first-order theory (that is, is either countable or of size c), which can rephrased as a question about this action (we refer the reader to A. S. Kechris and H. Becker [1996] for details).

For the rest of this section we will focus on the case of countable G, which is illustrative of the general case and includes many cases of interest, particularly in relation to dynamics, ergodic theory, and some aspects of descriptive set theory (we note here that the degree notions of descriptive set theory such as Turing degree, arithmetical degrees, Δ^1_1 degrees, etc., all give countable equivalence relations). We refer the reader to Dougherty, Jackson, and A. S. Kechris [1994], Jackson, A. Kechris, and Louveau [2002], and A. S. Kechris and Miller [2004] for more general background.

The Feldman-Moore theorem Feldman and Moore [1977] is fundamental to the study of countable Borel equivalence relations.

Theorem 10. *Let E be a countable Borel equivalence relation on the Polish space X. then there is countable group G and a Borel action $G \curvearrowright X$ of G on X such that $E = E_G$.*

Thus, we may approach the study of countable Borel equivalence relations "group by group," starting with the algebraically simplest groups and progressing through groups of increasing complexity. Finite groups only generate finite equivalence relations, and these are smooth since there is a Borel linear order on X which we can use to select the least element from each class. The simplest infinite group is $\mathbb{Z}$. Since E_0 is given by a Borel action of $\mathbb{Z}$, these relations need not be smooth. A basic result of Slaman-Steel identifies these as the *hyperfinite* equivalence relations.

Definition 11. A countable Borel equivalence relation E is hyperfinite if $E = \bigcup_n E_n$ is the increasing union of finite equivalence relations (that is, each E_n class is finite).

The Slaman-Steel theorem (see Dougherty, Jackson, and A. S. Kechris [1994]) says that a countable Borel equivalence relation is hyperfinite iff there is a Borel ordering $<_X$ on X such restricted to each class, $<_X \restriction [x]$ is either finite or order-isomorphic to $\mathbb{Z}$. That is, we have in a uniform Borel manner put the structure of a $\mathbb{Z}$ ordering onto each equivalence class.

The fundamental notion in the theory of Borel equivalence relations is the notion of a reduction: we say $(X, E) \leq (Y, F)$ if there is a Borel $f : X \to Y$ such that for all $x, y \in X$, $x \mathrel{E} y \leftrightarrow f(x) \mathrel{F} f(y)$. This is saying that have in a definable way (in this case a Borel way) an injection from the quotient space X/E to Y/F. In other words, this corresponds to saying that X/E has a definable cardinality no larger than that of Y/F. Again, "Borel" can be viewed as a stand-in for other notions of definability; we could consider models of determinacy and allow arbitrary functions f. The Cantor-Schroeder-Bernstein theorem applies here, so if $(X, E) \leq (Y, F)$ and $(Y, F) \leq (X, E)$, then the quotient spaces are in bijection. A result of Dougherty, Jackson, and A. S. Kechris [ibid.] says that all non-smooth hyperfinite equivalence relations are Borel bi-reducible, so they all the same definable cardinality. A central result in the subject is the *Harrington-Kechris-Louveau* dichotomy theorem (see Harrington, A. S. Kechris, and Louveau [1990]). This theorem states that if the Borel equivalence relation (X, E) is not smooth, then $E_0 \leq (X, E)$. That is, there is nothing between the trivial (smooth) relations and the hyperfinite relations. In other words, E_0 is the smallest definable cardinal past those given as subsets of a Polish space (among those representable as Borel equivalence relations).

Two general questions are immediately suggested. The first involves understanding the definable cardinalities of these quotient spaces. That is, determine the structure of the reducibility relation among the family of Borel equivalence relations (or within the countable Borel equivalence relations). The second questions concerns the hyperfinite equivalence relations: which countable groups G generate hyperfinite equivalence relations. That is, which groups G have the property that if $G \curvearrowright X$ is a Borel action of G on the Polish space X, then the orbit equivalence relation E_G is hyperfinite? This hyperfiniteness question was first raised explicitly by Kechris and Weiss. The Connes-Feldman-Weiss theorem answers this question in the ergodic theory/dynamics perspective, that is, up to measure 0 sets with respect to an invariant probability measure μ on X. Their theorem says that if G is *amenable* then, up to a measure 0 set, the action is hyperfinite, and conversely, if all the Borel actions of G are hyperfinite up to a measure 0 set for some such measure, then G is amenable. So, if G is non-amenable then there are Borel actions of G which are not (everywhere) hyperfinite. The other direction is far from clear, and is an important open problem in the area.

Concerning the first problem, a result of Dougherty, Jackson, and A. S. Kechris [1994] shows there is a "largest" countable Borel equivalence relation in the sense that every countable Borel equivalence relations reduces to it. This is given by the shift action of the group F_2 on 2^{F_2} (F_2 here is the free group on 2 generators). While it is not too difficult to show that there are incomparable Borel equivalence relations, the corresponding result for countable Borel equivalence relations was open for a significant time. Finally, A. S. Kechris and Adams [2000] resolved this problem using techniques from Zimmer's superrigidity theory in ergodic theory. They showed that there is a large family (of size continuum) of pairwise incomparable countable Borel equivalence relations. This result was strengthened by Hjorth. In Miller [n.d.] an elegant simplified presentation of some of these results can be found.

We mention the best currently known results on the hyperfiniteness problem. First, Weiss showed (unpublished, but see Jackson, A. Kechris, and Louveau [2002]) the following.

Theorem 12 (Weiss)**.** *All equivalence relations generated by a Borel action of* $\mathbb{Z}^n$ *are hyperfinite.*

Next, Gao and the author extended the result to general abelian groups:

Theorem 13 (Gao and Jackson [2015])**.** *All equivalence relations generated by a Borel action of a countable abelian group are hyperfinite.*

The method used to prove Theorem 13 is quite different from that of Theorem 12. Both proofs employ heavily the use of certain *marker structures* on the equivalence relation. By a marker structure we mean a Borel set $M \subseteq X$ which is complete (meets every equivalence class) and co-complete (its complement is complete). For the proofs, it is necessary to create marker structures with certain delicate geometric properties. Thus, some of the fundamental questions in this area are closely connected with the question of what types of marker structures we can put (in a Borel manner) on the equivalence relation. For the proof of Theorem 13, the notion of an *orthogonal* marker structure was introduced. This roughly says that the marker points M give a decomposition of the points in an equivalence class into rectangular regions such that any two parallel faces of nearby regions are separated by a certain fixed positive fraction of the side lengths. The technology used in this proof has other applications. For example, it allows us to show that there is a *continuous* embedding from $2^{\mathbb{Z}^n}$ (with the shift action) into E_0 (the fact that there is a Borel action follows from the shift action on $2^{\mathbb{Z}^n}$ being hyperfinite). It also allows us to show that the Borel chromatic number of $F(2^{\mathbb{Z}^n})$ is 3 (we discuss this more below), and answer other combinatorial structuring questions.

Theorem 13 was extended further by Schneider and Seward who extended the result to nilpotent groups, and in fact showed the following.

Theorem 14 (Schneider and Seward [n.d.])**.** *All equivalence relations generated by the action of a locally nilpotent group are hyperfinite.*

By a an important result of Gromov in geometric group theory, the class of finitely generated groups which have a nilpotent subgroup of finite index (the virtually nilpotent groups) coincides with the class of finitely generated groups of polynomial growth. We note that Theorem 14 for the case of finitely generated nilpotent groups (or finitely generated virtually nilpotent groups) was known previously, a result of Jackson, A. Kechris, and Louveau [2002]. This suggested the possibility that polynomial growth was the barrier to extending these hyperfiniteness results. However, in recent as yet unpublished work, Conley, Marks, Seward, Tucker-Drob, and the author have shown that there are finitely generated solvable, non-nilpotent (so not of polynomial growth) groups all of whose Borel actions are hyperfinite. Whether these arguments can be made to extend to all elementary amenable groups, or even all amenable groups, is not yet known.

Aside from the above questions concerning the cardinalities of the quotient spaces X/E, we are interested in questions about the combinatorial structure of these sets. We can ask these types of question at either the definable level, where we usually use "Borel" as a representative case, or at the topological level. Roughly speaking, in the latter case, we require the types of structures we are considering to be given in a continuous manner. As we said above, the hyperfiniteness arguments require certain types of marker structures, but there are many other kinds of structuring questions we can ask.

The notion of a continuous or Borel "structuring" of the countable Borel equivalence relation E can be made precise in a natural manner. If $\mathfrak{L} = (c_i, R_i, f_i)$ is a language of first-order logic, by an $\mathfrak{L}$-structuring of E we mean an assignment $[x] \mapsto \mathfrak{A}_x$ of $\mathfrak{L}$-structures $\mathfrak{A}_x$ to the equivalence classes of E, where the domain of the structure $\mathfrak{A}_x$ is the equivalence class $[x]$. If $E = E_G$ for some action of the group G, then we frequently also assume that there are unary function symbols f_g in the language $\mathfrak{L}$ for each group element $g \in G$ (these are intended to represent the function $f_g(x) = g \cdot x$). The notion of the structuring being Borel (or continuous) is defined in a natural manner (e.g., for each n-ary relation symbol R_i of $\mathfrak{L}$, the relation

$$R(x_1, \dots, x_n) \leftrightarrow x_1 \; E \; x_2 \cdots E \; x_n \wedge \mathfrak{A}_{[x_1]}(x_1, \dots, x_n)$$

is a Borel (or clopen) relation on X^n. We can then, for example, ask if Borel or continuous structurings of E exists with the structures $\mathfrak{A}_x$ satisfying certain properties (for example, if they satisfy a certain formula of first-order, or higher-order, logic).

Many types of interesting combinatorial questions can be phrased as instances of structuring questions. Consider a fixed countable group G. Given actions $G \curvearrowright X$ and $G \curvearrowright Y$ generating equivalence relations E_X and E_Y, we say $f : X \to Y$ is *equivariant* if f commutes with the actions, that is, $f(g \cdot x) = g \cdot f(x)$ for all $x \in X$. A one-to-one equivariant map is necessarily a reduction from E_X to E_Y. By a subshift of finite type we mean a closed, invariant (under the shift action) $Y \subseteq k^G$ for some $k \in \mathbb{N}$ which is defined by a finite set $p_1, \dots, p_t$ of "forbidden" patterns. Here a pattern is partial function $p : G \to k$ with finite domain. Then $y \in k^G$ is in the subshift Y determined by the p_i (with say $D_i = \mathrm{dom}(p_i)$) if for all $g \in G$, the function $p_g : D_i \to k$ given by $p_g(h) = g \cdot y(h)$ is not equal to any of the p_i. Asking if there is an equivariant map from E_X to the subshift Y is an instance of a structuring question. Subshift questions of this form are themselves quite general and include several interesting types of questions. We consider a few of these types of questions and some recent results concerning them.

If G is a marked group, that is, comes with a distinguished set of generators S (which does include the identity e), then there is a graphing $\Gamma(E_G)$ of the orbit equivalence relation E_G for any action $G \curvearrowright X$ given by $x \Gamma(E_G) y$ iff $\exists s \in S \; (s \cdot x = y \vee s \cdot y = x)$. If the action is free, then on each equivalence class this graphing is isomorphic to the

Cayley graph associated to (G, S). The *Borel chromatic number*, $\chi_b(E_G)$ of the equivalence relation is the least cardinal k such that there is a Borel map $c\colon X \to k$ which is a chromatic coloring of the graph $\Gamma(E_G)$. We likewise define the *continuous chromatic number* $\chi_c(E_G)$, using continuous functions f. The study of definable chromatic numbers was initiated by Kechris, Solecki, and Todorcevic in A. S. Kechris, Solecki, and Todorcevic [1999]. One of their basic results is that the Borel chromatic number satisfies $\chi_b(E_G) \leq d+1$, where d is the vertex degree of the Cayley graph, for any E_G generated by a free action of G. We refer to the determination of $\chi_c(E_G)$ and $\chi_b(E_G)$ as the chromatic number problem. This is an instance of the more general *subshift problem*, which is determine for which subshifts $Y \subseteq k^G$ (determined by k and the patterns $p_1, \dots, p_t$) there is a continuous or Borel equivariant map from E_G to Y. Another instance of the subshift problem is the *graph homomorphism problem*. Given a countable graph Γ, this problem is to determine whether there is a continuous or Borel graph homomorphism from $\Gamma(E_G)$ to Γ. Finally, we mention the *tiling problem*. By a tile we mean a finite set $T \subseteq G$. Given a finite set $T_1, \dots, T_\ell$ of tiles, the tiling problem asks whether there is a continuous or Borel tiling of E_G. By this we mean Borel sets $A_i \subseteq X$ such that the sets $\{T_i \cdot g\colon g \in A_i\}$ partition X (a "continuous" tiling means that the A_i are clopen sets in X). There are many other types of structuring questions one can ask, but these serve as test questions for the type of definable structures we can put on the equivalence classes. While these questions are of interest for general countable groups, let us now restrict our attention to simpler groups.

Consider the groups $G = \mathbb{Z}^n$. As we said above, all of these groups induce only hyperfinite actions. Nevertheless, structuring questions about the equivalence relations generated by actions of these groups are non-trivial. Perhaps even more surprising, given the fact that all of these shift spaces $2^{\mathbb{Z}^n}$ continuously embed into E_0, is that some continuous structuring questions have answers that depend on n.

We mentioned above the method of orthogonal markers, which has been used in recent hyperfiniteness proofs. This method is normally used in a "positive" sense, that is, to produce Borel structurings on various types in the equivalence relations E_G. Another method which has been used to obtain negative results in the continuous setting is the method of *hyperaperiodic* points. The notion of hyperaperiodic point was introduced by Gao, Seward, and the author in Gao, Seward, and Jackson [2009] and also independently by Glasner and Uspenskij. Consider the shift space 2^G. We say $x \in 2^G$ is a hyperaperiodic point if $\overline{[x]} \subseteq F(2^G)$, that is, the closure of the orbit of x lies entirely in the free part of 2^G. This definition can be reformulated as a purely combinatorial property of x. Namely, $x \in 2^G$ is hyperaperiodic iff it satisfies the following: for any $s \in G$ with $s \neq e$, there is a finite $T \subseteq G$ such that

$$\forall g \in G\ \exists t \in T\ (x(gt) \neq x(gst)).$$

This combinatorial property is sometimes referred to as x being a "2-coloring." Hyperaperiodic elements are easy to construct for simple groups such as $\mathbb{Z}^n$, however the following result of Gao, Seward, and Jackson [ibid.] states that they exist for any countable group.

Theorem 15 (Gao, Seward, and Jackson [ibid.]). *For every countable group G there is an $x \in 2^G$ which is a hyperaperiodic point.*

Hyperaperiodic points are useful since $\overline{[x]}$ is a compact set contained within the free part of 2^G, and this permits certain compactness arguments. However, to prove some more delicate results it is necessary to construct hyperiodic points with various addition properties. To illustrate the use of the orthogonal marker and hyperaperiodic element arguments, consider the Borel and continuous chromatic number problems for $F(2^{\mathbb{Z}^n})$. An easy category argument shows that $\chi_b(F(2^{\mathbb{Z}^n}) > 2$ for all n. Also, any easy argument using the existence of clopen marker sets (see Gao and Jackson [2015]) which are roughly d-spaced (for any $d > 1$) shows that $\chi_c(F(2^{\mathbb{Z}})) \leq 3$. It follows that in the $n = 1$ case we have $\chi_b(F(2^{\mathbb{Z}})) = \chi_c(F(2^{\mathbb{Z}})) = 3$. For $n \geq 2$, the arguments require the new methods. The result, from Gao, Jackson, Krohne, and Seward [n.d.], is the following.

Theorem 16 (Gao, J, Krohne,Seward). *For any $n \geq 2$ we have:*

$$3 = \chi_b(F(2^{\mathbb{Z}^n})) < \chi_c(F(2^{\mathbb{Z}^n})) = 4.$$

This result has two points of interest. First, it shows a difference between the dimension $n = 1$ and $n \geq 2$ cases, even though both equivalence relations are hyperfinite. Second, it shows a difference between the continuous and Borel versions of the question.

The proof of Theorem 16 was first first accomplished by the construction of a particular hyperaperiodic point. The basic idea was to construct $x \in 2^{\mathbb{Z}^n}$ with certain periodicity requirements in one direction, but yet keeping the point hyperaperiodic. This is possible as $n \geq 2$. Later, Gao, Krohne, Seward, and the author proved a general theorem applicable to general subshift questions. The theorem (see Gao, Jackson, Krohne, and Seward [ibid.]) reduces the subshift question for $F(2^{\mathbb{Z}^n})$ down to a question about a family of finite graphs. Consider the case $n = 2$. For each $1 \leq n < p, q$ we define a finite graph $\Gamma_{n,p,q}$. The graph is obtained by starting with 12 individual "grid-graphs." by a grid-graph we mean a graph which is isomorphic to a finite rectangular region of $\mathbb{Z}^2$ with edges inherited from the Cayley graphing of $\mathbb{Z}^2$. Certain vertices are identified among the vertices in these grid-graph, and the quotient graph is $\Gamma_{n,p,q}$. To give the reader a feel for the construction we show three of the grid graphs in Figure 4 (each of the other graphs comprising $\Gamma_{n,p,q}$ is similar to one of these). In each of these grid-graphs, certain rectangular subregions are marked with labels such as $R_\times$, R_a, etc. In the graph $\Gamma_{n,p,q}$ the corresponding points within regions with the same label are identified. For example, the upper-left points of each $R_\times$ region are identified in forming $\Gamma_{n,p,q}$.

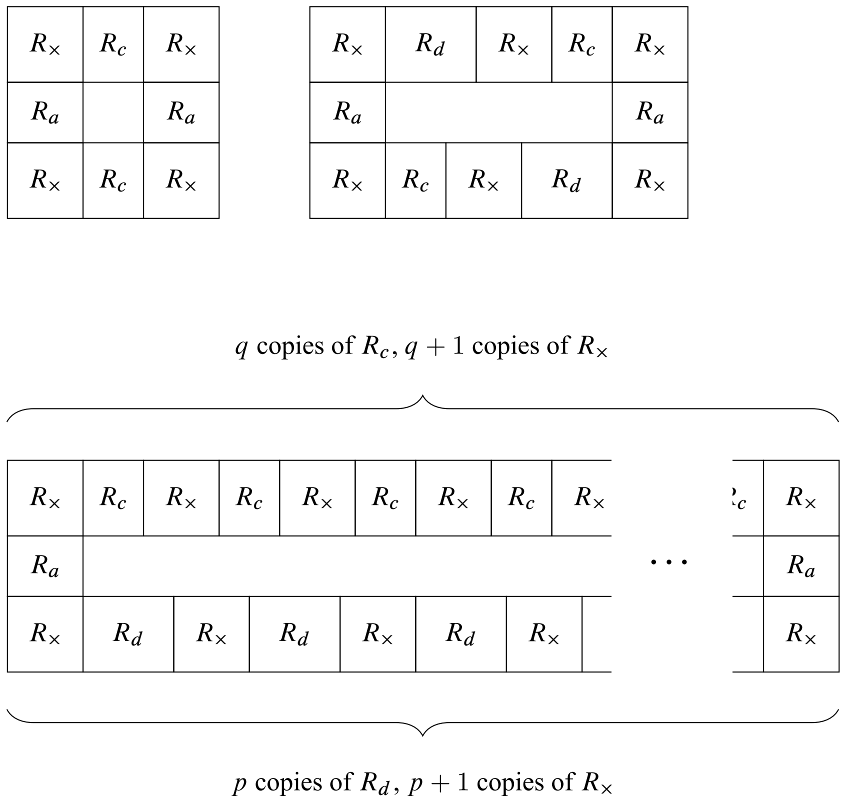

Figure 4: The grid-graphs in $\Gamma_{n,p,q}$.

The following result of Gao, Jackson, Krohne, and Seward [n.d.] shows that a subshift question for $F(2^{\mathbb{Z}^n})$ reduces to question about the graph $\Gamma_{n,p,q}$.

Theorem 17. *Let $Y \subseteq k^{\mathbb{Z}^2}$ be a subshift of finite type described by $(k; p_1, \dots, p_t)$. Then the following are equivalent.*

1. *There is a continuous, equivariant map $f\colon F(2^{\mathbb{Z}^2}) \to Y$.*
2. *There are positive integers n, p, q with $n < p, q$, $(p, q) = 1$, and $n \geq \max\{a_i, b_i : dom(p_i) = [0, a_i) \times [0, b_i)\} - 1$ and a $g\colon \Gamma_{n,p,q} \to k$ which respects Y.*
3. *For all $n \geq \max\{a_i, b_i : dom(p_i) = [0, a_i) \times [0, b_i)\} - 1$, for all sufficiently large p, q with $(p, q) = 1$ there is a $g\colon \Gamma_{n,p,q} \to k$ which respects Y.*

In this theorem, when we say $g\colon \Gamma_{n,p,q} \to k$ respects the subshift y we mean that in any $a_i \times b_i$ rectangular subregions R of one of the grid-graphs forming $\Gamma_{n,p,q}$, $g \restriction R$ is not equal to p_i. In other words, we can find a continuous equivariant map from $F(2^{\mathbb{Z}^2})$ into the subshift $Y \subseteq k^{\mathbb{Z}^2}$ iff we can find such a map from $\Gamma_{n,p,q} \to k$ for some p, q with $(p, q) = 1$ (equivalently, if we can such maps g for all sufficiently large p, q with $(p, q) = 1$).

Using this result, a number of subshift questions can be answered for $F(2^{\mathbb{Z}^n})$. Moreover, some general results about the decidability of the subshift problem in general can be shown which highlight a key difference between the dimension $n = 1$ and $n \geq 2$ cases. A subshift Y is coded by a finite sequence $(k; p_1, \ldots, p_t)$, which can be viewed as an integer. Let Y_m be the subshift coded by the integer m. Consider the set $S(n)$ of $m \in \omega$ such that there is a continuous, equivariant map from $F(2^{\mathbb{Z}^n})$ to Y_m. From Theorem 17 it follows that for each n the set $S(n)$ is computably enumerable, that is, is a Σ^0_1 set. The question we consider is whether this set is actually computable (i.e., a Δ^0_1 set). We have the following result of Gao, Jackson, Krohne, and Seward [ibid.].

Theorem 18. *For $n = 1$, the subshift problem is decidable, that is, $S(1)$ is computable. For $n \geq 2$ the subshift problem is not computable.*

Theorem 18 shows a remarkable difference between the shift actions of $\mathbb{Z}$ and $\mathbb{Z}^n$ for $n \geq 2$. In Gao, Jackson, Krohne, and Seward [ibid.] it is further shown that even the specific graph homomorphism problem for $F(2^{\mathbb{Z}^n})$ is not computable for $n \geq 2$.

The above results are for the shift actions of the groups $\mathbb{Z}^n$. Let us mention a result of a similar flavor but for a completely different class of groups. this result, obtained by Marks [2016] concerns the free product of groups. The result is:

Theorem 19 (Marks). *If G, H are finitely generated marked groups, then*

$$\chi_b(F(2^{G*H})) \geq \chi_b(F(2^G) + \chi_b(F(2^H)) - 1.$$

where $F(2^G)$ denotes the free part of the shift action of G on 2^G and $G * H$ denotes the free product of the groups G and H (the statement of Theorem 19 above actually incorporates an improvement of the result due to Seward and Tucker-Drob). What is interesting is that Marks' method in proving this result involves games and Borel determinacy (a result due to Martin). This surprising result introduces yet another new technique into the subject.

In this section we have been mainly concerned with objects given by Borel equivalence relations on Polish spaces. Although Borel is frequently taken as a representative of definable, let us finally return to considering general sets in a model determinacy. Woodin [2006] has shown an interesting result about cardinalities in determinacy models which shows that the exact determinacy hypotheses assumed may be important. Woodin shows that assuming $\mathsf{AD}_{\mathbb{R}}$, the axiom of real game determinacy (which is considerably stronger than AD or AD^+), there are exactly 5 cardinals below the set ω_1^ω. He also shows that there are more than 5 cardinals below this set if one assumes $\mathsf{AD} + \neg\mathsf{AD}_\mathbb{R}$. This surprising result shows that for some sets, questions about their definable structure may depend on the background axioms assumed.

The results we have discussed show that a very rich theory of definable sets is emerging, and is connected with many other areas of mathematics. We believe this will continue to be an interesting and fruitful line of investigation.

DECIDABILITY IN LOCAL AND GLOBAL FIELDS

Jochen Koenigsmann

Abstract

This lecture highlights some recent advances on classical decidability issues in local and global fields.

Contents

1 Introduction

In 1900, at the International Congress of Mathematicians in Paris, Hilbert presented his celebrated and influential list of 23 mathematical problems (Hilbert [1900]). One of them is

Hilbert's 10th Problem (H10) Find an algorithm which gives on INPUT any $f(X_1, \ldots, X_n) \in \mathbb{Z}[X_1, \ldots, X_n]$

$$\text{OUTPUT} \begin{cases} \textbf{YES} & \text{if } \exists \overline{x} \in \mathbb{Z}^n \text{ such that } f(\overline{x}) = 0 \\ \textbf{NO} & \text{else} \end{cases}$$

Hilbert did not ask to prove that there is such an algorithm. He was convinced that there should be one, and that it was all a question of producing it — one of those instances of

MSC2010: primary 11U05; secondary 03B25, 11F85, 12J10, 12L05.

Hilbert's optimism reflected in his famous slogan '*wir müssen wissen, wir werden wissen*' ('*we must know, we will know*'). As it happens, Hilbert was too optimistic: after previous work since the 50's by Martin Davis, Hilary Putnam and Julia Robinson (cf., e.g., Davis, Putnam, and J. Robinson [1961]), Yuri Matiyasevich showed in 1970 that there is no such algorithm (Y. V. Matiyasevich [1970b]). The key result here is the most remarkable so-called DPRM-Theorem that every (algorithmically) listable set of integers is *diophantine*, i.e., first-order definable in the language of rings $L_{ring} := \{+, \times, 0, 1\}$ by an *existential* formula.

The original formulation of Hilbert's 10th Problem was weaker than the standard version above in that he rather asked *'Given a polynomial f, find an algorithm ...'*. So maybe you could have different algorithms depending on the number of variables and the degree. Yet it is even possible to find a single polynomial for which no such algorithm exists — this is essentially because there are universal Turing Machines.

One should, however, mention that, in the special case of $n = 1$, that is, for polynomials in one variable, there is an easy algorithm: if, for some $x \in \mathbb{Z}$, $f(x) = 0$ then $x \mid f(0)$; hence one only has to check the finitely many divisors of $f(0)$. Similarly, by the effective version of the Hasse-Minkowski-Local-Global-Principle for quadratic forms and some extra integrality considerations, one also has an algorithm for polynomials in an arbitrary number of variables, but of total degree ≤ 2. And, even if there is no general algorithm, it is one of the major projects of computational arithmetic geometry to exhibit other families of polynomials for which such algorithms exist.

Let us point in a different direction of generalizing Hilbert's 10th Problem, namely, generalizing it to rings other than $\mathbb{Z}$: If R is an integral domain, there are two natural ways of generalizing **H10**:

H10/R = **H10** with the 2nd occurrence of $\mathbb{Z}$ replaced by R
H10$^+$/R = **H10** with both occurrences of $\mathbb{Z}$ replaced by R

Observation 1.1. *Let R be an integral domain whose field of fractions does not contain the algebraic closure of the prime field ($\mathbb{F}_p$ resp. $\mathbb{Q}$). Then*

$$\begin{aligned} \mathbf{H10}/R \text{ is solvable } &\Leftrightarrow \mathtt{Th}_{\exists^+}(R) \text{ is decidable} \\ \mathbf{H10}^+/R \text{ is solvable } &\Leftrightarrow \mathtt{Th}_{\exists^+}(\langle R; r \mid r \in R\rangle) \text{ is decidable,} \end{aligned}$$

where $\mathtt{Th}_{\exists^+}$ denotes the positive existential theory consisting of existential sentences where the quantifier-free part is a conjunction of disjunctions of polynomial equations (no inequalities).

Note that the language on the right hand side of the 2nd line contains a constant symbol for each $r \in R$.

Proof: '$\Leftarrow$' is obvious in both cases. For '$\Rightarrow$' one has to see that a disjunction of two polynomial equations is equivalent to (another) single equation, and, likewise, for conjunctions: By our assumption we can find some monic $g \in \mathbb{Z}[X]$ of degree > 1 which is irreducible over R. Then, for any polynomials f_1, f_2 over $\mathbb{Z}$ resp. R and for any tuple $\overline{x}$ over R,

$$f_1(\overline{x}) = 0 \vee f_2(\overline{x}) = 0 \iff f_1(\overline{x}) \cdot f_2(\overline{x}) = 0$$
$$f_1(\overline{x}) = 0 \wedge f_2(\overline{x}) = 0 \iff g\left(\frac{f_1(\overline{x})}{f_2(\overline{x})}\right) \cdot f_2(\overline{x})^{\deg g} = 0$$

□

Since in fields, inequalities can be expressed by a positive existential formula ($f(\overline{x}) \neq 0 \leftrightarrow \exists y \;\, f(\overline{x}) \cdot y = 1$), we immediately obtain the following:

Corollary 1.2. *Let K be a field not containing the algebraic closure of the prime field. Then*

$$\textbf{H10}/K \textit{ is solvable } \Leftrightarrow \mathtt{Th}_{\exists}(K) \textit{ is decidable.}$$

In fact, the same is true for $\mathcal{O}_K$, the ring of integers of a number field K:

Observation 1.3. *If K is a number field,*

$$\mathcal{O}_K \models \forall x[x \neq 0 \leftrightarrow \exists y \; x \mid (2y-1)(3y-1)].$$

Hence $\mathtt{Th}_{\exists}(\mathcal{O}_K) = \mathtt{Th}_{\exists^+}(\mathcal{O}_K)$.

One of the biggest open questions in the area is

Question 1.4. *Is* **H10**$/\mathbb{Q}$ *solvable?*

Let us recall that, by the ground breaking work of Kurt Gödel, the full first order theory of $\mathbb{Z}$ is undecidable, so there is no algorithm which decides, on INPUT any first-order L_{ring}-sentence ϕ, whether or not ϕ holds in $\mathbb{Z}$ (cf. Gödel [1931]). J. Robinson [1949] managed to find an L_{ring}-first-order definition of $\mathbb{Z}$ in $\mathbb{Q}$, thus showing, via Gödel's Theorem, that the full first-order theory of $\mathbb{Q}$ is also undecidable. If one had an *existential* first-order L_{ring}-formula defining $\mathbb{Z}$ in $\mathbb{Q}$ then one could, via Matiyasevich's Theorem, conclude that Hilbert's 10th Problem over $\mathbb{Q}$ is also unsolvable. However, the best we have at the moment (in terms of logical complexity) is a *universal* formula for $\mathbb{Z}$ in $\mathbb{Q}$ (cf. Theorem 3.1 below).

Hilbert's 10th Problem for the ring of integers of a number field (that is, a finite extension of $\mathbb{Q}$ — they are the *global* fields of characteristic 0) has been shown to be unsolvable in several cases, the general case could sofar only be proven modulo a (widely believed) conjecture regarding elliptic curves (see section 3.2).

For global fields of positive characterisitc, that is, for finite extensions of the rational function field $\mathbb{F}_p(t)$ over the finite field $\mathbb{F}_p$ in one variable t, Hilbert's 10th Problem, again, has no solution (cf. section 3.3).

Many of the results obtained for global fields rely heavily on results and techniques developed for *local fields*. Local fields are defined to be fields F which are locally compact with respect to the topology induced by some non-trivial absolute value on F. It turns out that local fields are precisely the completions of global fields (w.r.t such absolute values) and they are classified as follows: the *archimedean* local fields are just the field $\mathbb{R}$ of real numbers and the field $\mathbb{C}$ of complex numbers; the non-archimedean local fields of characteristic 0 are precisely all finite extensions of $\mathbb{Q}_p$, the field of *p-adic numbers*, where p is any rational prime; and the non-archimedean local fields of positive characteristic p are precisely the finite extensions of $\mathbb{F}_p((t))$, the field of formal Laurent series over the field $\mathbb{F}_p$ with p elements. For the non-archimedean local fields, the absolute value is induced by a canonical valuation, which is the p-adic valuation on $\mathbb{Q}_p$ and the t-adic valuation on $\mathbb{F}_p((t))$, and these valuations extend uniquely to all finite extensions, a property of valuations called *henselian*.

All decidability issues for the two archimedean local fields have been settled by Tarski in the 1930s: The full first order theory of $\mathbb{R}$ and of $\mathbb{C}$ is decidable (and hence, in particular, Hilbert's 10th Problem is solvable for those two fields).

The decidability of $\mathbb{Q}_p$ was proved independently by Ax and Kochen [1965] and by Eršov [1965]. They effectively axiomatized $\mathbb{Q}_p$ as a henselian valued field of characteristic 0 whose residue field is $\mathbb{F}_p$, whose value group is a $\mathbb{Z}$-group (so elementarily equivalent to the ordered abelian group of integers) such that the value of p is minimal positive. And there are similar axiomatizations for all finite extensions of $\mathbb{Q}_p$ (see Prestel and Roquette [1984] for a general treatment of p-adic fields).

Since those results of Ax-Kochen and Ershov in 1965 it has been a big open problem whether the theory of $\mathbb{F}_p((t))$ is decidable as well. Recently major progress has been made on this problem which we will discuss in section 2 below.

There are several important infinite extension of local and global fields for which decidability issues are of great interest, too. For example, the field $\mathbb{Q}^{ab}$, the maximal Galois extension of $\mathbb{Q}$ with an abelian Galois group which, by the famous Kronecker-Weber Theorem, is just the field obtained from $\mathbb{Q}$ by adjoining all roots of unity, is not known to be decidable or undecidable. Similarly, one does not know this about $\mathbb{Q}^{solv}$, the maximal Galois extension of $\mathbb{Q}$ with prosolvable Galois group which is obtained from $\mathbb{Q}$ by iteratedly adjoining radicals (n-th roots of elements for arbitrary n). It is an open problem in Field Arithmetic whether or not $\mathbb{Q}^{solv}$ is pseudo-algebraically closed in the sense that every absolutely irreducible curve defined over $\mathbb{Q}^{solv}$ has a $\mathbb{Q}^{solv}$-rational point (Problem 11.5.9(a) in Fried and Jarden [2008]). If this Problem has a positive answer and if the famous Shafarevich Conjecture that the absolute Galois group of $\mathbb{Q}^{ab}$ is a free profinite group is true then one can show that $\mathbb{Q}^{solv}$ is decidable.

In section 4 we will briefly consider two infinite extensions of $\mathbb{Q}_p$ for which there has been recent progress, namely $\mathbb{Q}_p^{ur}$, the maximal unramified extension of $\mathbb{Q}_p$ which turns out to be decidable and model theoretically well behaved, and $\mathbb{Q}_p^{ab}$, the maximal abelian extension of $\mathbb{Q}_p$, for which a promising new suggestion for a first-order axiomatization will be presented.

Some notation from valuation theory: The reader is expected to be acquainted with the basics of valuation theory (cf., e.g., Engler and Prestel [2005]). For a valued field (K, v), the valuation ring will be denoted by $\mathcal{O}_v$, the residue field by Kv and the value group by vK.

2 Local fields of positive characteristic

Regarding the question of decidability of the field $\mathbb{F}_q((t))$ of formal Laurent series over a finite field $\mathbb{F}_q$ there have been two recent breakthroughs: one is the result of Anscombe-Fehm that the *existential* L_{ring}-theory of $\mathbb{F}_q((t))$ is decidable (Theorem 2.1). The other is a new promising suggestion for an effective first order axiomatization for $\mathbb{F}_q((t))$ using the notion of *extremal valued fields*.

Throughout this section we will fix q, a power of the rational prime $p > 0$.

2.1 The existential theory of $\mathbb{F}_q((t))$. In Denef and Schoutens [2003], Jan Denef and Hans Shoutens managed to prove that the *existential* theory of $\mathbb{F}_q((t))$ in $L_{ring} \cup \{t\}$, the language of rings augmented by a constant symbol for t, is decidable if one assumes resolution of singularities in positive characteristic. Sylvy Anscombe and Arno Fehm then found a surprisingly elementary unconditional proof for the decidability of the existential L_{ring}-theory of $\mathbb{F}_q((t))$ (see S. Anscombe and Fehm [2016]). More generally they prove the following

Theorem 2.1. *Let (K, v) be an equicharacteristic henselian valued field (so char $K =$ char Kv). Then the existential L_{val}-theory of K is decidable if and only if the existential L_{ring}-theory of the residue field Kv is decidable.*

Here $L_{val} = L_{ring} \cup \{\mathcal{O}\}$ is the language of valued fields, that is, the language of rings augmented by a unary predicate symbol $\mathcal{O}$ for the valuation ring. There are many alternative possibilities for a first order language for valued fields (you could, for example, have a three-sorted language distinguishing the field sort, the residue field sort and the value group sort with additional function symbols for the valuation map and the canonical restriction map to the residue field). But it turns out that all these languages are mutually translatable into each other, so they all have the same expressive power.

Let us point out that, for the question of the decidability of the existential theory of $\mathbb{F}_q((t))$, it makes no difference whether you ask this question about the existential theory in L_{ring} or in L_{val}, because, by the main theorem of W. Anscombe and Koenigsmann [2014], the valuation ring $\mathbb{F}_q[[t]]$ of $\mathbb{F}_q((t))$ is existentially first-order definable in the language of rings. This leads immediately to the following

Corollary 2.2. *The existential L_{ring}-theory of $\mathbb{F}_q[[t]]$ is dedicable.*

So, in other words, Hilbert's 10th Problem has a positive solution both for $\mathbb{F}_q((t))$ and for $\mathbb{F}_q[[t]]$.

A more general result on almost existential definability of henselian valuation rings in valued fields with finite or pseudo-finite residue fields can be found in Cluckers, Derakhshan, Leenknegt, and Macintyre [2013].

Whether or not the existential $L_{ring} \cup \{t\}$-theory of $\mathbb{F}_q((t))$ is decidable (without assuming resolution of singularities) is still open.

2.2 Axiomatizing $\mathbb{F}_q((t))$. The biggest open question in the model theory of valued fields, however, is the question whether the full first-order theory of $\mathbb{F}_q((t))$ is decidable. There have been a number of suggestions of how to axiomatize this field. The most promising suggestion builds on the notion of *extremal* valued fields, originally introduced (though with a 'wrong' definition) by Ershov [2004], then, following a suggestion of Sergei Starchenko, the definition was amended and the 'correct' definition was put forward in Ershov [2009] and in Azgin, Kuhlmann, and Pop [2012]. The suggested axiomatization for $\mathbb{F}_q((t))$ given below first appeared in S. Anscombe and Kuhlmann [2016].

Definition 2.3. *A valued field (K, v) is* extremal *if, for every polynomial $f(X_1, \ldots, X_n) \in K[X_1, \ldots, X_n]$, the set*

$$\{v(f(a_1, \ldots, a_n)) \mid a_1, \ldots, a_n \in \mathcal{O}_v\} \subseteq vK \cup \{\infty\}$$

has a maximal element.

It turns out that extremal valued fields are *algebraically maximal*, that is, for each finite extension $(L, w)/(K, v)$, the fundamental equality '$n = e \cdot f$' holds, where $n = [L : K]$, $e = [wL : vK]$ and $f = [Lw : Kv]$, and so, in particular, extremal fields are henselian. Moreover, their value group is either divisible or a $\mathbb{Z}$-group (elementarily equivalent to the ordered abelian group $\mathbb{Z}$ of integers) and that in the first case the residue field has to be large in the sense of having infinitely many rational points for each algebraic curve with at least one rational point (cf. Pop [1996]).

The axiomatization for $\mathbb{F}_q((t))$ using this notion of extremal valued fields is now very simple:

(1) (K, v) is an extremal valued field of characteristic p,

(2) the value group vK is a $\mathbb{Z}$-group,

(3) the residue field Kv is the field $\mathbb{F}_q$.

It has long been known that the ‘naive’ axiomatization for $\mathbb{F}_q((t))$, where axiom (1) is replaced by just asking (K, v) to be henselian, is not complete.

3 Global fields

3.1 A universal definition for $\mathbb{Z}$ in $\mathbb{Q}$. Hilbert’s 10th problem over $\mathbb{Q}$, i.e., the question whether the existential L_{ring}-theory of $\mathbb{Q}$ is decidable, is still open.

If one had an *existential* (= *diophantine*) definition of $\mathbb{Z}$ in $\mathbb{Q}$ (i.e., a definition by an existential 1st-order $\mathfrak{L}_{ring}$-formula) then the existential theory of $\mathbb{Z}$ would be interpretable in that of $\mathbb{Q}$, and the answer would, by (for short) Matiyasevich’s Theorem, again be no. But it is still open whether $\mathbb{Z}$ is existentially definable in $\mathbb{Q}$.

The earliest 1st-order definition for $\mathbb{Z}$ in $\mathbb{Q}$, due to J. Robinson [1949], can be expressed by an $\forall\exists\forall$-formula of the shape

$$\phi(t):\ \forall x_1 \forall x_2 \exists y_1 \dots \exists y_7 \forall z_1 \dots \forall z_6\ f(t; x_1, x_2; y_1, \dots, y_7; z_1, \dots, z_6) = 0$$

for some $f \in \mathbb{Z}[T; X_1, X_2; Y_1, \dots, Y_7; Z_1, \dots, Z_6]$, i.e., for any $t \in \mathbb{Q}$,

$$t \in \mathbb{Z} \text{ iff } \phi(t) \text{ holds in } \mathbb{Q}.$$

In 2009, Bjorn Poonen ([P09a]) managed to find an $\forall\exists$-definition with 2 universal and 7 existential quantifiers (earlier, in Cornelissen and Zahidi [2007], an $\forall\exists$-definition with just one universal quantifier was proved modulo an open conjecture on elliptic curves).

In Koenigsmann [2016], the author then provided a $\forall$-definition of $\mathbb{Z}$ in $\mathbb{Q}$:

Theorem 3.1. *There is a polynomial $g \in \mathbb{Z}[T; X_1, \dots, X_{418}]$ such that, for all $t \in \mathbb{Q}$,*

$$t \in \mathbb{Z} \textit{ iff } \forall \overline{x} \in \mathbb{Q}^{418}\ g(t; \overline{x}) \neq 0.$$

If one measures logical complexity in terms of the number of changes of quantifiers then this is the simplest definition of $\mathbb{Z}$ in $\mathbb{Q}$, and, in fact, it is the simplest possible: there is no quantifier-free definition of $\mathbb{Z}$ in $\mathbb{Q}$.

Corollary 3.2. $\mathbb{Q} \setminus \mathbb{Z}$ *is diophantine in* $\mathbb{Q}$.

Corollary 3.3. $Th_{\forall\exists}(\mathbb{Q})$ *is undecidable.*

Theorem 3.1 came somewhat unexpected because it does not give what you would like to have, namely an existential definition of $\mathbb{Z}$ in $\mathbb{Q}$. However, if you had the latter the former would follow:

Observation 3.4. *If there is an existential definition of $\mathbb{Z}$ in $\mathbb{Q}$ then there is also a universal one.*

Proof: If $\mathbb{Z}$ is diophantine in $\mathbb{Q}$ then so is

$$\mathbb{Q} \setminus \mathbb{Z} = \{x \in \mathbb{Q} \mid \exists m, n, a, b \in \mathbb{Z} \text{ with } n \neq 0, \pm 1,\ am + bn = 1 \text{ and } m = xn\}$$

□

The machinery for proving these three first-order definitions of $\mathbb{Z}$ in $\mathbb{Q}$ is not very heavy: Julia Robinson made essentially use of the Hasse-Minkowski Local-Global Principle for quadratic forms, Bjorn Poonen augmented that using the Hasse bound for the number of rational points on genus-1 curves over finite fields (and he ingeniously rearranged the use of quadratic form theory), while in Koenigsmann [2016] the Quadratic Reciprocity Law came in as additional tool, and then some elementary tricks (inspired by the model theory of valued fields) for transforming existential formulas into universal ones were needed to complete the proof.

Using more serious number theory, (Park [2013])has generalised Theorem 3.1 to number fields:

Theorem 3.5. *For any number field K, the ring of integers $\mathcal{O}_K$ is universally definable in K.*

In the course of the proof of Koenigsmann [2016] many new diophantine subsets of $\mathbb{Q}$ emerged, for example the set of non-squares turned out to be diophantine (this was obtained earlier in Poonen [2009b] using much deeper techniques). If, however, $\mathbb{Z}$ was also diophantine in $\mathbb{Q}$ then there would be many more important diophantine subsets of $\mathbb{Q}$, for example the set of tuples of coefficients of irreducible polynomials (of fixed degree) over $\mathbb{Q}$. Later, Philip Dittmann managed to prove this unconditionally and in much greater generality (Dittmann [2016]):

Theorem 3.6. *Irreducibility of polynomials over global fields is diophantine.*

3.2 Hilbert's 10th Problem for number rings using elliptic curves. In this section only one major achievement is being reported on. There is a multitude of surveys on the subject, each with its own emphasis. For the interested reader, let us mention at least some of them: R. M. Robinson [1951], Mazur [1994], Pheidas [1994], Y. Matiyasevich [2000], Pheidas and Zahidi [2000], Shlapentokh [2000], Poonen [2003], Shlapentokh [2007], Poonen [2008], and Koenigsmann [2014].

For number rings and number fields, the question of decidability has been answered in the negative by J. Robinson [1959]. The question whether Hilbert's 10th Problem is solvable is much harder. Given that we don't know the answer over $\mathbb{Q}$ (though almost everyone working in the field believes it to be no) there is even less hope that we find the answer for arbitrary number fields in the near future. For number *rings* the situation is much better.

Let K be a number field with ring of integers $\mathcal{O}_K$. Then Hilbert's 10th Problem could be shown to be unsolvable over $\mathcal{O}_K$ in the following cases:

- if K is totally real or a quadratic extension of a totally real number field (Denef [1975], Denef and Lipshitz [1978] and Denef [1980]),
- if $[K : \mathbb{Q}] \geq 3$ and $c_K = 2$ (Pheidas [1988])[1],
- if $K/\mathbb{Q}$ is abelian (Shapiro and Shlapentokh [1989]).

In each of the proofs the authors managed to find an existential definition of $\mathbb{Z}$ in $\mathcal{O}_K$ using Pell-equations, the Hasse-Minkowski Local-Global Principle (which holds in all number fields) and ad hoc methods that are very specific to each of these special cases.

The hope for a uniform proof of the existential undecidability of all number rings only emerged when elliptic curves were brought into the game:

Theorem 3.7 ([Poo02]). *Let K be a number field. Assume*[2] *there is an elliptic curve E over $\mathbb{Q}$ with $\mathtt{rk}(E(\mathbb{Q})) = \mathtt{rk}(E(K)) = 1$. Then $\mathbb{Z}$ is existentially definable in $\mathcal{O}_K$ and so Hilbert's 10th Problem over $\mathcal{O}_K$ is unsolvable.*

In his proof, Poonen uses divisibility relations for denominators of x-coordinates of $n \cdot P$, where $P \in E(K) \setminus E_{tor}(K)$ and $n \cdot P \in E(\mathbb{Q})$ (for a similar approach cf. Cornelissen, Pheidas, and Zahidi [2005]).

The assumption made in the theorem turns out to hold modulo a generally believed conjecture, the so called *Tate-Shafarevich Conjecture*. For an elliptic curve E over a number field K, it refers to the *Tate-Shafarevich group* (or *Shafarevich-Tate group*) $Ш_{E/K}$, an abelian group defined via cohomology groups. It measures the deviation from a local-global principle for rational points on E.

---

[1] c_K denotes the *class number* of K, that is, the size of the ideal class group of K. It measures how far $\mathcal{O}_K$ is from being a PID: $c_K = 1$ iff $\mathcal{O}_K$ is a PID, so $c_K = 2$ is 'the next best'. It is not known whether there are infinitely many number fields with $c_K = 1$.

[2] The set $E(K)$ of K-rational points of E is a finitely generated abelian group isomorphic to the direct product of its torsion subgroup $E_{tor}(K)$ and a free abelian group of rank '$\mathtt{rk}(E(K))$'.

Tate-Shafarevich Conjecture *$Ш_{E/K}$ is finite.*

Weak Tate-Shafarevich Conjecture $\dim_{\mathbb{F}_2} Ш_{E/K}/2$ *is even.*

The latter follows from the former due to the Cassels pairing (Theorem 4.14 in Silverman [1986] which is an excellent reference on elliptic curves).

Theorem 3.8 ([MR10]). *Let K be a number field. Assume the weak Tate-Shafarevich Conjecture for all elliptic curves E/K. Then there is an elliptic curve $E/\mathbb{Q}$ with $\mathtt{rk}(E(\mathbb{Q})) = \mathtt{rk}(E(K)) = 1$.*

Taking those two theorems together you obtain immediately the following

Corollary 3.9. *Let K be a number field. Assume the weak Tate-Shafarevich Conjecture for all elliptic curves E/K. Then Hilbert's 10th Problem is unsolvable over $\mathcal{O}_K$.*

3.3 Global fields of positive characteristic. It is natural to ask decidability questions not only over number fields, but also over global fields of positive characteristic, i.e., algebraic function fields in one variable over finite fields, and also, more generally, for function fields.

Hilbert's 10th Problem (with t resp. t_1, t_2 in the language) has been shown to be unsolvable for the following function fields:

- $\mathbb{R}(t)$ (Denef [1978]),
- $\mathbb{C}(t_1, t_2)$ (Kim and Roush [1992]),
- $\mathbb{F}_q(t)$ (Pheidas [1991] and Videla [1994]),
- finite extensions of $\mathbb{F}_q(t)$ (Shlapentokh [1992] and Eisenträger [2003]).

The first two cases were achieved by existentially defining $\mathbb{Z}$ in the field, and then applying Matiyasevich's Theorem. This is, clearly, not possible in the last two cases. Instead of existentially *defining* $\mathbb{Z}$ the authors existentially *interpret* $\mathbb{Z}$ via elliptic curves: the multiplication by n-map on an elliptic curve E/K where $E(K)$ contains non-torsion points easily gives a diophantine interpretation of the additive group $\langle \mathbb{Z}; + \rangle$. The difficulty is to find an elliptic curve E/K such that there is also an existential definition for multiplication on that additive group.

For the ring of *polynomials* $\mathbb{F}_q[t]$, Demeyer has even shown the analogue of the DPRM-Theorem: listible subsets are diophantine (Demeyer [2007]).

Generalizing earlier results (Cherlin [1984], Duret [1986] and Pheidas [2004]), it is shown in Eisenträger and Shlapentokh [2009], that the *full* first-order theory of any function field of characteristic > 2 is undecidable.

For analogues of Hilbert's 10th Problem for fields of meromorphic or analytic functions cf., e.g., Rubel [1995], Vidaux [2003] and Pasten [2013].

4 Two infinite extensions of $\mathbb{Q}_p$

Let us recall that the field $\mathbb{Q}_p$ is axiomatized as a valued field (K, v) satisfying the following four axioms:

(1) (K, v) is henselian of mixed characteristic $(0, p)$,

(2)' $Kv = \mathbb{F}_p$,

(3)' $vK \equiv \mathbb{Z}$, so vK is a $\mathbb{Z}$-group,

(4)' $v(p)$ is minimal positive.

It is an immediate consequence of the main result of Derakhshan and Macintyre [2016] that the field $\mathbb{Q}_p^{ur}$, the maximal unramified extension of $\mathbb{Q}_p$ (obtained from $\mathbb{Q}_p$ by adjoining all prime to p roots of unity), is model complete, that is, every first order definable subset is already existentially definable. Using this, you can easily give an axiomatization of $\mathbb{Q}_p^{ur}$, namely as valued field (K, v) satisfying these axioms:

(1) (K, v) is henselian of mixed characteristic $(0, p)$,

(2) $Kv = \overline{Kv}$, so the residue field is algebraically closed,

(3)' $vK \equiv \mathbb{Z}$, so vK is a $\mathbb{Z}$-group,

(4)' $v(p)$ is minimal positive.

The next natural challenge is to find an axiomatization for $\mathbb{Q}_p^{ab}$, the maximal abelian extension of $\mathbb{Q}_p$, which, by the local Kronecker-Weber Theorem, is obtained from $\mathbb{Q}_p$ by adjoining all roots of unity. The axiomatization suggested (but not yet proved to be complete) in Koenigsmann [2018] is the axiomatization as valued field (K, v) satisfying these axioms:

(1) (K, v) is henselian of mixed characteristic $(0, p)$,

(2) $Kv = \overline{Kv}$,

(3) $vK \equiv \frac{1}{p^\infty}\mathbb{Z}$,

(4) $q \nmid v(1 - \zeta_p)$ for any prime $q \neq p$,

(5) $K \cap \overline{\mathbb{Q}} = \mathbb{Q}_p^{ab} \cap \overline{\mathbb{Q}}$,

(6) $v = v_K^p$,

(7) the Frobenius map $x \mapsto x^p$ is surjective on $\mathcal{O}_v / p\mathcal{O}_v$.

Here $\frac{1}{p^\infty}\mathbb{Z}$ is the ordered subgroup of the group of rational numbers having only p-th powers as denominators, ζ_p is a primitive p-th root of unity, and v_K^p is the *canonical p-henselian valuation* on K, that is here the coarsest p-henselian valuation with p-closed residue field, where p-henselian means that the valulation extends uniquely to every Galois extension of degree p. That these axioms can be expressed by (recursive sets of) first-order formulas is not too hard to show, except for axiom (6), for which this is proved in Jahnke and Koenigsmann [2015]. It is also not too difficult to check that all these axioms are true in $\mathbb{Q}_p^{ab}$. However, it requires substantial work to prove that these axioms are independent, that is, for each of the seven axioms one finds a valued field not satisfying this particular axiom, but satisfying all the other axioms (this is done in Koenigsmann [2018]. The planned strategy for establishing that these axioms are complete is via showing quantifier elimination in a variant of the Macintyre language for valued fields including n-th power predicates.

PROOF-THEORETIC METHODS IN NONLINEAR ANALYSIS

ULRICH KOHLENBACH

Abstract

We discuss applications of methods from proof theory, so-called proof interpretations, for the extraction of explicit bounds in convex optimization, fixed point theory, ergodic theory and nonlinear semigroup theory.

1 Introduction: Proof Theory, Hilbert's Program and Kreisel's 'Unwinding of Proofs'

Proof theory has its origin in what has been called 'Hilbert's program': Since the 19th century noneffective and nonfinitary (set-theoretic) principles became increasingly important which raised the issue of their legitimacy. Hilbert's approach was to establish the consistency of a suitable formalization T of mathematics (first number theory and then analysis and set theory) within some finitary reasoning T_{fin}. In the language of number theory and with a minimal amount of number-theoretic tools one can express the consistency of T (axiomatized by an effective list of axioms) as a purely universal number-theoretic sentence (a so-called Π^0_1-sentence)

$$Con_T := \forall n \in \mathbb{N} \neg Prov_T(n, \ulcorner 0 = 1 \urcorner)$$

which states that no $n \in \mathbb{N} := \{0, 1, 2, \ldots\}$ is the code of a T-proof of $0 = 1$.

Consider now an arbitrary Π^0_1-sentence (called a 'real statement' by Hilbert) $S := \forall n \in \mathbb{N}\ (t(n) = 0)$, where t is some primitive recursive function term. If S is provable in T (using any nonfinitary 'ideal elements' of T), then also $T_{fin} + Con_T$ proves S (see Smorynski [1977][5.2.1]). So if Con_T could be proved in T_{fin}, one could convert the 'ideal' proof of S in T into a finitistic proof of S in T_{fin}.

Obviously, Gödel's second incompleteness theorem rules out that the consistency of any

MSC2010: primary 03F10; secondary 03F35, 47H10, 47H20, 47H25, 90C30.
Keywords: Proof mining, effective bounds, convex optimization, fixed points, ergodic theory, nonlinear semigroups.

$T \supseteq T_{fin}$ can be established inside of T_{fin}. Nevertheless, Hilbert's program gave rise to many 'relative consistency proofs' where the consistency of T is reduced to that of an in **some** sense more elementary theory T'. 'More elementary' often is related to being 'quantifier-free': e.g. Gentzen's proof-theoretic analysis of first-order number theory PA (Gentzen [1936]) reduces logically complex instances of ordinary induction to quantifier-free instances of transfinite induction (along ordinals $\alpha < \varepsilon_0$) and Gödel's consistency proof for PA (Gödel [1958]) reduces PA to a quantifier-free calculus of so-called primitive recursive functionals of finite type (considered already by Hilbert himself in Hilbert [1926]).
In the early 50's, Georg Kreisel suggested to re-orient proof theory by applying proof-theoretic methods - which in some way eliminate quantifiers in terms of quantifier-free constructions - to proofs of theorems which are not purely universal (as consistency statements) but e.g. of the form

$$(*)\ \forall n \in \mathbb{N}\, \exists m \in \mathbb{N}\, A_{qf}(n,m) \quad (A_{qf} \text{ quantifier-free}).$$

Kreisel noted that the respective consistency proofs for PA due to Gentzen (see Kreisel [1951, 1952]) and Gödel resp. (see Kreisel [1959] (3.4)) actually characterize the class of subrecursive functions f needed to realize $(*)$ in the form

$$\forall n \in \mathbb{N}\, A_{qf}(n, f(n))$$

for theorems $(*)$ which are provable in PA, namely as the class of $\alpha < \varepsilon_0$-recursive functions (in the case of Gentzen's proof) and - equivalently - as the class of functions definable in the aforementioned calculus of primitive recursive functionals (in the case of Gödel's proof Gödel [1941, 1958]), see also Parsons [1972].
While such results concern (the provability of $\forall\exists$-sentences in) formal systems such as PA rather than individual proofs, Kreisel already in Kreisel [1952] also launched the program of analyzing specific prima facie nonconstructive proofs with the aim of extracting new (e.g. effective) information on the theorem proven:

Input: A (prima facie) noneffective proof P of a conclusion C.

Goal: Additional information on C such as:

- effective bounds,
- algorithms,
- continuous dependency or full independence from certain parameters,
- generalizations of proofs: weakening of premises.

Kreisel's examples and suggestions for applications mainly concerned proofs in number theory. E.g. in Kreisel [1982], Kreisel suggested to analyze finiteness statements such as Roth's theorem in diophantine approximation with the aim of extracting bounds on the number of solutions. In Luckhardt [1989], Luckhardt extracted the first polynomial such bound for Roth's theorem from a proof due to Esnault and Viehweg (independently, this result was also obtained in Bombieri and van der Poorten [1988]). Since the 90's, the program has been developed most systematically and with specially designed so-called logical metatheorems (see the next section) in the context of nonlinear analysis ('proof mining'). Also while Kreisel's unwindings were based on techniques related to cut-elimination (Herbrand theory, ε-substitution etc.) the applications to analysis are all based on functional interpretations which have their origin in Gödel's 'Dialectica' interpretation on which Gödel's aforementioned consistency proof is based.

2 Logical metatheorems for bound extractions

In order to establish general theorems on the extractability of effective uniform bounds from given proofs one has to set up an appropriate formal deductive context. As the bound extraction methods are based on modern ('monotone') extensions and variants (see Kohlenbach [2008a]) of Gödel's functional interpretation (Gödel [1941, 1958]) one uses formal systems formulated in the language of functionals in all finite types such as appropriate forms of Peano arithmetic in all finite types PA^ω. In such systems one already can represent complete separable metric ('Polish') spaces (X, d) as continuous images of the Baire space $\mathbb{N}^{\mathbb{N}}$. However, this requires the separability of the space X and for separable spaces one can show that the independence of the extracted bounds from parameters in subspaces of X in general can only be expected if these subspaces are compact (see Kohlenbach [2008a] for discussions of this point). Many theorems in nonlinear analysis, however, involve - in addition to **concrete** Polish spaces such as $\mathbb{R}$ - general classes of **abstract** spaces X (e.g. general Hilbert spaces) which are not required to be separable and one can extract bounds that are independent from parameters in X (and even functions $T : X \to X$) if general metric bounds ('majorants') are given.

Many abstract types of metric structures can be added as atoms to our formal systems. E.g. this applies to metric, W-hyperbolic (see below), CAT(0), CAT(1), δ-hyperbolic, normed, uniformly convex, Hilbert, abstract L^p, abstract $C(K)$ spaces and $\mathbb{R}$-trees, and, in fact, all normed structures that are axiomatizable in so-called positive bounded logic (see Günzel and Kohlenbach [2016]). In order to be able to speak about such spaces one adds a **new base type** X to the formal system and forms all finite types over $\mathbb{N}, X$ (see Kohlenbach [2005b]; one may also have several such types: see Kohlenbach [2008a], section 17.6). One also adds constants for the metric d_X or normed space operators with appropriate axioms that characterize the class of structures in question.

Condition: the defining axioms must have a monotone functional interpretation (possibly with the addition of appropriate moduli, see Kohlenbach [2008a]).

Counterexamples (to the extractability of uniform bounds) exist for the classes of strictly convex or separable spaces which get upgraded by the monotone functional interpretation to uniformly convex resp. boundedly compact spaces.

Formal systems for analysis with abstract spaces X

Types: (i) $\mathbb{N}, X$ are types, (ii) with ρ, τ also $\rho \to \tau$ is a type.

Functionals of type $\rho \to \tau$ map type-ρ objects to type-τ objects.

$\mathrm{PA}^{\omega,X}$ is the extension of PA to all types, $\mathcal{A}^{\omega,X}$:=$\mathrm{PA}^{\omega,X}$+DC, where

DC: axiom schema of dependent choice for all types,

which implies the axiom schema of countable choice and so, applied to the law-of-excluded middle, full comprehension for numbers

$$\text{CA: } \exists f^{\mathbb{N}\to\mathbb{N}}\ \forall n^{\mathbb{N}}\ (f(n) = 0 \leftrightarrow A(n)),$$

where $A(n)$ may contain quantifiers (and parameters) of arbitrary types.

$\mathcal{A}^{\omega}[X, d, \ldots]$ results by adding constants $d_X, \ldots$ with axioms expressing that $(X, d, \ldots)$ is a nonempty metric, hyperbolic …space (we deviate here from the notation used in Kohlenbach [ibid.] where this theory is denoted by $\mathcal{A}^{\omega}[X, d, \ldots]_{-b}$, and $\mathcal{A}^{\omega}[X, d, \ldots]$ denotes the theory with an axiom stating the boundedness of (X, d) by some constant b being added).

A warning concerning equality: our formal theories only have a **quantifier-free rule of extensionality** (with A_{qf} being a quantifier-free formula)

$$\frac{A_{qf} \to s =_{\rho} t}{A_{qf} \to r[s/x] =_{\tau} r[t/x]},$$

where only $x =_{\mathbb{N}} y$ is a primitive predicate but for X and $\rho \to \tau$ one defines

$$x^X =_X y^X :\equiv d_X(x, y) =_{\mathbb{R}} 0_{\mathbb{R}},\ x =_{\rho\to\tau} y :\equiv \forall v^{\rho}(x(v) =_{\tau} y(v)).$$

This is crucial as the uniform quantitative rendering of the extensionality axiom $x =_X y \to Tx =_X Ty$ for T of type $X \to X$ implies the uniform continuity of T (on bounded subsets) and we want (in contrast to the setting of current continuous model theory; see, however, the recent Cho [2016]) also to be able to treat discontinuous situations (see Kohlenbach [2008a] for extensive discussions of this point).

Extension of majorizability to the new types: A crucial notion used is an extension of Howard's (Howard [1973]) concept of majorizability to the new types, where we 'bound' an element in a metric space by the distance it has from a fixed reference point $a \in X$ (where $a = 0_X$ in the normed case): let y, x be functionals be of types $\rho, \widehat{\rho} := \rho[\mathbb{N}/X]$ and a^X of type X:

$$x^{\mathbb{N}} \gtrsim^a_{\mathbb{N}} y^{\mathbb{N}} :\equiv x \geq y, \; x^{\mathbb{N}} \gtrsim^a_X y^X :\equiv x \geq d(y, a).$$

For complex types $\rho \to \tau$ this is extended in a hereditary fashion.

Example: for monotone T^* one defines

$$T^* \gtrsim^a_{X \to X} T \equiv \forall n \in \mathbb{N}, x \in X[n \geq d(a, x) \to T^*(n) \geq d(a, T(x))]$$

(see Gerhardy and Kohlenbach [2008] and Kohlenbach [2008a]).
$T : X \to X$ is nonexpansive (n.e.) if $d(T(x), T(y)) \leq d(x, y)$.
Then $\lambda n.n + b \gtrsim^a_{X \to X} T$, if $d(a, T(a)) \leq b$.
Proof mining exhibits the finitary combinatorial kernel of a proof and as a consequence of this it often is easy to generalize things from a normed linear setting to some geodesic setting. In fact, the approach has been particularly useful in the context of hyperbolic spaces which is a variant of notions considered by Takahashi [1970], Goebel and Kirk [1983] and Kirk [1981/82] and Reich and Shafrir [1990] (see Kohlenbach [2005b] for the precise relationship):

Definition 2.1 (Kohlenbach [ibid.]). *A $(W$-$)$hyperbolic space is a triple (X, d, W) where (X, d) is a metric space and $W : X \times X \times [0, 1] \to X$ s.t. for all $x, y, z \in W$ and $\lambda, \tilde{\lambda} \in [0, 1]$*

(i) $d(z, W(x, y, \lambda)) \leq (1 - \lambda)d(z, x) + \lambda d(z, y)$,

(ii) $d(W(x, y, \lambda), W(x, y, \tilde{\lambda})) = |\lambda - \tilde{\lambda}| \cdot d(x, y)$,

(iii) $W(x, y, \lambda) = W(y, x, 1 - \lambda)$,

(iv) $d(W(x, z, \lambda), W(y, w, \lambda)) \leq (1 - \lambda)d(x, y) + \lambda d(z, w)$.

CAT(0)-spaces (Gromov) are hyperbolic spaces (X, d, W) which satisfy the CN-inequality of Bruhat-Tits (determining W uniquely): for all $x, y_0, y_1, y_2 \in X$

$$\begin{cases} d(y_0, y_1) = \frac{1}{2}d(y_1, y_2) = d(y_0, y_2) \to \\ d(x, y_0)^2 \leq \frac{1}{2}d(x, y_1)^2 + \frac{1}{2}d(x, y_2)^2 - \frac{1}{4}d(y_1, y_2)^2. \end{cases}$$

Small types (over $\mathbb{N}, X$) include: $\mathbb{N}, \; \mathbb{N} \to \mathbb{N}, \; X, \; \mathbb{N} \to X, \; X \to X$.

Theorem 2.2 (Gerhardy and Kohlenbach [2008] and Kohlenbach [2008a]). *Let P, K be Polish resp. compact metric spaces (definable in $\mathcal{A}^\omega$), $A_\exists$*[1] *be an $\exists$-formula and $\underline{\tau}$ be a tuple of small types.*
If $\mathcal{A}^\omega[X, d, W]$ proves

$$\forall x \in P\, \forall y \in K\, \forall \underline{z}^{\underline{\tau}}\, \exists v^{\mathbb{N}}\, A_\exists(x, y, \underline{z}, v),$$

then one can extract a computable $\Phi : \mathbb{N}^{\mathbb{N}} \times \underline{\mathbb{N}}^{(\mathbb{N})} \to \mathbb{N}$ s.t. the following holds in every nonempty hyperbolic space: for all representatives $r_x \in \mathbb{N}^{\mathbb{N}}$ of $x \in P$ and all $\underline{z}^{\underline{\tau}}$ and $\underline{z}^* \in \mathbb{N}^{(\mathbb{N})}$ s.t. $\exists a \in X(\underline{z}^* \gtrsim^a_{\underline{\tau}} \underline{z})$:

$$\forall y \in K\, \exists v \le \Phi(r_x, \underline{z}^*)\, A_\exists(x, y, \underline{z}, v).$$

For the case of bounded hyperbolic spaces, see Kohlenbach [2005b].

As a special case of the above metatheorem one has:

Corollary 2.3 (Gerhardy and Kohlenbach [2008] and Kohlenbach [2008a]). *If $\mathcal{A}^\omega[X, d, W]$ proves*

$$\forall x \in P\, \forall y \in K\, \forall z \in X\, \forall T : X \to X\, \big(T \text{ n.e.} \to \exists v \in \mathbb{N}\, A_\exists\big),$$

then one can extract a computable $\Phi : \mathbb{N}^{\mathbb{N}} \times \mathbb{N} \to \mathbb{N}$ s.t. for all $x \in P, b \in \mathbb{N}$

$$\forall y \in K\, \forall z \in X\, \forall T : X \to X\, \big(T \text{ n.e.} \wedge d_X(z, T(z)) \le b \to \exists v \le \Phi(r_x, b) A_\exists\big)$$

holds in all nonempty hyperbolic spaces (X, d, W).

Similar results hold for the other classes of metric and normed structures listed above. In the normed case, one additionally needs $\|z\| \le b$ as an assumption in the conclusion of the corollary.

Remark 2.4. *Usually, proofs in ordinary mathematics only require a small fragment of $\mathcal{A}^\omega[X, d, \ldots]$ with e.g. the binary ('weak') König's lemma* WKL *instead of* DC *and Σ^0_1-induction only, which guarantees the extractability of primitive recursive (in the sense of Kleene) bounds.* WKL *is equivalent to a sentence of the form $\forall f^{\mathbb{N}\to\mathbb{N}}\, \exists b \le_{\mathbb{N}\to\mathbb{N}} 1 \forall x^{\mathbb{N}}\, A_{qf}(f, b, x)$ and can be added to the system via a Skolem constant B with the purely universal axiom $\forall f, x(Bf \le 1 \wedge A_{qf}(f, Bf, x))$ which is satisfiable in the full set-theoretic model and B is trivially majorized by the constant-1 functional in the extracted bound (see* Kohlenbach [2008a]*).*

[1] There are some mild restrictions on the types of the quantified variables in $A_\exists$.

3 General types of applications

3.1 Asymptotic regularity theorems. Consider a metric space (X, d) and a continuous function $F : X \to \mathbb{R}$. Many problems can be stated in the form of finding a zero $z \in X$ of F. Such problems are often algorithmically approached by setting up some iterative procedure resulting in a sequence (x_n) in X which converges to a zero z of F :

$$(*)\ F(\lim_{n\to\infty} x_n) = F(z) = 0.$$

In this case one, in particular, has that

$$(**)\ F(x_n) \to 0.$$

Quite often, $(**)$ holds under much more general conditions than those needed to ensure the convergence of (x_n) itself. In the case of fixed point problems for mappings $T : X \to X$, i.e. the case where $F(x) := d(x, Tx)$, results of the form $(**)$ are usually referred to as asymptotic regularity statements where this term was originally introduced by Browder and Petryshyn [1966] to refer to the property of T that the sequence $x_n := T^n x$ of Picard iterates satisfies $d(x_n, Tx_n) \to 0$. In many cases (see below) $(d(x_n, Tx_n))_{n\in\mathbb{N}}$ for some iterative process not only converges to 0 but does so in a nonincreasing way. In this situation the asymptotic regularity statement can be equivalently written in the form

$$\forall k \in \mathbb{N}\, \exists n \in \mathbb{N}\ (d(x_n, Tx_n) < 2^{-k}) \in \forall\exists$$

and any upper bound $\Phi(k)$ on '$\exists n$' provides a rate of convergence. This means that one can apply the logical metatheorems mentioned in the previous section to extract effective and highly uniform rates of asymptotic regularity even from prima facie noneffective proofs of asymptotic regularity. In fact, this has been achieved in many instances in the context of nonlinear analysis (see some of the applications below and Kohlenbach [2008b, 2017] for general surveys).

3.2 Strong convergence theorems. Suppose that the theorem to be studied is not about an asymptotic regularity result but about the convergence of the sequence (x_n) itself, e.g. towards a zero of F or a fixed point of T. Already the Cauchy property of (x_n)

$$(+)\ \forall k \in \mathbb{N}\, \exists n \in \mathbb{N}\, \forall i, j \geq n\ (d(x_i, x_j) \leq 2^{-k}) \in \forall\exists\forall$$

has too complicated a logical form to directly apply the logical metatheorems on uniform bound extractions and, in fact, there are already simple cases of computable monotone sequences of rational numbers in $[0, 1]$ which do not have a computable rate of convergence (Specker [1949]).

Roughly speaking, one can distinguish the following situations:
1) The proof of the Cauchy property of (x_n) (or of the convergence of (x_n) to some known element $x \in X$) uses - on top of constructive ('intuitionistic') reasoning - at most the law-of-excluded-middle schema LEM for negated formulas

$$\text{LEM}_\neg : \ \neg A \vee \neg\neg A$$

which, in particular covers the case where A is $\exists$-free (e.g. $A \in \Pi^0_1$) as such formulas are equivalent to their double negation (using the stability of the prime formulas in our formal systems).
Alternatively (but not combined), one may use the so-called Markov principle

$$\text{M} : \ \neg\neg\exists n \in \mathbb{N}\, A_{qf}(n) \to \exists n \in \mathbb{N}\, A_{qf}(n) \ \ (A_{qf} \text{ quantifier-free with parameters})$$

together with the following weak form of LEM (weaker than LEM for Π^0_1-formulas):

$$\text{LLPO} : \ \neg(\exists n \in \mathbb{N}\, A_{qf}(n) \wedge \exists n \in \mathbb{N}\, B_{qf}(n)) \to \forall n \in \mathbb{N}\, \neg A_{qf}(n) \vee \forall n \in \mathbb{N}\, \neg B_{qf}(n),$$

where A_{qf}, B_{qf} are quantifier-free formulas. In both scenarios one can set up logical bound extraction metatheorems, where instead of the purely existential formula $A_\exists$ one may now have an arbitrary formula (see Kohlenbach [2008a]). Since $(+)$ is monotone w.r.t. '$\exists n \in \mathbb{N}$' any upper bound on $n \leq \Phi(k)$ in fact is a Cauchy rate for (x_n) and so one can in these cases extract effective rates of convergence.
2) If the proof of the Cauchy property of (x_n) uses LEM for Σ^0_1-formulas (purely existential formulas for natural numbers) as in the case of the Specker sequences from Specker [1949], then one often has the following dichotomy: either one can show that (x_n) converges to the **unique** zero of F or fixed point of T, or one can use the non-uniqueness of the solution to construct an instance of the Cauchy statement in question which provably does not allow for an effective Cauchy rate.

(i) **Unique existence:** in many cases one can obtain effective rates of convergence (and in fact also with a constructive verification of this fact) for (x_n) if (x_n) converges towards a **unique** zero of F resp. fixed point of T: consider a function $F : X \to \mathbb{R}$ on some metric space (X, d) which has exactly one zero z. The uniqueness part

$$(a)\ \forall x, y \in X\ (F(x) = 0 = F(y) \to x = y)$$

can be written equivalently as

$$(b)\ \forall x, y \in X\ \forall k \in \mathbb{N}\ \exists n \in \mathbb{N}\ (|F(x)|, |F(y)| \leq 2^{-n} \to d(x, y) < 2^{-k}) \in \forall\exists.$$

Then logical metatheorems can be applied to extract from a proof of (a) an effective uniform bound $\Phi(k)$ on '$\exists n \in \mathbb{N}$' in (b), which we called in Kohlenbach [1993] a 'modulus of uniqueness', where $\Phi(k)$ depends on x, y only via general majorizing data and, in particular, is independent of x, y if X is bounded (in the case where X can be treated as an abstract space and, otherwise, if X is compact). Suppose now that we can construct some (bounded) sequence (x_n) of approximate zeros, i.e.

$$(c)\ \forall k \in \mathbb{N}\, \exists n \in \mathbb{N} (|F(x_n)| < 2^{-k}) \in \forall\exists$$

from which we then can extract (using again a logical metatheorem) an effective bound $\Psi(k)$ on '$\exists n \in \mathbb{N}$' in (c), then for $\chi(k) := \Psi(\Phi(k))$ we have

$$\forall k \in \mathbb{N}\, \exists n \leq \chi(k)\, (d(x_n, z) < 2^{-k})$$

and, if we even have that $(|F(x_n)|)_n$ is nonincreasing, it follows that χ is a rate of convergence for $\lim x_n = z$. In Briseid [2009], it is shown that for Picard iterations $x_n = T^n x$ for suitable classes of mappings T the aforementioned logical metatheorems can be used to obtain such rates of convergence even when $(|F(x_n)|)_n$ (for $F(x) := d(x, Tx)$) is not nonincreasing which explains the explicit construction of effective rates of convergence for the classes of asymptotic contractions in the sense of Kirk and of uniformly generalized p-contractive mappings given by Briseid (see Briseid [ibid.] and the literature cited there).

(ii) **Non-unique existence:** when F or T possess many zeros resp. fixed points, one usually can construct computable instances of iterative procedures (x_n) (converging to some zero or fixed point) that do not have a computable rate of convergence. In fact, Neumann [2015] shows that this is the case for the usual iterative schemes used in metric fixed point theory, ergodic theory and convex optimization which even for (firmly) nonexpansive selfmappings $T : [0, 1] \to [0, 1]$ fail to have a computable rate of convergence for simple computable such mappings T. One then has to weaken the goal to what has been called an effective rate of metastability: Noneffectively, (+) is equivalent to

$$(++)\ \forall k \in \mathbb{N}\, \forall g \in \mathbb{N}^{\mathbb{N}}\, \exists n \in \mathbb{N}\, \forall i, j \in [n, n + g(n)]\, (d(x_i, x_j) < 2^{-k}) \in \forall\exists,$$

the so-called Herbrand normal of $(+)$, and a bound $\Phi(k, g)$ on '$\exists n$' is a bound for the Kreisel 'no-counterexample interpretation' (Kreisel [1951, 1952]) of the Cauchy property. Since Tao [2008b] calls an interval $[n, n + g(n)]$ with the property in $(++)$ an interval of 'metastability', we call bounds $\Phi(k, g)$ on '$\exists n$' in $(++)$ rates of metastability. If one additionally knows that (x_n) is converging to a zero of F or a fixed point of T with some rate of metastability then one can actually combine both rates into a common one (formulated here for the case of fixed points), i.e. a bound $\Phi(k, g)$ such that for all $k \in \mathbb{N}$ and $g : \mathbb{N} \to \mathbb{N}$

$$(+++)\ \exists n \leq \Phi(k, g)\, \forall i, j \in [n, n + g(n)]\, (d(x_i, x_j), d(x_i, Tx_i) \leq 2^{-k}).$$

If one has a rate of convergence for $d(x_n, Tx_n) \to 0$, one can even achieve that

$$\exists n \leq \Phi(k,g)\, \forall i,j \in [n, n+g(n)]\, \forall l \geq n\, (d(x_i,x_j), d(x_l,Tx_l) \leq 2^{-k})$$

(see e.g. Kohlenbach, Leuştean, and Nicolae [2018] and Kohlenbach [2016], Rem.2.11). The extraction of explicit bounds Φ on the metastable form of Cauchy or convergence statements is of interest for the following reasons:

a) Disregarding bounded quantifiers, the statement $(+++)$ is purely universal ('real') and captures all the mathematical content of the theorem $\lim x_n = x = Tx$: by a fixed piece of proof it implies back the original convergence theorem: forgetting the bound Φ gives the Herbrand normal form which by recursive comprehension (more precisely QF-AC^{0,0} in the terminology of Kohlenbach [2008a]) and LEM implies the Cauchy property and so by arithmetical comprehension (more precisely Π^0_1-AC^{0,0} in our formal context, see Kohlenbach [ibid.]) the convergence of (x_n). Applying $(+++)$ to the constant function $g(n) := K \in \mathbb{N}$ shows the existence of $i \geq K$ with $d(x_i, Tx_i) < 2^{-k}$ which - together with the continuity of T - gives $Tx = x$ for $x := \lim x_n$.

b) The proof-theoretic extraction of a rate of metastability from a convergence proof exhibits the finitary combinatorial content of that proof which may lead to generalizations of the resulting metastable statement and so - when unpacked into the full convergence statement (see above) - to generalized convergence theorems.

c) The concrete bounds extracted are of numerically interest: often they provide explicit information on the **algorithmic learnability** of a rate of convergence which - if a gap condition is satisfied - yields **oscillation bounds** (Avigad and Rute [2015] and Kohlenbach and Safarik [2014] and Section 5 below).

d) In many cases, asymptotic regularity is just the special case of metastability where $g(n) := 1$, e.g. for Picard iterates of nonexpansive functions T.
Some history:

- 2004, first rate of metastability (for the asymptotic regularity of asymptotically nonexpansive mappings) extracted (Kohlenbach and Lambov [2004]).
- 2005, rate of metastability for Krasnoselski-Mann iterations of nonexpansive selfmappings $T : X \to X$ of compact hyperbolic spaces X (Kohlenbach [2005a]).
- 2007, Tao [2008b] introduced the term 'metastability' in connection with the von Neumann Mean Ergodic Theorem (MET).
- 2007, independently from Tao, the first rate of asymptotic regularity for MET was extracted in Avigad, Gerhardy, and Towsner [2010].

- 2008, Kohlenbach and Leuştean [2009] generalized this with a better bound to uniformly convex Banach spaces which, subsequently, led to oscillation bounds by Avigad and Rute [2015] (see below).

- Since then, many papers extracting explicit rates of metastability have appeared, including Avigad and Rute [2015], Kohlenbach [2011, 2012, 2016], Kohlenbach and Koutsoukou-Argyraki [2015], Kohlenbach and Leuştean [2009, 2012, 2014], Kohlenbach, Leuştean, and Nicolae [2018], Kohlenbach, López-Acedo, and Nicolae [2017b], Körnlein [2016], Leuştean and Nicolae [2016], Safarik [2012], and Sipoş [2017a].

We like to emphasize that sometimes in analyzing convergence proofs one uses a combination of the approach used in the semi-constructive context discussed further above (applied to those parts of the proof that do not require Σ^0_1-LEM) and the approach to proofs based on full classical logic (applied to the more noneffective parts of the proof). E.g. Leuştean [2014] and Sipoş [2017b] provide interesting instances of such a hybrid approach.

In very special, but important, cases for applications one can extract rates of convergence for iterative procedures towards some non-unique zero of F or fixed point of T, namely when one has an effective so-called modulus of regularity which is closely related to the concepts of weak sharp minima and metric regularity used in convex optimization (see Kohlenbach, López-Acedo, and Nicolae [2017a]).

3.3 Inclusions between sets of solutions. Consider functions $F, G : X \to \mathbb{R}$ on a metric space (X, d) such that every zero of F is also one of G :

$$\forall x \in X\ (F(x) = 0 \to G(x) = 0)$$

which can be re-written in $\forall\exists$-form as

$$\forall x \in X\ \forall k \in \mathbb{N}\ \exists n \in \mathbb{N}\ \overbrace{(|F(x)| \le 2^{-n} \to |G(x)| < 2^{-k})}^{\in\Sigma^0_1}$$

so that logical metatheorems can be applied to extract effective uniform bounds (which due to monotonicity are in fact realizers) for '$\exists n$', i.e.

$$\forall k \in \mathbb{N}\ (|F(x)| \le 2^{-\Phi(x^*,k)} \to |G(x)| < 2^{-k}),$$

where x^* are appropriate majorizing data for x.
For concrete instances of such applications see sections 4 and 6 below.

3.4 Extraction of effective moduli. The first applications of the proof mining methodology in analysis concerned the extraction of explicit moduli of uniqueness in the aforementioned sense (as well as so-called constants of strong unicity) in Chebycheff approximation by us in 1990-1993 which in 2003 - together with Paulo Oliva - was also carried out for best L^1-approximation (see Kohlenbach [2008a] for an extensive coverage of this and the references given there). However, many more concepts of quantitative 'moduli' exist in mathematics or have been introduced as quantitative proof-theoretic versions of qualitative concepts in analysis. Proof mining has been used to explicitly transform moduli for one situation into moduli for another one. This e.g. is used essentially in Bačák and Kohlenbach [2018] and Kohlenbach, López-Acedo, and Nicolae [2017a].

In the rest of the paper we give a few typical examples of explicit bounds which have been obtained by the proof-theoretic machinery discussed so far. For more comprehensive surveys, see Kohlenbach [2008b] for results up to 2008 and Kohlenbach [2017] for applications since 2008.

4 Proof Mining in Convex Analysis

A polynomial rate of asymptotic regularity in Bauschke's solution of the 'zero displacement conjecture'

Consider a real Hilbert space H and nonempty closed and convex subsets $C_1, \ldots, C_N \subseteq H$ with metric projections P_{C_i}, define $T := P_{C_N} \circ \ldots \circ P_{C_1}$. In 2003, Bauschke proved the 'zero displacement conjecture' (Bauschke [2003]) which was first stated in Bauschke, Borwein, and Lewis [1997]:

$$\|T^{n+1}x - T^n x\| \to 0 \quad (x \in H).$$

Previously, this was only known for $N = 2$ or $Fix(T) \neq \emptyset$ (or even $\bigcap_{i=1}^N C_i \neq \emptyset$) or C_i half spaces etc.

The proof uses the Bruck and Reich [1977] theory of firmly and strongly nonexpansive mappings and the abstract theory of maximal monotone operators: Minty's theorem, Brézis-Haraux theorem, Rockafellar's maximal monotonicity and sum theorems, conjugate functions, normal cone operator.

The sequence $(\|T^{n+1}x - T^n x\|)_{n\in\mathbb{N}}$ is nonincreasing and hence the conclusion in Bauschke's theorem is of the form $\forall\exists$. Logical metatheorems as discussed above, therefore, guarantee (modulo the formalizability of the proof in the resp. formal system which, however, does not need to be checked if one explicitly has carried out the extraction) the extractability of an effective uniform rate of asymptotic regularity which only depends on the error $\varepsilon > 0$, $N \in \mathbb{N}$ and majorants for $x \in H$ and $P_{C_1}, \ldots, P_{C_N}$, i.e. $b \geq \|x\|$ and

$K \geq \|c_1\|, \ldots, \|c_N\|$ for some points $c_1 \in C_1, \ldots, c_N \in C_N$ since

$$n \geq \|y\| \to n + K \geq \|P_{C_i} y - P_{C_i} 0\| + \|P_{C_i} 0\| \geq \|P_{C_i} y\|.$$

So one gets a computable $\Phi(\varepsilon, N, b, K)$ s.t. for $b \geq \|x\|$

$$\forall \varepsilon > 0 \, \forall n \geq \Phi(\varepsilon, N, b, K) \, (\|T^{n+1}x - T^n x\| < \varepsilon).$$

Strongly nonexpansive mappings

Definition 4.1 (Kohlenbach [2016]). *Let $S \subseteq X$ be a nonempty subset of a normed space X. $T : S \to X$ is strongly nonexpansive with SNE-modulus $\omega : \mathbb{R}^*_+ \times \mathbb{R}^*_+ \to \mathbb{R}^*_+$ if*

$$\forall d, \varepsilon > 0 \, \forall x, y \in S \, (\|x - y\| \leq d \ \wedge \|x - y\| - \|Tx - Ty\| < \omega(d, \varepsilon) \to \|(x - y) - (Tx - Ty)\| < \varepsilon).$$

Remark: T is strongly nonexpansive in the sense of Bruck and Reich [1977] iff it possesses an SNE-modulus.

Recall that in Hilbert spaces $H = X$, a function $T : S \to H$ is called firmly nonexpansive if

$$\forall x, y \in S \, (\|Tx - Ty\|^2 \leq \langle x - y, Tx - Ty \rangle)$$

and metric projections onto closed convex subsets of H are firmly nonexpansive.

The next two results have been obtained by a proof-theoretic analysis of Bruck and Reich [ibid.]:

Lemma 4.2 (Kohlenbach [2016]). *Let H be a real Hilbert space and $T = T_N \circ \ldots \circ T_1$ with firmly nonexpansive $T_1, \ldots, T_N : H \to H$. Then T is SNE with modulus*

$$\omega_T(d, \varepsilon) := \frac{1}{16d} \left(\frac{\varepsilon}{N}\right)^2.$$

A rate of asymptotic regularity for SNE-mappings

Theorem 4.3 (Kohlenbach [2018]). *Let $T : S \to S$ be SNE with modulus ω s.t.* $\inf\{\|x - Tx\| : x \in S\} = 0$ *and let $\alpha : \mathbb{R}^*_+ \to \mathbb{R}^*_+$ be such that*

$$\forall \varepsilon > 0 \, \exists y \in S \ \ (\|y\| \leq \alpha(\varepsilon) \wedge \|y - Ty\| \leq \varepsilon) \, .$$

Then for $x \in S$, $x_n := T^n x$ and $D > 0$ such that $\|x - Tx\| \leq D$ one has

$$\forall \varepsilon > 0 \, \forall n \geq \psi(\varepsilon, b, D, \alpha, \omega) \ \ (\|x_{n+1} - x_n\| < \varepsilon) \, , \text{ where}$$

$$\psi(\varepsilon, b, D, \alpha, \omega) := \left\lceil \frac{18b + 12\alpha(\varepsilon/6)}{\varepsilon} - 1 \right\rceil \left\lceil \left(\frac{D}{\omega(D, \tilde{\varepsilon})}\right) \right\rceil, \ \tilde{\varepsilon} := \frac{\varepsilon^2}{27b + 18\alpha(\varepsilon/6)}.$$

The proof-theoretic analysis of the **operator-theoretic part of Bauschke's proof** gives:

Theorem 4.4 (Kohlenbach [2018]). *Let H be real Hilbert space, $C_1, \ldots, C_N \subseteq H$ nonempty closed and convex subsets, P_{C_i} metric projections onto C_i for $i = 1, \ldots, N$. Let $c = (c_1, \ldots, c_N) \in C_1 \times \ldots \times C_N$ be arbitrary and $K \geq \|c\| = \sqrt{\sum_{i=1}^N \|c_i\|^2}$. Let $T := P_{C_N} \circ \ldots \circ P_{C_1}$. Then for every $\varepsilon \in (0,1)$ there exists a point $y \in C_N$ with*

$$\|y\| \leq \alpha(\varepsilon) \text{ and } \|Ty - y\| \leq \varepsilon, \text{ where}$$

$$\alpha(\varepsilon) := \frac{(K^2 + N^3(N-1)^2K^2)N^2}{\varepsilon}.$$

Corollary 4.5 (Kohlenbach [ibid.]).

$$\Phi(\varepsilon, N, b, K) := \left\lceil \frac{18b + 12\alpha(\varepsilon/6))}{\varepsilon} - 1 \right\rceil \left\lceil \left(\frac{D}{\omega(D, \tilde{\varepsilon})} \right) \right\rceil$$

is a rate of asymptotic regularity in Bauschke's result, where

$$\tilde{\varepsilon} := \frac{\varepsilon^2}{27b + 18\alpha(\varepsilon/6)}, \quad D := 2b + NK, \quad \omega(D, \tilde{\varepsilon}) := \frac{1}{16D}(\tilde{\varepsilon}/N)^2.$$

$$\alpha(\varepsilon) := \frac{(K^2 + N^3(N-1)^2K^2)N^2}{\varepsilon}.$$

The case where $Fix(T) \neq \emptyset$ is much simpler:

Theorem 4.6 (Kohlenbach [2016]). *Let $C \subseteq H$ be any nonempty subset of a real Hilbert space H, $T_1, \ldots, T_N : C \to C$ be firmly nonexpansive. Let $T := T_N \circ \ldots \circ T_1$ possess a fixed point $p \in C$ and, for $x \in C$, let $b \geq \|x - p\|, b > 0$. Then for $x_n := T^n x$:*

$$\forall \varepsilon > 0\, \forall n \geq \lceil b/\omega_T(b, \varepsilon) \rceil \, (\|x_{n+1} - x_n\| < \varepsilon), \text{ where}$$

$$\omega_T(b, \varepsilon) := \frac{1}{16b}(\varepsilon/N)^2.$$

Convex feasibility problems

If in Theorem 4.6 the fixed point sets $Fix(T_1), \ldots, Fix(T_N)$ have a nonempty intersection, then any fixed point of T in fact is a common fixed point of $T_1, \ldots, T_N$. This even holds for arbitrary strongly nonexpansive mappings $T_1, \ldots, T_N$ in arbitrary Banach spaces X. In Kohlenbach [ibid.], an explicit bound $\rho(b, \varepsilon)$ (in terms of SNE-moduli for $T_1, \ldots, T_N$) is extracted from the classical proof of this fact such that for $x, p \in C$, p a common fixed point of $T_1, \ldots, T_N$ and $b \geq \|x - p\|$

$$\forall \varepsilon > 0\, (\|T_N T_{N-1} \ldots T_1 x - x\| < \rho(b, \varepsilon) \to \bigwedge_{i=1}^{N} (\|T_i x - x\| < \varepsilon)).$$

Combined with a rate of asymptotic regularity for $T = T_N \circ \ldots \circ T_1$ (which even in this generality is provided in Kohlenbach [ibid.]) this quantitatively solves the problem of constructing a common approximate fixed point of $T_1, \ldots, T_N$.

All this largely holds even in general metric spaces and for strongly quasi-nonexpansive mappings in the sense of Bruck [1982]. Metric projections in so-called CAT(κ)-spaces X (in the sense of Gromov) with $\kappa > 0$ are strongly quasi-nonexpansive and one can construct an explicit modulus for this property which then makes it possible to quantitatively solve the problem to construct a point in the intersection of (ε-neighbourhoods of) finitely many overlapping closed convex subsets of X (i.e. the so-called convex feasibility problem for CAT(κ)-spaces). In the case where X is compact one obtains a rate of metastability for the strong convergence of the iterative use of the composition of the corresponding projections towards a point in the intersection of these sets (see Kohlenbach [2016]).

Other quantitative results in convex optimization have been obtained in

- Ariza-Ruiz, López-Acedo, and Nicolae [2015] and Kohlenbach, López-Acedo, and Nicolae [2017b]: rates of asymptotic regularity and - for compact X - metastability for iterations of compositions of two resolvents in CAT(0)-spaces.
- Kohlenbach, Leuştean, and Nicolae [2018], Kohlenbach, López-Acedo, and Nicolae [2017a], and Sipoş [2017a] rates of asymptotic regularity, strong convergence (in special cases) resp. metastability for the proximal point algorithm.
- Körnlein [2016] explicit such rates for Yamada's hybrid steepest descent method.

5 Proof Mining in Ergodic Theory

Let H be a real Hilbert space, $T : H \to H$ be linear and $\|T(x)\| \leq \|x\|$ for all $x \in H$. Consider the Cesàro mean of the iterates of T :

$$A_n(x) := \frac{1}{n} S_n(x), \text{ where } S_n(x) := \sum_{i=0}^{n-1} T^i(x) \quad (n \geq 1).$$

The von Neumann Mean Ergodic Theorem in the formulation of Riesz states:

Theorem 5.1 (von Neumann Mean Ergodic Theorem)**.** *For every $x \in H$, the sequence $(A_n(x))_n$ strongly converges.*

In Avigad, Gerhardy, and Towsner [2010], it is shown that in general there is no computable rate of convergence, but a primitive recursive rate of metastability is extracted using the proof-theoretic methods discussed above. Tao [2008a] also established (without bound) a uniform metastable version of the Mean Ergodic Theorem in Hilbert space and used that uniformity as a base step for a generalization to commuting families of operators. On the connection to the proof-theoretic approach he comments:

'We shall establish Theorem 1.6 by "finitary ergodic theory" techniques, reminiscent of those used in [Green-Tao]...' 'The main advantage of working in the finitary setting ... is that the underlying dynamical system becomes extremely explicit'...'In proof theory, this finitisation is known as Gödel functional interpretation...which is also closely related to the Kreisel no-counterexample interpretation' (T. Tao [2008a]).
In 1939, Garrett Birkhoff proved:

Theorem 5.2 (Birkhoff [1939]). *The Mean Ergodic Theorem holds for arbitrary uniformly convex Banach spaces.*

Remark 5.3. *In the same year as Birkhoff [ibid.], Lorch [1939] showed that the mean ergodic theorem even holds in all reflexive spaces. However, the class of reflexive spaces does not have enough uniformity to allow for a logical metatheorem on uniform bound extractions and, in fact, in Avigad and Rute [2015] it is shown that a uniform rate of metastability has to depend on the modulus of uniform convexity.*

Since Birkhoff's proof formalizes in the deductive framework of uniformly convex normed spaces (with modulus η) $\mathfrak{A}^\omega[X, \|\cdot\|, \eta]$ (see Kohlenbach [2008a] for the definition of this system) the following is guaranteed a-priorily:

Let X be a uniformly convex Banach space with modulus η and $T : X \to X$ nonexpansive linear operator. Let $b > 0$. Then there is an effective functional Φ in ε, g, b, η s.t. for all $x \in X$ with $\|x\| \le b$, all $\varepsilon > 0$, all $g : \mathbb{N} \to \mathbb{N}$:

$$\exists n \le \Phi(\varepsilon, g, b, \eta)\, \forall i, j \in [n, n + g(n)]\, \big(\|A_i(x) - A_j(x)\| < \varepsilon\big).$$

Note that $T^* := id$ majorizes T.

Based on the logical metatheorem above (for uniformly convex normed spaces) the following rate of metastability was extracted from Birkhoff's proof:

Theorem 5.4 (Kohlenbach and Leuştean [2009]). *Let X be a uniformly convex Banach space, η a modulus of uniform convexity, $T : X \to X$ be as above and $b > 0$. Then for all $x \in X$ with $\|x\| \le b$, all $\varepsilon > 0$ and all $g : \mathbb{N} \to \mathbb{N}$:*

$$\exists n \le \Phi(\varepsilon, g, b, \eta)\, \forall i, j \in [n, n + g(n)]\, \big(\|A_i(x) - A_j(x)\| < \varepsilon\big), \text{ where}$$

$$\Phi(\varepsilon, g, b, \eta) := M \cdot \tilde{h}^{(K)}(1), \text{ with } M := \left\lceil \frac{16b}{\varepsilon} \right\rceil, \gamma := \frac{\varepsilon}{16}\eta\left(\frac{\varepsilon}{8b}\right), \quad K := \left\lceil \frac{b}{\gamma} \right\rceil,$$
$$h, \tilde{h} : \mathbb{N} \to \mathbb{N},\ h(n) := 2(Mn + g(Mn)), \quad \tilde{h}(n) := \max_{i \le n} h(i).$$

If $\eta(\varepsilon) = \varepsilon \cdot \tilde{\eta}(\varepsilon)$ with increasing $\tilde{\eta}$, then we can replace 'η' by '$\tilde{\eta}$' and '16' by '8'. In particular, for $X = L^p$ with $1 < p < \infty$, we may take $\tilde{\eta}(\varepsilon) = \varepsilon^{p-1}/(p2^p)$.

Bounding the number of fluctuations: We say that (x_n) admits k ε-fluctuations if there are $i_1 \leq j_1 \leq \ldots i_k \leq j_k$ s.t. $\|x_{j_n} - x_{i_n}\| \geq \varepsilon$ for $n = 1, \ldots, k$.

Using the analysis of Birkhoff's proof in Kohlenbach and Leuştean [ibid.], Avigad and Rute subsequently improved the rate of metastability to a bound on the number of ε-fluctuations:

Theorem 5.5 (Avigad and Rute [2015]). *$(A_n(x))$ admits at most*

$$\left\lfloor 4\log(M) \cdot \frac{b}{\varepsilon} \right\rfloor + \left\lfloor \frac{b}{\gamma} \right\rfloor \cdot \left\lfloor (4\log(2M) \cdot \frac{b}{\varepsilon} \right\rfloor + \left\lfloor \frac{b}{\gamma} \right\rfloor$$

many ε-fluctuations with b, M, γ as in Theorem 5.4.

In the Hilbert space case, fluctuation bounds had already been obtained in Jones, Ostrovskii, and Rosenblatt [1996].
If the linearity of the nonexpansive operator T is dropped, then the convergence of (x_n) holds weakly (but in general not strongly, see Genel and Lindenstrauss [1975]) by Baillon's nonlinear ergodic theorem:

Theorem 5.6 (Baillon [1975]). *Let H be a real Hilbert space, $C \subseteq H$ bounded closed and convex and $T : C \to C$ be nonexpansive. Then for every $x_0 \in C$, the sequence of Cesàro means (x_n) converges weakly to a fixed point of T.*

A rate of metastability for the weak Cauchy property is extracted in Kohlenbach [2012].

If one either changes the Cesàro means slightly (or adds some weak form of linearity, see below) one can achieve strong convergence. Consider the so-called Halpern iteration Halpern [1967]: Let $T : C \to C$ be nonexpansive, $x_1 \in C$, $\alpha_n \in [0, 1]$

$$x_{n+1} := \alpha_n x_1 + (1 - \alpha_n) T(x_n) \quad (n \geq 1).$$

In contrast to other iterative schemes such as Krasnoselski-Mann iterations, the Halpern iteration often converges strongly (one reason, though, why it is less used convex optimization is that it is not Fejér monotone; see Kohlenbach, Leuştean, and Nicolae [2018] for explicit rates of metastability from strong convergence proofs based on Fejér monotonicity).
Using a weak compactness argument, Wittmann proved in 1992 the following strong convergence result:

Theorem 5.7 (Wittmann [1992]). *Let H be a real Hilbert space, $C \subseteq H$ closed and convex, $x_0 \in C$ and $Fix(T) \neq \emptyset$. Under suitable conditions on (α_n) (e.g. for $\alpha_n := \frac{1}{n+1}$) (x_n) converges strongly towards the fixed point of T that is closest to x_0.*

Remark 5.8. 1. *Wittmann's theorem is a nonlinear generalization of the Mean Ergodic Theorem: for* $\alpha_n := 1/(n+1), C := H$ *and linear* T*, the Halpern iteration coincides with the Cesàro means.*

2. *Another nonlinear generalization of the Mean Ergodic Theorem has been obtained in* Baillon [1976]. *Here one keeps the original Cesàro means but requires that* T *(in addition to being nonexpansive) is odd (and* C *is symmetric). This was further generalized in* Wittmann [1990] *from which an explicit rate of metastability was extracted in* Safarik [2012].

Wittmann's result has been generalized to CAT(0)-spaces by Saejung [2010] using Banach limits. Explicit rates of metastability have been extracted in Kohlenbach [2011] (for Hilbert spaces) with an elimination of the use of weak compactness and in Kohlenbach and Leuştean [2012, 2014] (for CAT(0) spaces) with an elimination of the use of Banach limits.

Moreover, one has a quadratic rate of asymptotic regularity $d(x_n, T(x_n)) \to 0$:

$$\forall \varepsilon > 0\, \forall n \geq \frac{4M}{\varepsilon} + \frac{32M^2}{\varepsilon^2}\ (d(x_n, T(x_n)) < \varepsilon)$$

(See Kohlenbach and Leuştean [2012].) In Leuştean and Nicolae [2016], the proof-theoretic analysis of Saejung's proof has been further generalized to the highly nontrivial case of CAT(κ)-spaces for $\kappa > 0$ producing an explicit rate of metastability even in this context.

6 Proof Mining in Nonlinear Semigroup Theory

Let X be a Banach space, $C \subseteq X$ be a nonempty subset and $\lambda \in (0,1)$.

Definition: A family $\{T(t) : t \geq 0\}$ of nonexpansive mappings $T(t) : C \to C$ is a nonexpansive semigroup if

(i) $T(s+t) = T(s) \circ T(t)\ \ (s,t \geq 0)$,
(ii) for each $x \in C$, the mapping $t \mapsto T(t)x$ is continuous.

Theorem 6.1 (Suzuki [2006]). *Let* $0 < \alpha < \beta$ *such that* α/β *is irrational. Then any fixed point* $p \in C$ *of*

$$S := \lambda T(\alpha) + (1-\lambda)T(\beta) : C \to X$$

is a common fixed point of $T(t)$ *for all* $t \geq 0$.

Let $t \mapsto T(t)x$ be equicontinuous on norm-bounded subsets of C with modulus ω, let f_γ be an effective irrationality measure for $\gamma := \alpha/\beta$, $\Lambda, N, D \in \mathbb{N}$ be s.t. $1/\Lambda \leq \lambda, 1-\lambda$

and $1/N \le \beta \le D$. Then one can extract a bound (see Section 3.3) $\Phi(\varepsilon, M, b) := \Phi(\varepsilon, M, b, N, \Lambda, D, f_\gamma, \omega)$ s.t. for all $M, b \in \mathbb{N}$, $p \in C$, $\varepsilon > 0$

$$\|p\| \le b \wedge \|S(p) - p\| \le \Phi(\varepsilon, M, b) \to \forall t \in [0, M]\,(\|T(t)p - p\| \le \varepsilon).$$

The main noneffective tool used in Suzuki's proof is the binary König's lemma WKL and by Remark 2.4 it is guaranteed to have a primitive recursive (in the sense of Kleene) bound Φ. In fact, the bound actually extracted in Kohlenbach and Koutsoukou-Argyraki [2016] is of rather low complexity:

$$\Phi(2^{-m}, M, b) = \frac{2^{-m}}{8(\sum_{i=1}^{\phi(k,f_\gamma)-1} \Lambda^i + 1)(1 + MN)}, \text{ where}$$

$$k := D2^{\omega_{D,b}(3+[\log_2(1+MN)]+m)+1},\ \phi(k, f) := \max\{2f(i) + 6 \,:\, 0 < i \le k\}.$$

Example: $\alpha = \sqrt{2}, \beta = 2, \lambda = 1/2$. Then $\Lambda = 2, N = 1, D = 2, f_\gamma(p) = 4p^2$. If C is convex (so that $S : C \to C$) and $x_{n+1} := \frac{1}{2}x_n + \frac{1}{2}Sx_n \in C$ starting from $x_0 \in C$ is a d-bounded Krasnoselski iteration sequence of S one has a quadratic rate of asymptotic regularity $\Psi(\varepsilon, d) := 4d^2/(\pi\varepsilon^2)$ (Baillon and Bruck [1996]) and so

$$\forall n \ge \Psi(\Phi(\varepsilon, M, b), d)\ \forall t \in [0, M]\,(\|T(t)x_n - x_n\| \le \varepsilon).$$

Nonexpansive semigroups feature prominently - via the Crandall-Liggett formula - in the study of abstract Cauchy problems that are given by accretive set-valued operators. Explicit rates on the asymptotic behavior of solutions have been obtained by our proof-theoretic methods in Kohlenbach and Koutsoukou-Argyraki [2015] and Koutsoukou-Argyraki [2017].

MODEL THEORY AND ULTRAPRODUCTS

Maryanthe Malliaris

Abstract

The article motivates recent work on saturation of ultrapowers from a general mathematical point of view.

Introduction

In the history of mathematics the idea of the limit has had a remarkable effect on organizing and making visible a certain kind of structure. Its effects can be seen from calculus to extremal graph theory.

At the end of the nineteenth century, Cantor introduced infinite cardinals, which allow for a stratification of size in a potentially much deeper way. It is often thought that these ideas, however beautiful, are studied in modern mathematics primarily by set theorists, and that aside from occasional independence results, the hierarchy of infinities has not profoundly influenced, say, algebra, geometry, analysis or topology, and perhaps is not suited to do so.

What this conventional wisdom misses is a powerful kind of reflection or transmutation arising from the development of model theory. As the field of model theory has developed over the last century, its methods have allowed for serious interaction with algebraic geometry, number theory, and general topology. One of the unique successes of model theoretic classification theory is precisely in allowing for a kind of distillation and focusing of the information gleaned from the opening up of the hierarchy of infinities into definitions and tools for studying specific mathematical structures.

By the time they are used, the form of the tools may not reflect this influence. However, if we are interested in advancing further, it may be useful to remember it. Along this seam, so to speak, may be precisely where we will want to re-orient our approach.

1 The model theoretic point of view

The model theoretic setup is designed to allow in a specific way for placing a given infinite mathematical structure in a class or family in which size and certain other features, such as the appearance of limit points, may vary.

Suppose we wanted to look abstractly at the structure the reals carry when viewed as an ordered field. We might consider $\mathbb{R}$ as a set decorated by the following: a directed graph edge representing the ordering, a first directed hyperedge representing the graph of addition, a second directed hyperedge representing the graph of multiplication, perhaps a third for the graph of subtraction, and two constant symbols marking the additive and multiplicative identities. Stepping back, and retaining only this data of a set of size continuum along with the data of which sets of elements or tuples correspond to which constants, edges, or hyperedges, we might try to analyze the configurations which do or do not arise there.

Suppose we were interested in the structure the group operation gives to the discrete Heisenberg group H. We might consider H simply as an infinite set along with the data of the multiplication table. A priori, this setup just records a countably infinite set made into a group in the given way; it doesn't a priori record that its elements are matrices, much less uni-upper-triangular matrices over $\mathbb{Z}$.

These examples suggest how models arise – simply as sets decorated by the data of relations or functions we single out for study.[1]

The initial loss of information in such a representation will be balanced by the fact that it allows us to place a model within a class and to study models in the class alongside each other. From the model theoretic point of view – the following statement is a starting point for investigation, not its conclusion – this class contains all other models which differ from M in inessential ways.

To place our model M in its class, we consider the *theory* of the model, that is, the set of all sentences of first order logic which hold in M. The elementary class of M is the class of all other models with the same theory. We may frame our study as: of such classes, or of theories.

Every model carries what are essentially derived relations, the boolean algebras of definable sets (see the Appendix). We might say very informally that the theory of a model takes a photograph of these boolean algebras which remembers only finitary information,

[1] A k-place relation on a set X is a subset of X^k. The set of first coordinates of a binary relation is called its domain. A k-place function on a set X is a single-valued binary relation whose domain is X^k. To specify a model, we first choose a language, which can include relation symbols, function symbols, and constant symbols. Then a model is given by the following data: a set X, called the domain; for each relation symbol, a relation on X of the right arity; for each function symbol, a function on X of the right arity; for each constant symbol, an element of X.

such as which finite intersections are and are not empty. The models which share the theory of M will also share this photograph.

The differences among models with the same theory come essentially from the infinite intersections which are finitely approximated, in other words, with the filters and ultrafilters on the boolean algebra of definable sets, as we now explain.

2 Limit points

To see what engenders variation within an elementary class, the following story will motivate the definition of *type*. (The motivation is in the telling, not an historical assertion. Filters independently arose in other, earlier contexts in the early part of the twentieth century.)

Writing their book on general topology in 1937, Bourbaki were discussing whether the definition of limit could be liberated from the countable. Cartan's suggestion was effectively that working in a topological space X, one might turn the problem around and look from the point of view of a limit point. Given a point $x \in X$, the family of neighborhoods containing x had certain very nice features – such as upward closure, closure under finite intersection – which may be abstracted as the definition of *filter*.[2]

Definition 2.1. *For I an infinite set, $\mathfrak{F} \subseteq \mathcal{P}(I)$ is a* filter *on I when (i) $A \subseteq B \subseteq I$ and $A \in \mathfrak{F}$ implies $B \in \mathfrak{F}$, (ii) $A, B \in \mathfrak{F}$ implies $A \cap B \in \mathfrak{F}$, (iii) $\emptyset \notin \mathfrak{F}$.*

Conversely, to any filter, one can assign a (possibly empty) set of limit points: those elements of I which belong to all $A \in \mathfrak{F}$. In defining a filter, we may restrict to any boolean algebra $\mathfrak{B} \subseteq \mathcal{P}(I)$, asking that $\mathfrak{F} \subseteq \mathfrak{B}$, and adding that B in item (ii) belong to $\mathfrak{B}$. In the model theoretic context, this idea gives us a natural way to define limit points for any model, not requiring a metric or a topology per se:

Definition 2.2. *Informally, a* partial type p over a model M *is a filter on M for the boolean algebra of M-definable subsets of M. [More correctly, it is a set of formulas with parameters from M, whose solution sets in M form such a filter.*[3]*] It is a* type *if it*

[2] I learned this story from Maurice Mashaal's biography of Bourbaki, which also cites biographical work of Liliane Beaulieu. Regarding Cartan's definition of filters: "At first [the others] met the idea with skepticism, but Chevalley understood the importance of Cartan's suggestion and even proposed another idea based on it (which became the concept of ultrafilters). Once the approval was unanimous, someone yelled « boum ! » (French for "bang!") to announce that a breakthrough had been made – this was one of Bourbaki's many customs." Mashaal [2006]

[3] This difference is visible in the idea of realizing a given type over M in a model N extending M. The new limit point will belong to the solution sets, in N, of the formulas in the type. Note that 2.2 describes types of *elements*, corresponding to sets of formulas in one free variable plus parameters from M. For each $n > 1$ there is an analogous $\mathbf{S}_n(M)$ describing types of n-tuples.

is maximal, i.e. not strictly contained in any other partial type over M. The Stone space $\mathbf{S}(M)$ is the set of types over M.

A type is *realized* if a corresponding limit point exists in the model, otherwise it is *omitted*. For example, if $M = (\mathbb{Q}, <)$ is the rationals considered as a linear order, $\mathbf{S}(M)$ includes a type for each element of M, which are realized, and types for each irrational Dedekind cut, for $+\infty$, for $-\infty$, and for various infinitessimals, which are omitted.

The *compactness theorem* for first order logic ensures that for any model M and any type or set of types over M we can always find an extension of M to a larger model in the same class in which all these types are realized. (Put otherwise, we may realize types without changing the theory.) Types are fundamental objects in all that follows. From the depth and subtlety of their interaction comes much of the special character of the subject.[4]

In Definition 2.2, we may use "A-definable sets" instead of "M-definable sets" for some $A \subseteq M$ [more correctly, formulas in one free variable with parameters from A]. In this case, call p a type or partial type *of M over A*. Then the following fundamental definition, from work of Morley and of Vaught in the early 1960s, generalizing ideas from Hausdorff on η_α sets, gives a measure of the completeness of a model.

Definition 2.3. *For an infinite cardinal κ, we say a model N is κ^+-*saturated *if every type of N over every $A \subseteq N$ of size $\leq \kappa$ is realized in N.*

For example, if M is an algebraically closed field then for any subfield K of M, the types of M over K will include a distinct type for each minimal polynomial over K (describing a root) and one type describing an element transcendental over K. Since it is algebraically closed, M will be κ^+-saturated if and only if it has transcendence degree at least κ^+.

3 Towards classification theory

Having described a model theoretic point of view – first, regarding a given mathematical object as a model; second, placing it within an elementary class of models sharing the same first-order theory; third, studying as our basic objects these theories, looking both at how models may vary for a given theory (by paying close attention to the structure of types) and at structural differences across theories – some first notable features of this setup are:

[4]And a certain possible conversion of combinatorial into algebraic information, as in the remarkable group configuration theorems of Zilber and Hrushovski.

a) *one can study the truth of statements of first order logic by 'moving' statements among models in allowed ways*.[5]

b) *when working in a given elementary class, unusual constraints observed on variation of models may give leverage for a structural understanding of all models in the class*. E.g. Morley's theorem, the 'cornerstone' of modern model theory, says that if a countable theory has only one model up to isomorphism in *some* uncountable size κ, then this must be true in every uncountable size. Moreover its models must behave analogously to algebraically closed fields of a given characteristic in the sense that, e.g., there are prime models over sets, there are relatively few types, and for each model there is a single invariant, a dimension (the equivalent of transcendence degree) giving the isomorphism type.

c) *simply understanding the structure of the definable sets, say in specific classes containing examples of interest, can already involve deep mathematics*. For instance, Tarski's proof of quantifier elimination for the reals and the cell decomposition theorem for o-minimal structures.

In the examples given so far, as is often the case in mathematics, the specific role of the infinite may be mainly as a kind of foil reflecting the fine structure of compactness, irrespective of the otherwise depth of proofs.

To see the interaction of model theory and set theory which we invoked at the beginning, we need to go further up and further in. (As an aside, already in Hilbert's remarks, via Church, there is an implicit parallel between the understanding of infinite sizes and the development of different models.[6]) Suppose we step back and study the class of all theories.

A thesis of Shelah's groundbreaking *Classification Theory* (1978) is that one can find dividing lines among the class of first-order theories. A dividing line marks a sea change in the combinatorial structure. (The assertion that something is a dividing line requires evidence on both sides: showing that models of theories on one side are all complex in

[5] A clever example is Ax's proof that any injective polynomial map from $\mathbb{C}^n$ to $\mathbb{C}^n$ is surjective. For each finite k and n, there is a sentence $\varphi_{n,k}$ of first order logic in the language $\{+, \times, 0, 1\}$ asserting that any injective map given by $(x_1, \dots, x_n) \mapsto (p_1(x_1, \dots, x_n), \dots, p_n(x_1, \dots, x_n))$ where the p_i are of degree $\leq k$ is surjective. For each prime p, we may write $\bar{F}_p$ as the union of an increasing chain of finite fields. The assertion $\varphi_{n,k}$ is true in each finite field because it is finite, and it follows (e.g. from its logical form) that $\varphi_{n,k}$ holds in $\bar{F}_p$. For $\mathfrak{D}$ any nonprincipal ultrafilter on the primes, $\prod_{p \in P} \bar{F}_p / \mathfrak{D}$ is isomorphic to $\mathbb{C}$, so by Łos' theorem $\varphi_{n,k}$ is true in $\mathbb{C}$.

[6] "Hilbert does not say that the order in which the [list of 23] problems are numbered gauges their relative importance, and it is not meant to suggest that he intended this. But he does mention the arithmetical formulation of the concept of the continuum and the discovery of non-Euclidean geometry as being the outstanding mathematical achievements of the preceding century, and gives this as a reason for putting problems in these areas first, " Church [1968].

some given sense, while models of theories on the other side admit some kind of structure theory.) A priori it is not at all obvious that these should exist. Why wouldn't the seemingly unconstrained range and complexity of theories allow for some kind of continuous gradation along any reasonable axis? The example of extremal combinatorics may give a hint: graphs of a given large finite size are not so easily classifiable, but by examining asymptotic growth rates of certain phenomena, jumps may appear.

Stability, the dividing line which has most profoundly influenced the present field, arises in Shelah [1978] from counting limit points. For a theory T and an infinite cardinal λ, we say T is *λ-stable* if for every model M of T of size λ, $|\mathbf{S}(M)| = \lambda$. Conversely, if some model M of T of size λ has $|\mathbf{S}(M)| > \lambda$, T is *λ-unstable*. For a given λ, T is either λ-stable or λ-unstable by definition. But varying λ, the gap appears[7]:

Theorem 3.1 (Shelah 1978)**.** *Any theory T is either* stable*, meaning stable in all λ such that $\lambda^{|T|} = \lambda$, or* unstable*, meaning unstable in all λ.*

This theorem materializes in step with the development of the internal structure theory. The set theoretic scaffolding is not only in the statement, but intricately connected to its development. A few examples from chs. II-III of Shelah [ibid.] will give a flavor:

i) it turns out stability is local: if T is unstable, then there is a single formula φ such that in all λ, we can already get many types just using definable sets which are instances of φ. (This leads to discovering instability has a characteristic combinatorial configuration, the order property.) Its proof is a counting argument relying on the fact that T is unstable in some λ such that $\lambda = \lambda^{|T|}$.

ii) a characteristic property of stable theories is that once there is enough information, types have unique generic extensions to types over larger sets. This is first explained by the finite equivalence relation theorem which studies types over sets A of size at least 2 in models which are $(|A|^{|T|})^+$-saturated.

iii) conversely, large types are essentially controlled by their restrictions to "small" sets. The cardinal defining this use of "small," $\kappa(T)$, is $\leq |T|^+$. Above this cardinal the mist clears and stability's effects are easier to see; one can e.g. characterize larger saturated models of stable theories as those which are $\kappa(T)$-saturated and every maximal indiscernible set has the cardinality of the model.

iv) instability has a more random form and a more rigid form, and at least one must occur. To see the difference between the two by counting types, one has to know that 2^λ can potentially be different from the number of cuts in a dense linear order of size λ (or the number of branches in a tree with λ nodes), which was originally noted by appeal to an independence result.

[7] $|T|$, the size of T, will be the maximum of the size of the language and $\aleph_0$.

Of course, to say infinite cardinals are strongly connected to the development of stability doesn't mean they are necessarily there at the end. The order property, definability of types, forking, the independence property, and the strict order property, to name a few, don't bear the imprint of their origin. This translation is part of model theory's power.

Looking forwards: the effect of stability, inside and outside model theory, has been significant. Despite this conclusive evidence that some dividing lines do exist, and that they can be very useful, further ones have been challenging to find. We know very few in the vast territory of unstable theories, found – like stability – one by one in response to specific counting problems. To go further, perhaps we can try to shift the way in which set theory sounds out model theoretic information.

The reader may wonder: is model theory being described as a kind of extension to the infinite setting of extremal arguments in combinatorics, with the hierarchy of infinite cardinals replacing the natural numbers? This analogy is challenging, but incomplete. It is incomplete because the finitary, extremal picture doesn't seem to provide a precedent or explanation for the role of model theory, which builds in a remarkable way a bridge between the infinite combinatorial world and a more algebraic one. Still, it is challenging because it leads us to ask what in the infinite setting may play the role of those crucial tools of the combinatorial setting, which may seem to have little place in current model theoretic arguments – namely, probability and randomness.

4 Ultrapowers

Only in the move to ultrapowers does one really recover, albeit in a metaphorical way, that other key ingredient of extremal arguments, the understanding of probability and average behavior.

Stability arises from counting limit points. Recall from 2.3 that saturation is a notion of completeness for a model: λ^+-saturation means all types over all submodels of size at most λ are realized. The ultrapower construction, given formally below, starts with a given model and amplifies it – staying within the elementary class – according to a specific kind of averaging mechanism, an ultrafilter. The resulting larger model, which depends only on the model we began with and the ultrafilter, is called an ultrapower. The level of saturation in the ultrapower reflects whether the given averaging mechanism, applied to the given model, leads to the appearance of many limit points of smaller sets.

If so, this may indicate either that the ultrafilter is powerful, or that the types of the model are not complex. Since we can apply the same ultrafilter to different models and compare the results, however, we can use this construction to compare the 'complexity' of different models (and, dually, of ultrafilters). Restricting to the powerful class of *regular* ultrafilters, whose ability to produce saturation in ultrapowers will be an invariant of the elementary class of the model we begin with, we can use this construction to compare the complexity of theories. Informally for now, the relation on complete countable theories setting $T_1 \trianglelefteq T_2$

> if for any regular ultrafilter $\mathfrak{D}$, if $\mathfrak{D}$-ultrapowers of models of T_2 are sufficiently saturated, so are $\mathfrak{D}$-ultrapowers of models of T_1

is Keisler's order, defined in 1967. It is a pre-order on theories, considered as a partial order on the equivalence classes of theories.

The theorem which convinced the author of this essay, reading around 2005, that it was urgent to study $\trianglelefteq$ further was a theorem in Shelah's *Classification Theory* in a chapter devoted to the ordering. The theorem says that the union of the first two equivalence classes in Keisler's order is precisely the stable theories.

This theorem can be understood as saying that the class of stable theories, which we can see by counting types, can also be seen by asking about good average behavior. Beyond stability, our counting is less useful, and yet the other half, about average behavior, retains its power.

5 In more detail

The idea of a filter was used in 2.2 above to find limit points, but it can also be used to give averages. Maximal filters, called ultrafilters, can be thought of as a coherent choice of which subsets of a given set I are "large."

Definition 5.1. *For an infinite set I, $\mathfrak{D} \subseteq \mathcal{P}(I)$ is an ultrafilter if it is a filter not strictly contained in any other filter.* (*We will assume ultrafilters contain all co-finite sets.*)

The ultraproduct by $\mathfrak{D}$ of a family of models $\langle M_i : i \in I \rangle$ is a model, built in two steps, reflecting the definition of model. First, we define the domain. Identify two elements $\langle a[i] : i \in I \rangle$, $\langle b[i] : i \in I \rangle$ of the Cartesian product $\prod_i M_i$ if $\{i \in I : a[i] = b[i]\} \in \mathfrak{D}$. Definition 2.1 makes this an equivalence relation, and the domain of our ultraproduct N is the set of equivalence classes. Next, fix for transparency a representative of each equivalence class, so that for $a \in N$ and $i \in I$, "$a[i]$" makes sense. The relations, functions, and constants of our language are defined on the ultraproduct by consulting the average of the models: e.g. we say a given k-place relation R holds on $a_1, \dots, a_k$ in N iff $\{i : R(a_1[i], \dots, a_k[i])$ holds in $M_i\} \in \mathfrak{D}$, and for an n-place function f, define $f(a_1, \dots, a_n)$ to be the equivalence class of $\langle b[i] : i \in I \rangle$ where $b[i] = f(a_1[i], \dots, a_n[i])$ computed in M_i. The special case of an ultrapower, where all the factor models are isomorphic, transforms a given structure into a larger, 'amplified' model in the same elementary class. For example, letting $\mathfrak{D}$ be a regular ultrafilter on the set of primes, $\prod_p \overline{\mathbb{F}}_p/\mathfrak{D} \cong \mathbb{C}$, but if we consider the ultrapower $M^P/\mathfrak{D}$ where M is the algebraic closure of the rationals, we also get $\mathbb{C}$.

There is a veiled interaction between the two model theoretic uses of filters: the realization of *types* in the ultrapower, and the *ultrafilter* used in the construction. This is most useful when the ultrafilter is *regular*, ensuring that saturation depends only on finitary input from each factor model. For each regular $\mathfrak{D}$, whether or not an ultrapower $M^I/\mathfrak{D}$ is $|I|^+$-saturated is an invariant of the elementary class of the model M we began with.[8]

Keisler's suggestion was that this could be used to compare theories.

Definition 5.2 (Keisler's order, 1967)**.** *Let T_1, T_2 be complete countable theories.*

$$T_1 \trianglelefteq T_2$$

if for every infinite λ, every regular ultrafilter $\mathfrak{D}$ on λ, every model M_1 of T_1 and every model M_2 of T_2, if $(M_2)^\lambda/\mathfrak{D}$ is λ^+-saturated, then $(M_1)^\lambda/\mathfrak{D}$ is λ^+-saturated.

Informally, say "$\mathfrak{D}$ saturates T" if for some (by regularity of $\mathfrak{D}$, the choice does not matter) model M of T, $M^\lambda/\mathfrak{D}$ is λ^+-saturated: all limit points over small submodels appear. Then Keisler's order puts T_1 less than T_2 if every regular ultrafilter able to saturate T_2 is able to saturate T_1. Note that any two theories may in principle be compared – algebraically closed fields of fixed characteristic, random graphs, real closed fields. Keisler proved his order was well defined and had a minimum and a maximum class (he gave a sufficient condition for membership in each), and asked about its structure.

The crucial chapter on Keisler's order in Shelah [1978] was already mentioned. Its structure on the unstable, non-maximal theories was left there as an important open question. Following Shelah [ibid.], work on Keisler's order stalled for about thirty years. The question was reopened in Malliaris' thesis and in the series of papers Malliaris [2009, 2010b,a, 2012a,b], guided by the perspective described above. Then in the last few years, a very productive ongoing collaboration of Malliaris and Shelah [2015a, 2014a, 2013a,b, 2016a,b, 2018b]... has advanced things considerably.

6 The current picture

Along this road, what does one find?
(a) First, we do indeed see evidence of dividing lines – many more than previously thought. Much remains to be done in understanding them and in characterizing the structure/nonstructure which come with the assertion of a dividing line, but already their appearance, in a region

[8] That can be taken as a definition of regular; alternatively, $\mathfrak{D}$ is a regular ultrafilter on I if there is a set $\{X_\alpha : \alpha < |I|\} \subseteq \mathfrak{D}$ such that the intersection of any infinitely many of its elements is empty. Regular ultrafilters are easy to build and exist on any infinite set.

of theories thought to be relatively tame, is surprising and exciting. In Malliaris and Shelah [2018b], Malliaris and Shelah prove that Keisler's order has infinitely many classes. The theories which witness these different classes come from higher analogues of the countable triangle-free random graph, originally studied by Hrushovski [2002]: the infinite generic tetrahedron-free three-hypergraph, the infinite generic 4-uniform hypergraph with no complete hypergraph on 5 vertices, and so on. The proof shows they may have very different average behavior, as reflected in their differing sensitivity to a certain degree of calibration in the ultrafilters.

These results build on advances in ultrafilter construction, which allow for a greater use of properties of cardinals, even for ultrafilters in ZFC.

Several incomparable classes are known Malliaris and Shelah [2018a], Ulrich [2017], Malliaris and Shelah [2015b] and it may be that future work will reveal many. Perhaps the way that such averages could be perturbed or distorted, and by extension the structure of dividing lines among unstable theories, will be much finer than what we now see. If so, even independence results could be quite useful model theoretically. These may simply witness that the boolean algebras associated to different theories are essentially different, because they react differently to certain exotic averaging mechanisms, when these appear. The internal theories of each equivalence class, giving an account of what allows for the different reactions, would presumably be, like IP or SOP, absolute.

(b) Second, this line of work has led to some surprising theorems about the finite world. These theorems have the following general form. We know that among theories with infinite models, stability is a dividing line, with models of stable theories admitting a strong structure theory. There is a specific combinatorial configuration, the order property, which (in infinite models) characterizes instability. In an infinite graph, instability for the edge relation would correspond to having arbitrarily large *half-graphs*, that is, for all k having vertices $a_1, \dots, a_k$ and $b_1, \dots, b_k$ with an edge between a_i and b_j iff $i < j$. (Note that there are no assertions made about edges among the a's and among the b's, so in forbidding k-half graphs, we forbid a family of configurations.) The thesis of Malliaris and Shelah [2014b] is essentially that finite graphs with no long half-graphs, called *stable graphs*, behave much better than all finite graphs, in the sense predicted by the infinite case.

Szemerédi's celebrated regularity lemma says, roughly, that for every $\epsilon > 0$ there is $N = N(\epsilon)$ such that any sufficiently large graph may be equitably partitioned into $k \leq N$ pieces such that all but at most ϵk^2 pairs of pieces have the edges between them quite evenly distributed (i.e. are ϵ-regular). The elegant picture of this lemma absorbs the general complexity of graphs in two ways: first, by work of Gowers, N is a very large function of ϵ; second, as noticed independently by a number of researchers, the condition that some pairs of pieces be irregular cannnot be removed, as shown by the example of half-graphs (Komlós and Simonovits [1996]). As a graph theorist, one might expect half-graphs to be just one example of bad behavior, not necessarily unique; but in light of the above, a model theorist may guess that in the absence of long half-graphs one will find structured behavior. The stable regularity lemma of Malliaris and Shelah [2014b] shows that indeed, half-graphs are the only reason for irregular pairs: finite stable graphs admit regular partitions with no irregular pairs and the number of pieces singly-exponential in ϵ.

A second theorem in that paper, a stable Ramsey theorem, proves that for each k there is $c = c(k)$ such that if G is a finite graph with no k-half graphs then G contains a clique or an independent set of size $|G|^c$, much larger than what is predicted by Ramsey's theorem. This meets the prediction of the Erdős-Hajnal conjecture, which says that for any finite graph H there is $c = c(H)$ such that if G contains no induced copies of H then G contains a clique or an independent set of size $|G|^c$. But very few other cases of this conjecture are known. What is the contribution of the infinite here? The infinite version of Ramsey's theorem says that a countably infinite graph contains a countable clique or a countable independent set. Extending this to larger cardinals doesn't get far: Erdős-Rado shows the graph and the homogeneous set may not, in general, increase at the same rate. Model theory, however, refracts this result across different classes of theories, and across dividing lines, and in some classes, such as the stable theories, it behaves differently: the existence of large sets of indiscernibles in stable theories implies, a fortiori, that an infinite stable graph of size κ^+ will have a clique or independent set of size κ^+, much larger than predicted by Erdős–Rado. Once one knows where to look, one can find the analogous phenomenon in the finite case (also for hypergraphs).

The stable Ramsey theorem was applied by Malliaris and Terry [2018] to re-prove a theorem in the combinatorics literature, by re-organizing the proof into cases which take advantage of the stable Ramsey theorem, and thus to obtain better bounds for the original theorem; finitary model-theoretic analysis may be useful even where model theoretic hypotheses are not used in the theorems.

It may seem that these theorems of Malliaris and Shelah [2014b], from the first joint paper of Malliaris and Shelah, could in principle have been discovered earlier, and yet they were not. They belong to the perspective of this program in a deep way. They were motivated by work in Malliaris [2010b] and Malliaris [2010a], directed towards Keisler's order, which first applied Szemerédi regularity to study the complexity of formulas (and showed that the simple theories, of special interest in Keisler's order, were in some sense controlled by stable graphs).

(c) Third, by means of these methods model theory has paid an old debt to set theory and general topology, by solving a seventy-year-old problem about cardinal invariants of the continuum. Two infinite cardinals, $\mathfrak{p}$ and $\mathfrak{t}$, known to be uncountable but no larger than the continuum, are shown in Malliaris and Shelah [2013b], Malliaris and Shelah [2016a] to be unconditionally equal. The proof is model-theoretic, and comes in the context of the solution of an a priori unrelated problem, determining a new sufficient condition for maximality in Keisler's order.

In slightly more detail, in order for a regular ultrafilter to handle the most complex theories, those in the maximum class, it must be in some sense very balanced. Distortions and so to speak imperfections which might pass unnoticed in more robust theories will translate immediately in maximal theories to the omission of types. However, a surprising fact from Shelah [1978] is that what is needed for the theory to be complex is not necessarily that it be expressive. A kind of brittleness or overall rigidity as exemplified by the theory of linear order will also suffice. Remarkably, it turns out even less will suffice: the engine of the proof in Malliaris and Shelah [2016a] is in showing that if the ultrafilter can ensure certain paths through trees have upper bounds, it must be strong enough to produce the needed limit points for any theory. The resulting comparison of theories whose models contain the relevant trees, to models of linear orders, via ultrapowers, turns out to be parallel in a precise sense to the comparison of $\mathfrak{p}$ and $\mathfrak{t}$. It was possible to give a fundamental model-theoretic framework encompassing both problems and so to solve them both. A commentary and an expository account of the proof are Moore [2013], Casey and Malliaris [2017].

Still, a model theoretic necessary condition for maximality remains open.
It has been almost ten years since Malliaris [2009]. Profound questions remain, urgent in their simplicity.

Appendix: on definable sets

By convention, we always assume our language $\mathfrak{L}$ contains a binary relation symbol $=$, and that in every $\mathfrak{L}$-model this symbol is interpreted as equality. Besides the symbols of $\mathfrak{L}$, our alphabet for building formulas includes infinitely many variables along with logical symbols $(,), \wedge, \vee, \neg, \iff, \implies, \forall, \exists$.

For awhile let $M_\star$ denote a model for the language $\mathfrak{L}_\star = \{+, \times, -, 0, 1, <\}$, where $+$, $\times$, $-$ are binary function symbols, $<$ is a binary relation, and $0, 1$ are constants. Let us say the domain of $M_\star$ is $\mathbb{R}$ and the symbols have their usual interpretation.[9]

The *terms* of a language are elaborate names. We define terms by induction. All variables and constant symbols are terms; if f is a k-place function symbol and $t_1, \dots, t_k$ are terms, then $f(t_1, \dots, t_k)$ is a term; and a finite string of allowed symbols is a term iff it can be built in finitely many steps in this way.

[9] Pedantically, the form of the symbols makes no demands on their interpretation (other than the basic conditions in the footnote on p. 102); we could, for example, give a perfectly valid model by interpreting both $+$ and $\times$ by projection onto the first coordinate.

The $\mathfrak{L}_\star$-terms include 0, 1, $1+1$ which we may abbreviate 2, $x+1$, $x \times y$, $(x \times 1) + (y + 0)$, $((x \times x) \times x)$ which we may abbreviate x^3. Using similar abbreviations, and dropping parentheses for readability, $x^5 + 15x^2 + 3x + 5$ is also a term.

A key feature of terms is that *if* we are working in a model, and we are given a term along with instructions of which elements of the model to put in for which, if any, variables in the term (recall that in any model, any constant symbols must already refer to specific elements), then the term will evaluate unambiguously to some other element of the model.

Next, by induction, we define *formulas*. Atomic formulas are assertions that a given relation symbol of our language holds on a given sequence of terms. (In $\mathfrak{L}_\star$, the relation symbols are $=$ and $<$, so these will include $x^3+5x+2 = 0$ and also $5+x+15y^2 > 37-z$.) Atomic formulas are formulas. If φ is a formula, then $\neg(\varphi)$ is a formula. If φ and ψ are formulas, then $(\varphi \wedge \psi)$, $(\varphi \vee \psi)$, $(\varphi \implies \psi)$, $(\varphi \iff \psi)$ are also formulas. If φ is a formula, and x is a variable, then $(\exists x)\varphi$ and $(\forall x)\varphi$ are formulas. A finite string of allowed symbols is a formula iff it can be built in finitely many steps in this way.

In our example here are some more formulas: $(\forall x)(x + 0 = x)$, $(\exists x)(y + x^2 = z)$. Note an important difference between the two. $(\forall x)(x+0 = x)$ is an assertion which will be true or false in any given model; in our given $M_\star$ it is true. By contrast, $(\exists x)(y+x^2 = z)$ is neither true nor false, since it has two free variables; rather, it has a *solution set*, the pairs (a, b) of elements of M such that $(\exists x)(a + x^2 = b)$. In any model N, the solution sets of formulas with one or more [but always finitely many] free variables are called the *definable sets*. The closure properties of the set of formulas show that for each n, the definable sets on N^n form a boolean algebra.

The formulas with no free variables are called *sentences*, and the theory of a model N is the set of all sentences which hold in N. The elementary class of N is the class of all other models in the same language with the same theory. The reason a theory may make assertions about definable sets which are meaningful across different models is by referring to their defining formulas.

When a formula has many free variables, it may be useful to look at the restricted solution set we get after specifying that certain of the free variables take certain values in the model. For example, in the formula $xy^2 + zy + w = 0$ with free variables x, y, z, w, we might want to consider the solution set under specific values of x, z and w. Such a solution set is called *definable with parameters*, the specific values being the parameters. We may wish to record their provenance: given a subset A of a model N, the sets definable with parameters from A are called *A-definable sets*. Finally, a word on types. Given M and $A \subseteq M$, the set of formulas with parameters from A and (say) one free variable can be made into a boolean algebra once the formulas are identified up to logical equivalence (equivalently, identified if they define the same set in M). Its Stone space is the set of types of M over A in the sense of 2.2 above, and its compactness as a topological space is explained by the compactness theorem.

Some examples – here, definable means with parameters:

1) in the model $M_\star$ above, the definable sets include the semialgebraic sets (and it is a theorem that they are exactly the semialgebraic sets). Its elementary class is the class of real closed ordered fields.

2) if $\mathcal{L} = \{+, \times, -, 0, 1\}$ and M is the algebraic closure of the rationals on which the symbols have their usual interpretation, the definable sets include (and, in fact, are) the constructible sets. The elementary class of M is the class of all algebraically closed fields of characteristic zero.

3) if $\mathcal{L} = \{<,\}$, and M is the rationals on which $<$ has its usual interpretation, the definable sets in one free variable are finite unions of points and intervals (and the definable sets in $k > 1$ free variables satisfy a cell decomposition theorem). The elementary class of M, the class of dense linear orders without a first or last element, has only one countable model, up to isomorphism, but 2^λ nonisomorphic models of each uncountable size λ.

QUIVERS WITH RELATIONS FOR SYMMETRIZABLE CARTAN MATRICES AND ALGEBRAIC LIE THEORY

Christof Geiß

Abstract

We give an overview of our effort to introduce (dual) semicanonical bases in the setting of symmetrizable Cartan matrices.

1 Introduction

One of the original motivations of Fomin and Zelevinsky for introducing cluster algebras was "to understand, in a concrete and combinatorial way, G. Lusztig's theory of total positivity and canonical bases" Fomin [2010]. This raised the question of finding a cluster algebra structure on the coordinate ring of a unipotent cell, and to study its relation with Lusztig's bases. In a series of works culminating with Geiß, Leclerc, and Schröer [2011] and Geiß, Leclerc, and Schröer [2012], we showed that the coordinate ring of a unipotent cell of a symmetric Kac-Moody group has indeed a cluster algebra structure, whose cluster monomials belong to the dual of Lusztig's semicanonical basis of the enveloping algebra of the attached Kac-Moody algebra. Since the semicanonical basis is built in terms of constructible functions on the complex varieties of nilpotent representations of the preprojective algebra of a quiver, it is not straightforward to extend those results to the setting of symmetrizable Cartan matrices, which appears more natural from the Lie theoretic point of view. The purpose of these notes is to give an overview of Geiß, Leclerc, and Schröer [2017a] - Geiß, Leclerc, and Schröer [2017d], where we are trying to make progress into this direction.

The starting point of our project was Hernandez and Leclerc [2016], where they observed that certain quivers with potential allowed to encode the q-characters of the Kirillov-Reshetikhin modules of the quantum loop algebra $U_q(L\mathfrak{g})$, where $\mathfrak{g}$ is a complex simple Lie algebra of arbitrary Dynkin type. This quiver with potential served as model for the definition of our generalized preprojective algebras $\Pi = \Pi_K(C, D)$ associated to a symmetrizable Cartan matrix C with symmetrizer D over an arbitrary field K, which extends

MSC2010: primary 16G20; secondary 17B67, 13F60, 14M15.

the classical construction of Gelfand and Ponomarev [1979]. After the completion of a preliminary version of Geiß, Leclerc, and Schröer [2017a] we learned that Cecotti and Del Zotto [2012] and Yamakawa [2010] had introduced similar constructions for quite different reasons. In comparison to the classical constructions of Dlab and Ringel [1974], Dlab and Ringel [1980] for a symmetrizable Cartan matrix C, we replace field extensions by truncated polynomial rings. Many of the core results of representations of species carry over over to this setting if we restrict our attention to the so-called locally free modules, see Geiß, Leclerc, and Schröer [2017a]. In particular, we have for each orientation Ω of C an algebra $H = H_K(C, D, \Omega)$ such that in many respects Π can be considered as the preprojective algebra of H. Our presentation of these results in Section 3 is inspired by the thesis Geuenich [2016], he obtains similar results for a larger class of algebras.

Since our construction works in particular over algebraically closed fields, we can extend to our algebras H and Π several basic results about representation varieties of quivers and of varieties of nilpotent representations of the preprojective algebra of a quiver in our new context, again if we restrict our attention to locally free modules, see Section 4. Nandakumar and Tingley [2016] obtained similar results by studying the set of K-rational points of the representation scheme of a species preprojective algebra, which is defined over certain infinite, non algebraically closed fields K.

In our setting we can take $K = \mathbb{C}$, and study algebras of constructible functions on those varieties of locally free modules and realize in this manner the universal enveloping algebra $U(\mathfrak{n})$ of the positive part $\mathfrak{n}$ of a complex semisimple Lie algebra, together with a Ringel type PBW-basis in terms of the representations of H. For arbitrary symmetrizable Cartan matrices we can realize $U(\mathfrak{n})$ together with a semicanonical basis, modulo our *support conjecture*, see Section 5.

Conventions. We use basic concepts from representation theory of finite dimensional algebras, like Auslander-Reiten theory or tilting theory without further reference. A good source for this material is Ringel [1984]. For us, a quiver is an oriented graph $Q = (Q_0, Q_1, s, t)$ with vertex set Q_0, arrow set Q_1 and functions $s, t\colon Q_1 \to Q_0$ indicating the start and terminal point of each arrow. We also write $D = \operatorname{Hom}_K(-, K)$. We say that an A-module M is *rigid* if $\operatorname{Ext}^1_A(M, M) = 0$.

2 Combinatorics of symmetrizable Cartan matrices

2.1 Symmetrizable Cartan matrices and quivers. Let $I = \{1, 2, \dots, n\}$. A *symmetrizable Cartan matrix* is an integer matrix $C = (c_{ij}) \in \mathbb{Z}^{I\times I}$ such that the following holds:

- $c_{ii} = 2$ for all $i \in I$ and $c_{ij} \leq 0$ for all $i \neq j$,

- there exist $(c_i)_{i\in I} \in \mathbb{N}_+^I$ such that $\operatorname{diag}(c_1, \dots, c_n) \cdot C$ is a symmetric.

In this situation $D := \operatorname{diag}(c_1, \dots, c_n) \in \mathbb{Z}^{I\times I}$ is called the *symmetrizer* of C. Note that the symmetrizer is not unique. In particular, for all $k \in \mathbb{N}_+$ also kD is a symmetrizer of C.

It is easy to see that the datum (C, D) of a symmetrizable Cartan matrix C and its symmetrizer D is equivalent to displaying a weighted graph $(\Gamma, \underline{d})$ with

- I the set of vertices of Γ,
- $g_{ij} := \gcd(c_{ij}, c_{ji})$ edges between i and j,
- $\underline{d}\colon I \to \mathbb{N}_+, i \mapsto c_i$.

Here we agree that $\gcd(0,0) = 0$. We have then $c_{ij} = -\frac{\operatorname{lcm}(c_i,c_j)}{c_i} g_{ij}$ for all $i \neq j$.

2.2 Bilinear forms, reflections and roots. We identify the root lattice of the Kac-Moody Lie algebra $\mathfrak{g}(C)$ associated to C with $\mathbb{Z}^I = \oplus_{i\in I}\mathbb{Z}\alpha_i$, where the simple roots $(\alpha_i)_{i\in I}$ form the standard basis. We define on $\mathbb{Z}^I$ by

$$(\alpha_i, \alpha_j)_{C,D} = c_i c_{ij},$$

a symmetric bilinear form. The *Weyl group* $W = W(C)$ is the subgroup of $\operatorname{Aut}(\mathbb{Z}^I)$, which is generated by the simple reflections s_i for $i \in I$, where

$$s_i(\alpha_j) = \alpha_j - c_{ij}\alpha_i.$$

The *real roots* are the set

$$\Delta_{\text{re}}(C) := \cup_{i\in I} W(\alpha_i).$$

The *fundamental region* is

$$F := \{\alpha \in \mathbb{N}^I \mid \operatorname{supp}(\alpha) \text{ is connected, and } (\alpha, \alpha_i)_{C,D} \leq 0 \text{ for all } i \in I\}.$$

Here, $\operatorname{supp}(\alpha)$ is the full subgraph of $\Gamma(C)$ with vertex set $\{i \in I \mid \alpha(i) \neq 0\}$. Then the imaginary roots are by definition the set

$$\Delta_{\text{im}}(C) := W(F) \cup W(-F).$$

Finally the set of all roots is

$$\Delta(C) := \Delta_{\text{re}} \cup \Delta_{\text{im}}(C).$$

The positive roots are $\Delta^+(C) := \Delta(C) \cap \mathbb{N}^I$, and it is remarkable that $\Delta(C) = \Delta^+(C) \cup -\Delta^+(C)$.

A sequence $\mathbf{i} = (i_1, i_2, \dots, i_l) \in I^l$ is called a *reduced expression* for $w \in W$ if $w = s_{i_l} \cdots s_{i_2} s_{i_1}$ and w can't be expressed as a product of less than $l = l(w)$ reflections of the form s_i $(i \in I)$. In this case we set

$$\beta_{\mathbf{i},k} := s_{i_1} s_{i_2} \cdots s_{i_{k-1}}(\alpha_{i_k}) \text{ and } \gamma_{\mathbf{i},k} := s_{i_l} s_{i_{l-1}} \cdots s_{i_{k+1}}(\alpha_{i_k}) \tag{2.1}$$

for $k = 1, 2, \dots, l$, and understand $\beta_{\mathbf{i},1} = \alpha_{i_1}$ as well as $\gamma_{\mathbf{i},l} = \alpha_{i_l}$. It is a standard fact that $\beta_{\mathbf{i},k} \in \Delta^+$ for $k = 1, 2, \dots, l$, and that these roots are pairwise different. Obviously,

$$w(\beta_{\mathbf{i},k}) = -\gamma_{\mathbf{i},k} \text{ for } k = 1, 2, \dots, l.$$

The following result is well known.

Proposition 2.1. *For a connected, symmetrizable Cartan matrix C the following are equivalent:*

- *C is of Dynkin type.*
- *The Weyl group $W(C)$ is finite.*
- *The root system $\Delta(C)$ is finite*
- *All roots are real: $\Delta(C) = \Delta_{\mathrm{re}}(C)$.*

Moreover, if in this situation $\mathbf{i}$ is a reduced expression for w_0, the longest element of W, then $\Delta^+ = \{\beta_{\mathbf{i},1}, \beta_{\mathbf{i},2}, \dots, \beta_{\mathbf{i},l}\}$.

2.3 Orientation and Coxeter elements. An *orientation* of C is a set $\Omega \subset I \times I$ such that

- $|\Omega \cap \{(i,j),(j,i)\}| > 0 \iff c_{ij} < 0$,
- for each sequence $i_1, i_2, \dots, i_{k+1}$ with $(i_j, i_{j+1}) \in \Omega$ for $j = 1, 2, \dots, k$ we have $i_1 \neq i_{k+1}$.

The orientation Ω can be interpreted as upgrading the weighted graph $(\Gamma, \underline{d})$ of (C, D) to a weighted quiver $(Q^\circ, \underline{d})$ with g_{ij} arrows $\alpha_{ij}^{(1)}, \dots \alpha_{ij}^{(g_{ij})}$ from j to i if $(i,j) \in \Omega$, such that $Q^\circ = Q^\circ(C, \Omega)$ has no oriented cycles.

For an orientation Ω of the symmetrizable Cartan matrix $C \in \mathbb{Z}^{I \times I}$ and $i \in I$ we define

$$s_i(\Omega) := \{(r,s) \in \Omega \mid i \notin \{r,s\}\} \cap \{(s,r) \in I \times I \mid (r,s) \in \Omega \text{ and } i \in \{r,s\}\}.$$

Thus, in $Q^\circ(C, s_i(\Omega))$ the orientation of precisely the arrows in $Q^\circ(C,\Omega)$, which are incident with i, is changed. If i is a sink or a source of $Q^\circ(C,\Omega)$ then $s_i(\Omega)$ is also an orientation of C. It is convenient to define

$$\Omega(-,i) := \{j \in I \mid (j,i) \in \Omega\} \text{ and } \Omega(j,-) := \{i \in I \mid (j,i) \in \Omega\}.$$

We have on $\mathbb{Z}^I$ the *non-symmetric bilinear form*

$$\langle -,- \rangle_{C,D,\Omega} \colon \mathbb{Z}^I \times \mathbb{Z}^I \to \mathbb{Z}, (\alpha_i, \alpha_j) \mapsto \begin{cases} c_i & \text{if } i = j, \\ c_i c_{ij} & \text{if } (j,i) \in \Omega, \\ 0 & \text{else.} \end{cases} \tag{2.2}$$

We leave it as an exercise to verify that

$$\langle \alpha, \beta \rangle_{C,D,\Omega} = \langle s_i(\alpha), s_i(\beta) \rangle_{C,D,s_i(\Omega)} \tag{2.3}$$

if i is a sink or a source for Ω.

We say that a reduced expression $\mathbf{i} = (i_1, i_2, \dots, i_l)$ of $w \in W$ is $+$-*admissible* for Ω if i_1 is a sink of $Q^\circ(C,\Omega)$, and i_k is a sink of $Q^\circ(C, s_{i_{k-1}} \cdots s_{i_2} s_{i_1}(\Omega))$ for $k = 2, 3, \dots, l$. If moreover $l = n$ and $\{i_1, \dots, i_n\} = I$, we say that $c = s_{i_n} \cdots s_{i_2} s_{i_1}$ is the *Coxeter element* for (C,Ω).

2.4 Kac-Moody Lie algebras. For a symmetrizable Cartan matrix $C \in \mathbb{Z}^{I\times I}$, the derived Kac-Moody Lie algebra $\mathfrak{g}' = \mathfrak{g}'(C)$ over the complex numbers has a presentation by $3n$ generators e_i, h_i, f_i $(i \in I)$ subject to the following relations:

(i) $[e_i, f_j] = \delta_{ij} h_i$;

(ii) $[h_i, h_j] = 0$;

(iii) $[h_i, e_j] = c_{ij} e_j, \quad [h_i, f_j] = -c_{ij} f_j$;

(iv) $(\operatorname{ad} e_i)^{1-c_{ij}}(e_j) = 0, \quad (\operatorname{ad} f_i)^{1-c_{ij}}(f_j) = 0 \qquad (i \neq j)$.

Note that for C of Dynkin type this is the Serre presentation of the corresponding semisimple Lie algebra. In case rank $C < |I|$ we have of $\mathfrak{g}'(C) \neq \mathfrak{g}(C)$ and the latter has in this case a slightly larger Cartan subalgebra, which makes for a more complicated definition, see for example Geiß, Leclerc, and Schröer [2017c, Sec. 5.1] for a few more details. Of course, the main reference is Kac [1990].

Let $\mathfrak{n} = \mathfrak{n}(C)$ be the Lie subalgebra generated by the e_i $(i \in I)$. Then $U(\mathfrak{n})$ is the associative $\mathbb{C}$-algebra with generators e_i $(1 \le i \le n)$ subject to the relations

$$(\operatorname{ad} e_i)^{1-c_{ij}}(e_j) = 0, \qquad (i, j \in I, i \neq j). \tag{2.4}$$

$U(\mathfrak{n})$ is $\mathbb{N}^I$ graded with $\deg(e_i) = \alpha_i$ $(i \in I)$. With

$$\mathfrak{n}_\alpha := \mathfrak{n} \cap U(\mathfrak{n})_\alpha \text{ for } \alpha \in \Delta^+(C)$$

we recover the usual root space decomposition of $\mathfrak{n}$.

3 Quivers with relations for symmetrizable Cartan matrices

We keep the notations from the previous section, in particular $C \in \mathbb{Z}^{I\times I}$ is a symmetrizable Cartan matrix with symmetrizer D and Ω is an orientation for C.

3.1 A class of 1-Iwanaga-Gorenstein algebras. Let K be a field and $Q = Q(C, D, \Omega)$ the quiver obtained from $Q^\circ(C, D, \Omega)$, see Section 2.3, by adding a loop ϵ_i at each vertex $i \in I$. Then $H = H_K(C, D, \Omega)$ is the path algebra KQ modulo the ideal which is generated by the following relations:

- $\epsilon_i^{c_i}$ for all $i \in I$
- $\epsilon_i^{-c_{ji}/g_{ji}} \alpha_{ij}^{(k)} - \alpha_{ij}^{(k)} \epsilon_j^{-c_{ij}/g_{ij}}$ for all $(i, j) \in \Omega$ and $k = 1, 2, \dots g_{ij}$.

Recall that $g_{ij} = g_{ji} = \gcd(c_{ij}, c_{ji})$, thus $-c_{ij}/g_{ij} = \operatorname{lcm}(c_i, c_j)/c_i$.

For $(i, j) \in \Omega$ let $c'_{ij} = c_{ij}/g_{ij}$ and $c'_{ji} = c_{ji}/g_{ij}$. We may consider the following symmetrizable Cartan matrix, symmetrizer and orientation:

$$C^{(i,j)} = \begin{pmatrix} 2 & c'_{ij} \\ c'_{ji} & 2 \end{pmatrix}, \quad D^{(i,j)} = \begin{pmatrix} c_i & 0 \\ 0 & c_j \end{pmatrix} \quad \text{and} \quad \Omega^{(i,j)} = \{(i, j)\}.$$

Thus,

$$Q^{(i,j)} := Q(C^{(i,j)}, \Omega^{(i,j)}) \quad = \quad \epsilon_i \circlearrowright i \xleftarrow{\alpha_{ij}} j \circlearrowleft \epsilon_j$$

and

$$H^{(i,j)} := H_K(C^{(i,j)}, D^{(i,j)}, \Omega^{(i,j)}) = KQ^{(i,j)}/\langle \epsilon_i^{c_i}, \epsilon_j^{c_j}, \epsilon_i^{-c'_{ji}} \alpha_{ij} - \alpha_{ij} \epsilon_j^{-c'_{ij}} \rangle.$$

Note, that with

$${}_iH'_j := e_i H^{(i,j)} e_j \quad \text{and} \quad H_i = e_i H_i e_i = K[\epsilon_i]/(\epsilon_i^{c_i})$$

it is easy to see that ${}_iH_j := {}_iH_j'^{\oplus g_{ij}}$ is a H_i-H_j-bimodule, which is free of rank $-c_{ij}$ as a H_i-module, and free of rank $-c_{ji}$ as H_j-(right)-module. If we define similarly $H^{(j,i)} :=$

$H_K(C^{(i,j)}, D^{(i,j)}, \{(j,i)\})$ and ${}_jH_i' := e_j H^{(j,i)} e_j$, then ${}_jH_i = {}_jH_i'^{\oplus g_{ij}}$ is a H_j-H_i-bimodule, which is free of rank $-c_{ji}$ as H_j-module and free of rank $-c_{ij}$ as H_i-(left)-module. It is easy to see that we get an isomorphism of H_i-H_j-bimodules

$$ {}_iH_j \cong \operatorname{Hom}_K({}_jH_i, K). $$

The adjunction yields for H_k-modules M_k, for $k \in \{i, j\}$, a natural isomorphism of vector spaces

$$ \operatorname{Hom}_{H_i}({}_iH_j \otimes_{H_j} M_j, M_i) \to \operatorname{Hom}_{H_j}(M_j, {}_jH_i \otimes_{H_i} M_i),\ f \mapsto f^{\vee}. \tag{3.1} $$

Quite similarly to the representation theory of modulated graphs, in the sense of Dlab and Ringel [1974], we have the following basic results from Geiß, Leclerc, and Schröer [2017a, Prop. 6.4] and Geiß, Leclerc, and Schröer [ibid., Prop. 7.1].

Proposition 3.1. *Set $H := H_K(C, D, \Omega)$. With $S := \times_{i\in I} H_i$ we can consider $B := \bigoplus_{(i,j)\in\Omega} {}_iH_j$ as an S-S-bimodule and find:*

(a) $H \cong T_S(B) := \bigoplus_{j\in\mathbb{N}} B^{\otimes_S j}$, i.e. H is a tensor algebra.

(b) There is a canonical short exact sequence of H-H-bimodules

$$ 0 \to H \otimes_S B \otimes_S H \xrightarrow{\delta} H \otimes_S H \xrightarrow{\text{mult}} H \to 0, $$

where $\delta(h_l \otimes b \otimes h_r) = h_l b \otimes h_r - h_l \otimes b h_r$.

Note that the H-H-bimodules $H \otimes_S B \otimes_S H$ and $H \otimes_S H$ are in general only projective as H-left- or right-modules, but not as bimodules. Anyway, the above sequence yields a functorial projective resolution for certain modules which we are going to define now. We say that a H-module M is *locally free* if $e_i M$ is a free H_i-module for all $i \in I$. In this case we define

$$ \underline{\operatorname{rank}}(M) := (\operatorname{rank}_{H_i}(e_i M))_{i\in I}. $$

For example, there is a unique (indecomposable) locally free H-module E_i with $\underline{\operatorname{rank}}(E_i) = \alpha_i$ for each $i \in I$. For later use we define for all $\mathbf{r} \in \mathbb{N}^I$ the module $\mathbf{E}^{\mathbf{r}} := \oplus_{i\in I} E_i^{\mathbf{r}(i)}$, and observe that $\underline{\operatorname{rank}}(\mathbf{E}^{\mathbf{r}}) = \mathbf{r}$. Let us write down the following consequences of Proposition 3.1, see Geiß, Leclerc, and Schröer [ibid., Sec. 3.1] and Geiß, Leclerc, and Schröer [ibid., Cor.7.1].

Corollary 3.2. *For H as above we have:*

(a) *The projective and injective H-modules are locally free. More precisely we have*

$$\underline{\mathrm{rank}}(He_{i_k}) = \beta_{\mathbf{i},k} \quad \text{and} \quad \underline{\mathrm{rank}}(De_{i_k}H) = \gamma_{\mathbf{i},k} \text{ for } k \in I,$$

where $\mathbf{i}$ *is a reduced expression for the Coxeter element of* (C, Ω).

(b) *Each locally free H-module M has a functorial projective resolution*

$$0 \to H \otimes_S B \otimes_S M \xrightarrow{\delta \otimes M} H \otimes_S M \xrightarrow{\mathrm{mult}} M \to 0.$$

Moreover, if M is not locally free, then $\operatorname{proj.dim} M = \infty$.

(c) *H is 1-Iwanaga-Gorenstein, i.e.* $\operatorname{proj.dim}({}_H DH) \leq 1$ *and* $\operatorname{inj.dim}({}_H H) \leq 1$. *Moreover an H-module M is locally free if and only if* $\operatorname{proj.dim}(M) \leq 1$.

It follows that the Ringel (homological) bilinear form descends as the non-symmetric bilinear form (2.2) to the Grothendieck group of locally free modules, where we identify the classes of the generalized simples E_i with the coordinate vector α_i ($i \in I$), see also Geiß, Leclerc, and Schröer [2017a, Prop. 4.1].

Corollary 3.3. *If M and N are locally free H-modules, we have*

$$\dim \mathrm{Hom}_H(M, N) - \dim \mathrm{Ext}^1_H(M, N) = \langle \underline{\mathrm{rank}}(M), \underline{\mathrm{rank}}(N) \rangle_{C,D,\Omega}.$$

By combining Corollary 3.2 with standard results from Auslander-Reiten theory we obtain now the following result.

Corollary 3.4. *Let M be an indecomposable, non projective, locally free H-module such that the Auslander-Reiten translate $\tau_H M$ is locally free. Then*

$$\underline{\mathrm{rank}}(\tau_H M) = c \cdot (\underline{\mathrm{rank}}(M)),$$

where $c = s_{i_n} \cdots s_{i_1}$ is the Coxeter element for (C, Ω). Moreover, if we take $R \in \mathbb{Z}^{I \times I}$, such that $D \cdot R$ is the matrix of $\langle -, - \rangle_{C,D,\Omega}$ with respect to the standard basis, we get $c = -R^{-1}(C - R)$.

This is the K-theoretic shadow of a deeper connection between the Auslander-Reiten translate and reflection functors, which we will discuss in the next subsection.

3.2 Auslander-Reiten theory and Coxeter functors. By Proposition 3.1 we may view $H = H_K(C, D, \Omega)$ as a tensor algebra. Thus, we identify a H-module M naturally with a S-module $\mathbf{M} = \oplus_{i \in I} M_i$ together with an element $(M_{ij})_{(i,j) \in \Omega}$ of

$$H(\mathbf{M}) := \bigoplus_{(i,j) \in \Omega} \in \mathrm{Hom}_{H_i}({}_i H_j \otimes_{H_j} M_j, H_i). \tag{3.2}$$

Write $s_i(H) := H_k(C, D, s_i(\Omega))$ for any $i \in I$. If k is a sink of $Q^\circ(C, \Omega)$, we have for each H-module M a canonical exact sequence
(3.3)

$$0 \to \operatorname{Ker}(M_{k,\text{in}}) \to \bigoplus_{j \in \Omega(k,-)} {}_kH_j \otimes_{H_j} M_j \xrightarrow{M_{k,\text{in}}} M_k, \text{ where } M_{k,\text{in}} = \oplus_{j \in \Omega(k,-)} M_{kj}.$$

We can define now the BGP-reflection functor

$$F_k^+ \colon \operatorname{rep}(H) \to \operatorname{rep}(s_i(H)), \quad (F_k^+ M)_i = \begin{cases} M_i & \text{if } i \neq k, \\ \operatorname{Ker}(M_{k,\text{in}}) & \text{if } i = k. \end{cases}$$

We can moreover define in this situation dually the left adjoint $F_k^- \colon \operatorname{rep}(s_k(H)) \to \operatorname{rep}(H)$. Note that k is a source of $Q^\circ(C, s_k\Omega)$. See Geiß, Leclerc, and Schröer [ibid., Sec. 9.2] for more details. We observe that the definitions imply easily the following:

Lemma 3.5. *If k is a sink for Ω and M is a locally free H-module which has no direct summand isomorphic to E_k and $F_k^+(M)$ is locally free, then $\underline{\operatorname{rank}}(F_k^+ M) = s_k(\underline{\operatorname{rank}}(M))$.*

The proof of Geiß, Leclerc, and Schröer [ibid., Prop. 9.6] implies the following, less obvious result:

Lemma 3.6. *Suppose that k is a sink for Ω and M a locally free rigid H-module, with no direct summand isomorphic to E_k, then* $\operatorname{Hom}_H(M, E_k) = 0$.

We can interpret F_k^+ as a kind of APR-tilting functor Auslander, Platzeck, and Reiten [1979]. See Geiß, Leclerc, and Schröer [2017a, Sec. 9.3] for a proof of this non-trivial result.

Theorem 3.7. *Let k be a sink of $Q^\circ(C, \Omega)$. Then $X := {}_HH/He_k \oplus \tau^- He_k$ is a classical tilting module for H. With $B := \operatorname{End}_H(X)^{\text{op}}$ we have an equivalence $S \colon \operatorname{rep}(s_k(H)) \to \operatorname{rep}(B)$ such that the functors $S \circ F_l^+$ and $\operatorname{Hom}_H(X, -)$ are isomorphic.*

Standard tilting theory arguments and Auslander–Reiten theory, together with Lemma 3.5 and Lemma 3.6 yield the following important consequence:

Corollary 3.8. *Let $k \in I$ be a sink for Ω and M a locally free rigid H-module, then $F_k^+(M)$ is a rigid, locally free $s_k(H)$-module.*

Consider the algebra automorphism of H, which is defined by multiplying the non-loop arrows of $Q(C, \Omega)$ by -1. It induces the so called *twist* automorphism $T \colon \operatorname{rep}(H) \to \operatorname{rep}(H)$. Moreover, let $s_{i_n} \cdots s_{i_2} s_{i_1}$ be the Coxeter element for (C, Ω), corresponding to the $+$-admissible sequence $i_1, i_2, \ldots, i_n$, see Section 2.3. Now we can define the *Coxeter functor*

$$C^+ := F_{i_n}^+ \circ \cdots \circ F_{i_2}^+ \circ F_{i_1}^+ \colon \operatorname{rep}(H) \to \operatorname{rep}(H).$$

Following ideas of Gabriel [1980, Sec. 5], by a careful comparison of the definitions of the reflection functors and Auslander–Reiten translate, we obtain the following result. See Geiß, Leclerc, and Schröer [2017a, Sec. 10] for the lengthy proof.

Theorem 3.9. *With the H-H-bimodule $Y := \operatorname{Ext}^1_H(DH, H)$ we have an isomorphism of endofunctors of* $\operatorname{rep}(H)$*:*

$$\operatorname{Hom}_H(Y, -) \cong T \circ C^+$$

If M is locally free, we have functorial isomorphisms

$$\tau_H(M) \cong \operatorname{Hom}_H(Y, M) \quad \text{and} \quad \tau_H^- M \cong Y \otimes_H M.$$

In particular, in this case the Coxeter functor C^+ and the Auslander–Reiten translate τ may be identified up to the twist T.

It is not true in general that the Auslander–Reiten translate of a locally free H-module is again locally free. In Geiß, Leclerc, and Schröer [ibid., pp. 13.6–13.8] several examples of this behavior are documented. This motivates the following definition. A H-module M is *τ-locally free* if $\tau^k M$ is locally free for all $k \in \mathbb{Z}$. In particular, rigid locally free modules are τ-locally free. We call an indecomposable H-module *preprojective*, resp. *preinjective*, if it is of the form $\tau^{-k}(He_i)$ resp. $\tau^k(De_i H)$ for some $k \in \mathbb{N}_0$ and $i \in I$. Thus, these modules are particular cases of rigid τ-locally free modules.

3.3 Dynkin type. By combining the findings of previous section with standard Auslander–Reiten theory and the characterization of Dynkin diagrams in Proposition 2.1, we obtain the following analog of Gabriel's theorem, see Geiß, Leclerc, and Schröer [ibid., Thm. 11.10].

Theorem 3.10. *Let $H = H_K(C, D, \Omega)$ be as above. There are only finitely many isomorphism classes of indecomposable, τ-locally free H-modules if and only if C is of Dynkin type. In this case the map $M \mapsto \underline{\operatorname{rank}}(M)$ induces a bijection between the isomorphism classes of indecomposable, τ-locally free modules and the positive roots $\Delta^+(C)$. Moreover, all these modules are preprojective and preinjective.*

Note however, that even for C of Dynkin type, the algebra $H(C, D, \Omega)$ is in most cases not of finite representation type, see Geiß, Leclerc, and Schröer [ibid., Prop. 13.1] for details.

Let C be a symmetrizable Cartan matrix of Dynkin type and $\mathbf{i} = (i_1, i_2, \ldots, i_r)$ a reduced expression for the longest element w_0 of the Weyl group W, which is $+$-admissible for the orientation Ω. With the notation of (2.1) we abbreviate $\beta_j = \beta_{\mathbf{i},j}$ for $j = 1, \ldots, r$, and recall that this gives a complete list of the positive roots. By Theorem 3.10 we have for each j a unique, locally free, indecomposable and rigid representation $M(\beta_j)$ with $\underline{\operatorname{rank}}(M(\beta_j)) = \beta_j$.

Proposition 3.11. *With the above notations we have*

$$\langle \beta_i, \beta_j \rangle_{C,D,\Omega} = \begin{cases} \dim \operatorname{Hom}_H(M(\beta_i), M(\beta_j)) & \text{if } i \leq j, \\ -\dim \operatorname{Ext}^1_H(M(\beta_i), M(\beta_j)) & \text{if } i > j. \end{cases}$$

In particular, $\operatorname{Hom}_H(M(\beta_i), M(\beta_j)) = 0$ *if* $i > j$ *and* $\operatorname{Ext}^1_H(M(\beta_i), M(\beta_j)) = 0$ *if* $i \leq j$.

In fact, by Theorem 3.7 and equation (2.3) we may assume that either $i = 1$ or $j = 1$. In any case $M(\beta_1) = E_{i_1}$ is projective. In the first case we have $\operatorname{Ext}^1_H(E_1, M(\beta_j)) = 0$. In the second case we have $\operatorname{Hom}_H(M(\beta_i), E_{i_1}) = 0$ by Lemma 3.6. Now our claim follows by Corollary 3.3.

The next result is an easy adaptation of similar results by Dlab and Ringel [1979] for species. The proof uses heavily Proposition 3.11 and reflection functors. This version was worked out in Omlor's Masters thesis Omlor [2016], see also Geiß, Leclerc, and Schröer [2017d, Sec. 5].

Proposition 3.12. *With the same setup as above let* $k \in \{1, 2, \ldots, r\}$ *and* $\mathbf{m} = (m_1, \ldots, m_r) \in \mathbb{N}^r$ *such that* $\beta_k = \sum_{j=1}^r m_j \beta_j$ *and* $m_k = 0$. *Then* $M(\beta_k)$ *admits a non-trivial filtration by locally free submodules*

$$0 = M_{(0)} \subset M_{(1)} \subset \cdots \subset M_{(r)} = M(\beta_k)$$

such that $M_{(j)}/M_{(j-1)} \cong M(\beta_j)^{m_j}$ *for* $j = 1, 2, \ldots, r$. *It follows, that* $M(\beta_k)$ *has* <u>no</u> *filtration by locally free submodules*

$$0 = M^{(r)} \subset M^{(r-1)} \subset \cdots \subset M^{(0)} = M(\beta_k),$$

such that $\underline{\operatorname{rank}}(M^{(j-1)}/M^{(j)}) = m_j \beta_j$ *for* $j = 1, 2, \ldots, r$.

3.4 Generalized preprojective algebras. Let $\overline{Q} = \overline{Q}(C)$ be the quiver which is obtained from $Q(C, \Omega)$ by inserting for each $(i, j) \in \Omega$ additional g_{ij} arrows $\alpha_{ji}^{(1)}, \ldots, \alpha_{ji}^{(g_{ij})}$ from i to j, and consider the potential

$$W = \sum_{(i,j)\in\Omega} \sum_{k=1}^{g_{ij}} (\alpha_{ji}^{(k)} \alpha_{ij}^{(k)} \epsilon_j^{-c_{ij}/g_{ij}} - \alpha_{ij}^{(k)} \alpha_{ji}^{(k)} \epsilon_i^{-c_{ji}/g_{ij}}).$$

The choice of Ω only affects the signs of the summands of W. Recall that for a cyclic path $\alpha_1\alpha_2\cdots\alpha_l$ in $\overline{Q}$ by definition

$$\partial_\alpha^{\text{cyc}}(\alpha_1\alpha_2\cdots\alpha_l) := \sum_{i\in\{j\in[1,l] \mid \alpha_j=\alpha\}} \alpha_{i+1}\alpha_{i+2}\cdots\alpha_l\alpha_1\alpha_2\cdots\alpha_{i-1}.$$

The generalized preprojective algebra of H is

$$\Pi = \Pi(Q, D) := K\overline{Q}/\langle \partial^{\mathrm{cyc}}_{\alpha}(W)\,|_{\alpha\in\overline{Q}_1},\ \epsilon_i^{c_i}\,|_{i\in I}\rangle.$$

It is easy to see that Π does not depend on the choice of Ω, up to isomorphism. Notice that for $(i, j) \in \Omega$ we have

$$\partial^{\mathrm{cyc}}_{\alpha^{(k)}_{ji}}(W) = \alpha^{(k)}_{ij}\epsilon_j^{-c_{ij}/g_{ij}} - \epsilon_i^{-c_{ji}/g_{ij}}\alpha^{(k)}_{ij}.$$

It follows, that for any orientation Ω of C we can equip $\Pi_K(C, D)$ with a $\mathbb{N}_0$-grading by assigning each arrow $\alpha^{(k)}_{ji}$ with $(i, j) \in \Omega$ degree 1 and the remaining arrows get degree 0. We write then

$$\Pi_K(C, D) = \bigoplus_{i=0}^{\infty}\Pi(C, D, \Omega)_i,$$

and observe that $\Pi_K(C, D, \Omega)_0 = H_K(C, D, \Omega)$. We obtain from Theorem 3.9 the following alternative description of our generalized preprojective algebra, which justifies its name:

Proposition 3.13. *Let C be a symmetrizable Cartan matrix with symmetrizer D, and Ω an orientation for C. Then, with $H = H_K(C, D, \Omega)$ we have*

$$\Pi(C, D, \Omega)_1 \cong \mathrm{Ext}^1_H(DH, H)$$

as an H-H-bimodule, moreover

$$\Pi(C, D) \cong T_H(\mathrm{Ext}^1_H(DH, H)) \quad \textit{and} \quad {}_H\Pi(C, D) \cong \bigoplus_{i\in I, k\in\mathbb{N}_0} \tau_H^{-k} He_i.$$

Here the first isomorphism is an isomorphism of K-algebras, and the second one of H-modules.

Similarly to Proposition 3.1 we have the following straightforward description of our generalized preprojective algebra as a tensor algebra modulo canonical relations Geiß, Leclerc, and Schröer [2017a, Prop. 6.1], which yields a standard bimodule resolution. See Geiß, Leclerc, and Schröer [ibid., Sec. 12.1] for the proof, where we closely follow Crawley-Boevey and Shaw [2006, Lem. 3.1]. See also Brenner, Butler, and King [2002, Sec. 4].

Proposition 3.14. *Let C be a symmetrizable, connected Cartan matrix and $\Pi := \Pi_K(C, D)$. With $\overline{B} := \oplus_{(i,j)\in\Omega}({}_iH_j \oplus {}_jH_i)$ we have $\Pi \cong T_S(\overline{B})/\langle \partial^{\mathrm{cyc}}_{\epsilon_i}(W)\,|_{i\in I}\rangle$, where we interpret $\partial^{\mathrm{cyc}}_{\epsilon_i}(W) \in \overline{B}\otimes_S \overline{B}$ in the obvious way. We obtain an exact sequence of Π-Π-bimodules*

$$\Pi\otimes_S\Pi \xrightarrow{f} \Pi\otimes_S\overline{B}\otimes_S\Pi \xrightarrow{g} \Pi\otimes_S\Pi \xrightarrow{h} \Pi \to 0, \tag{3.4}$$

where

$$f(e_i \otimes e_i) = \partial_{\epsilon_i}^{\mathrm{cyc}}(W) \otimes e_i + e_i \otimes \partial_{\epsilon_i}^{\mathrm{cyc}}(W), \quad g(e_i \otimes b \otimes e_j) = e_i b \otimes e_j - e_i \otimes b e_j$$

and h is the multiplication map. Moreover $\mathrm{Ker}(f) \cong \mathrm{Hom}_\Pi(D\Pi, \Pi)$ *if C is of Dynkin type, otherwise f is injective.*

We collect below several consequences, which can be found with detailed proofs in Geiß, Leclerc, and Schröer [2017a, Sec. 12.2]. They illustrate that locally free Π-modules behave in many aspects like modules over classical preprojective algebras. Note that part (b) is an extension of Crawley-Boevey's remarkable formula Crawley-Boevey [2000, Lem. 1]

Corollary 3.15. *Let C be a connected, symmetrizable Cartan matrix, and $\Pi = \Pi_K(C, D)$ as above. Moreover, let M and N be locally free Π-modules.*

(a) If N finite-dimensional, we have a functorial isomorphism

$$\mathrm{Ext}^1_\Pi(M, N) \cong D\,\mathrm{Ext}^1_\Pi(N, M).$$

(b) If M and N are finite-dimensional, we have

$$\dim \mathrm{Ext}^1_\Pi(M, N) = \dim \mathrm{Hom}_\Pi(M, N) + \dim \mathrm{Hom}_\Pi(N, M) - (\underline{\mathrm{rank}}(M), \underline{\mathrm{rank}}(N))_{C,D}.$$

(c) If C is not of Dynkin type, $\mathrm{proj.dim}(M) \leq 2$.

(d) If C is of Dynkin type, Π is a finite-dimensional, self-injective algebra and $\mathrm{rep}_{\mathrm{l.f.}}(\Pi)$ *is a 2-Calabi-Yau Frobenius category.*

Similar to Corollary 3.2 (b) the complex (3.4) yields (the beginning of) a functorial projective resolution for all locally free Π-modules. Thus (a), (b) and (c) follow by exploring the symmetry of the above complex. For (d) we note that in this case Π is finite-dimensional and ${}_\Pi\Pi$ is a locally free module by Theorem 3.10 and Proposition 3.13.

4 Representation varieties

4.1 Notation. Let K be now an algebraically closed field. For Q a quiver and $\rho_j \in e_{t_j}(KQ_{\geq 2})e_{s_j}$ for $j = 1, 2, \ldots, l$ we set $A = KQ/\langle \rho_1, \ldots, \rho_l \rangle$. Note, that every finite dimensional basic K-algebra is of this form. We abbreviate $Q_0 = I$ and set for $\mathbf{d} \in \mathbb{N}_0^I$:

$$\mathrm{Rep}(KQ, \mathbf{d}) := \times_{a \in Q_1} \mathrm{Hom}_K(K^{\mathbf{d}(sa)}, K^{\mathbf{d}(ta)}) \quad \text{and} \quad \mathrm{GL}_\mathbf{d} := \times_{i \in I} \mathrm{GL}_{\mathbf{d}(i)}(K).$$

The reductive algebraic group $\mathrm{GL}_\mathbf{d}$ acts on $\mathrm{Rep}(KQ, \mathbf{d})$ by conjugation, and the $\mathrm{GL}_\mathbf{d}$-orbits correspond bijectively to the isoclasses of K-representations of Q. For $M \in$

$\operatorname{Rep}(KQ, \mathbf{d})$ and $\rho \in e_i KQ e_j$ we can define $M(\rho) \in \operatorname{Hom}_K(K^{\mathbf{d}(j)}, K^{\mathbf{d}(i)})$ in a natural way. We have then the $\mathrm{GL}_{\mathbf{d}}$-stable, Zariski closed subset

$$\operatorname{Rep}(A, \mathbf{d}) := \{M \in \operatorname{Rep}(KQ, \mathbf{d}) \mid M(\rho_i) = 0 \text{ for } j = 1, 2, \ldots, l\}.$$

The $\mathrm{GL}_{\mathbf{d}}$-orbits on $\operatorname{Rep}(A, \mathbf{d})$ correspond now to the isoclasses of representations of A with dimension vector $\mathbf{d}$. It is in general a hopeless task to describe the irreducible components of the affine variety $\operatorname{Rep}(A, \mathbf{d})$.

4.2 Varieties of locally free modules for H.

The set of locally free representations of $H = H_K(C, D, \Omega)$ is relatively easy to describe. Clearly, for each locally free $M \in \operatorname{rep}(H)$ we have $\underline{\dim}(M) = D \cdot \underline{\operatorname{rank}}(M)$.

Proposition 4.1. *For $\mathbf{r} \in \mathbb{N}^I$ we have the open subset*

$$\operatorname{Rep}_{\text{l.f.}}(H, \mathbf{r}) := \{M \in \operatorname{rep}(H, D \cdot \mathbf{r}) \mid M \textit{ is locally free}\} \subset \operatorname{Rep}(H, D \cdot \mathbf{r}),$$

which is irreducible and smooth with $\dim \operatorname{rep}_{\text{l.f.}}(H, \mathbf{r}) = \dim \mathrm{GL}_{D \cdot \mathbf{r}} - \frac{1}{2}(\mathbf{r}, \mathbf{r})_{C,D}$.

In fact, it is well known that the modules of projective dimension at most 1 form always an open subset of $\operatorname{rep}(A, \mathbf{d})$. One verifies next that $\operatorname{Rep}_{\text{l.f.}}(H, \mathbf{r})$ is a vector bundle over the $\mathrm{GL}_{D \cdot \mathbf{r}}$-orbit $\mathcal{O}(\oplus_{i \in I} E_i^{\mathbf{r}(i)})$, with the fibers isomorphic to the vector space $H(\mathbf{r}) := H(\mathbf{E}^{\mathbf{r}})$, see (3.2).

This yields the remaining claims. Note that the (usually) non-reductive algebraic group

$$G_{\mathbf{r}} := \times_{i \in I} \mathrm{GL}_{\mathbf{r}(i)}(H_i) = \operatorname{Aut}_S(\oplus_{i \in I} E_i^{\mathbf{r}(i)})$$

acts on the affine space $H(\mathbf{r})$ naturally by conjugation, and the orbits are in bijection with isoclasses of locally free H-modules with rank vector $\mathbf{r}$.

As a consequence, if M and N are rigid, locally free modules with $\underline{\operatorname{rank}}(M) = \underline{\operatorname{rank}}(N)$, then already $M \cong N$, since the orbits of rigid modules are open.

4.3 Varieties of E-filtered modules for Π.

Recall the description of $\Pi_K(C, D)$ in Proposition 3.14. A $\overline{H} := T_S(\overline{B})$-module M is given by a S-module $\mathbf{M} = \oplus_{i \in I} M_i$ such that M_i is a H_i-module for $i \in I$, together with an element $(M_{ij})_{(i,j) \in \overline{\Omega}}$ of

$$\overline{H}(\mathbf{M}) := \bigoplus_{(i,j) \in \overline{\Omega}} \operatorname{Hom}_{H_i}({}_iH_j \otimes_{H_j} M_j, M_i),$$

where $\overline{\Omega} = \Omega \cap \Omega^{\mathrm{op}}$. Extending somewhat (3.3) we set

$$M_{i,\mathrm{in}} := \left(\bigoplus_{j \in \overline{\Omega}(i,-)} \mathrm{sgn}(i,j) M_{ij} \right) : \bigoplus_{j \in \overline{\Omega}(i,-)} {}_iH_j \otimes_{H_j} M_j \to M_i \quad \text{and}$$

$$M_{i,\mathrm{out}} := \left(\prod_{j \in \overline{\Omega}(-,i)} M_{ji}^{\vee} \right) : M_i \to \bigoplus_{j \in \overline{\Omega}(-,i)} {}_iM_j \otimes_{H_j} M_j .$$

We define now for any S-module $\mathbf{M}$, as above, the affine variety

$$\mathrm{Rep}^{\mathrm{fib}}(\Pi, \mathbf{M}) := \{(M_{ij})_{(i,j) \in \overline{\Omega}} \in \overline{H}(\mathbf{M}) \mid M_{k,\mathrm{in}} \circ M_{k,\mathrm{out}} = 0 \text{ for all } k \in I\},$$

and observe that the orbits of the, usually non-reductive, group $\mathrm{Aut}_S(\mathbf{M})$ on $\mathrm{Rep}^{\mathrm{fib}}(\Pi, \mathbf{M})$ correspond to the isoclasses of possible structures of representations of Π on $\mathbf{M}$, since the condition $M_{k,\mathrm{in}} \circ M_{k,\mathrm{out}}$ corresponds to the relation $\partial^{\mathrm{cyc}}_{\epsilon_k}(W)$.

Similarly to the previous section we can define the open subset

$$\mathrm{Rep}_{\mathrm{l.f.}}(\Pi, \mathbf{r}) := \{M \in \mathrm{Rep}(\Pi, D \cdot \mathbf{r}) \mid M \text{ locally free}\} \subset \mathrm{Rep}(\Pi, D \cdot \mathbf{r}),$$

and observe that $\mathrm{Rep}_{\mathrm{l.f.}}(\Pi, \mathbf{r})$ is a fiber bundle over the $\mathrm{GL}_{D \cdot \mathbf{r}}$-orbit $\mathcal{O}(E^{\mathbf{r}})$, with typical fiber $\mathrm{Rep}^{\mathrm{fib}}(\Pi, \mathbf{E}^{\mathbf{r}})$. Finally we define for any projective S-module $\mathbf{M}$ the constructible subset

$$\Pi(\mathbf{M}) = \{(M_{ij})_{(i,j) \in \overline{\Omega}} \in \mathrm{Rep}^{\mathrm{fib}}(\Pi, \mathbf{M}) \mid ((M_{ij})_{ij}, \mathbf{M}) \text{ is } \mathbf{E}\text{-filtered}\}.$$

Here, a Π-module X is $\mathbf{E}$-filtered if it admits a flag of submodules $0 = X_{(0)} \subset X_{(1)} \subset \cdots \subset X_{(l)} = X$, such that for all k we have $X_{(k)}/X_{(k-1)} \cong E_{i_k}$ for some $i_1, i_2, \ldots, i_l \in I$. Note that for C symmetric and D trivial this specializes to Lusztig's notion of a nilpotent representation for the preprojective algebra of a quiver. However, if C is not symmetric even in the Dynkin case there exist finite-dimensional, locally free Π-modules which are not $\mathbf{E}$-filtered, see Geiß, Leclerc, and Schröer [2017c, Sec. 8.2.2] for an example.

We consider $\Pi(\mathbf{r})$ with the Zariski topology and call it by a slight abuse of notation a variety. In any case, it makes sense to speak of the dimension of $\Pi(\mathbf{r})$ and we can consider the set

$$\mathrm{Irr}(\Pi(\mathbf{r}))^{\max}$$

of top-dimensional irreducible components of $\Pi(\mathbf{r})$.

Theorem 4.2. *Let C be a symmetrizable generalized Cartan matrix with symmetrizer D and $H = H_K(C, D, \Omega), \Pi = \Pi_K(C, D)$ for an algebraically closed field K. For the spaces $\Pi(\mathbf{r})$ of $\mathbf{E}$-filtered representations of Π we have* *(a)* $\dim \Pi(\mathbf{r}) = \dim H(\mathbf{r}) = \sum_{i \in I} c_i \mathbf{r}(i)^2 - \frac{1}{2}(\mathbf{r}, \mathbf{r})_{C,D}$ *for all* $\mathbf{r} \in \mathbb{N}^I$.

(b) The set $\mathcal{B} := \coprod_{\mathbf{r} \in \mathbb{N}^I} \operatorname{Irr}(\Pi(\mathbf{r}))^{\max}$ *has a natural structure of a crystal of type* $B_C(-\infty)$ *in the sense of Kashiwara. In particular, we have*

$$|\operatorname{Irr}(\Pi(\mathbf{r}))^{\max}| = \dim U(\mathfrak{n})_{\mathbf{r}},$$

where $U(\mathfrak{n})$ *the universal enveloping algebra of the positive part* $\mathfrak{n}$ *of the Kac-Moody Lie algebra* $\mathfrak{g}(C)$.

We will sketch in the next two sections a proof of these two statements, which are the main result of Geiß, Leclerc, and Schröer [2017c].

4.4 Bundle constructions. The bundle construction in this section is crucial. It is our version Geiß, Leclerc, and Schröer [ibid., Sec. 3] of Lusztig's construction Lusztig [1991, Sec. 12].

For $m \in \mathbb{N}$ we denote by $\mathcal{P}_m$ the set of sequences of integers $\mathbf{p} = (p_1, p_2, \dots, p_t)$ with $m \geq p_1 \geq p_2 \geq \cdots \geq p_t \geq 0$. Obviously $\mathcal{P}_{c_k}$ parametrizes the isoclasses of H_k-modules, and we define $H_k^{\mathbf{p}} = \oplus_{j=1}^t H_k/(\epsilon_k^{p_j})$. For $k \in I$ and $M \in \operatorname{rep}(\Pi)$ we set

$$\operatorname{fac}_k(M) := M_k / \operatorname{Im}(M_{k,\mathrm{in}}) \quad \text{and} \quad \operatorname{sub}_k(M) := \operatorname{Ker}(M_{k,\mathrm{out}}).$$

With this we can define

$$\Pi(\mathbf{M})^{k,\mathbf{p}} = \{M \in \Pi(\mathbf{M}) \mid \operatorname{fac}_k(M) \cong H_k^{\mathbf{p}}\} \text{ and}$$
$$\Pi(\mathbf{M})_{k,\mathbf{p}} = \{M \in \Pi(\mathbf{M}) \mid \operatorname{sub}_k(M) \cong H_k^{\mathbf{p}}\}$$

for $\mathbf{p} \in \mathcal{P}_{c_k}$. We abbreviate $\Pi(\mathbf{M})^{k,m} = \Pi(\mathbf{M})^{k,c_k^m}$. In what follows, we will focus our exposition on the varieties of the form $\Pi(\mathbf{M})^{k,\mathbf{p}}$, however one should be aware that similar statements and constructions hold for the dual versions $\Pi(\mathbf{M})_{k,\mathbf{p}}$.

For an $\mathbf{E}$-filtered representation $M \in \operatorname{rep}(\Pi)$ there exists always a $k \in I$ such that $\operatorname{fac}_k(M)$, viewed as an H_k-module, has a non-trivial free summand. It is also important to observe that $\Pi(\mathbf{M})^{k,0}$ is an open subset of $\Pi(\mathbf{M})$.

Fix now $k \in I$, let $\mathbf{M}$ be a projective S-module and $\mathbf{U}$ be a proper, projective S-submodule of $\mathbf{M}$ with $U_j = M_j$ for all $j \neq k$. Thus, $\mathbf{M}/\mathbf{U} \cong E_k^r$ for some $r \in \mathbb{N}_+$, and can choose a (free) complement T_k, such that $M_k = U_k \oplus T_k$. For partitions $\mathbf{p} = (c_k^r, q_1, q_2, \dots, q_t)$ and $\mathbf{q} = (q_1, \dots, q_t)$ in $\mathcal{P}_{c_k}$ we set moreover $\operatorname{Hom}_S^{\mathrm{inj}}(\mathbf{U}, \mathbf{M}) := \{f \in \operatorname{Hom}_S(U, M) \mid f \text{ injective}\}$, and define

$$Y^{k,\mathbf{p},\mathbf{q}} := \{(U, M, f) \in \Pi(\mathbf{U})^{k,\mathbf{q}} \times \operatorname{Rep}^{\mathrm{fib}}(\Pi, \mathbf{M}) \times \operatorname{Hom}_S^{\mathrm{inj}}(\mathbf{U}, \mathbf{M}) \mid f \in \operatorname{Hom}_\Pi(U, M)\}.$$

Note that for $(U, M, f) \in Y^{k,\mathbf{p},\mathbf{q}}$ we have in fact $M \in \Pi(\mathbf{M})^{k,\mathbf{p}}$, and that the group $\mathrm{Aut}_S(\mathbf{U})$ acts freely on $Y^{k,\mathbf{p},\mathbf{q}}$ via

$$g \cdot (U, M, f) := ((g_i U_{ij}(\mathrm{id} \otimes g_j^{-1}))_{(i,j)\in\overline{\Omega}},\ M,\ g \cdot f^{-1}).$$

Lemma 4.3. *Consider in the above situation the diagram*

$$\begin{array}{ccc} & Y^{k,\mathbf{p},\mathbf{q}} & \\ {}^{p'}\swarrow & & \searrow^{p''} \\ \Pi(\mathbf{U})^{k,\mathbf{q}} \times \mathrm{Hom}_S^{\mathrm{inj}}(\mathbf{U}, \mathbf{M}) & & \Pi(\mathbf{M})^{k,\mathbf{p}} \end{array}$$

with $p'(U, M, f) = (U, f)$ and $p''(U, M, f) = M$. Then the following holds:

(a) p' is a vector bundle of rank m, where

$$m = \sum_{j\in\overline{\Omega}(-,k)} \dim_K \mathrm{Hom}_K(T_k, {}_kM_j \otimes_{H_j} M_j) - \dim_K \mathrm{Hom}_{H_k}(T_k, \mathrm{Im}(U_{k,\mathrm{in}})).$$

(b) p'' is a fiber bundle with smooth irreducible fibers isomorphic to

$$\mathrm{Aut}_S(\mathbf{U}) \times \mathrm{Gr}_{H_k}^{T_k}(H_k^{\mathbf{p}}),$$

where $\mathrm{Gr}_{H_k}^{T_k}(H_k^{\mathbf{p}}) := \mathrm{Hom}_{H_k}^{\mathrm{surj}}(H_k^{\mathbf{p}}, T_k)/\, \mathrm{Aut}_{H_k}(T_k).$

Corollary 4.4. *In the situation of Lemma 4.3, the correspondence*

$$Z' \mapsto p''(p'^{-1}(Z' \times \mathrm{Hom}_S^{\mathrm{inj}}(\mathbf{U}, \mathbf{M})) := Z''$$

induces a bijection between the sets of irreducible components $\mathrm{Irr}(\Pi(U)^{k,\mathbf{q}})$ *and* $\mathrm{Irr}(\Pi(\mathbf{M})^{k,\mathbf{p}})$*. Moreover we have then*

$$\dim Z'' - \dim Z' = \dim H(\mathbf{M}) - \dim(\mathbf{U}).$$

Note, that this implies already part (a) of Theorem 4.2. In fact the Corollary allows us to conclude by induction that $\dim \Pi(\mathbf{r}) \leq \dim \mathrm{Rep}^{\mathrm{fib}}(H, \mathbf{r})$. On the other hand, we can identify $H(\mathbf{r})$ with an irreducible component of $\Pi(\mathbf{r})$.

4.5 Crystals. For $M \in \mathrm{rep}(\Pi)$ and $j \in I$ there are two canonical short exact sequences

$$0 \to K_j(M) \to M \to \mathrm{fac}_j(M) \to 0 \quad \text{and} \quad 0 \to \mathrm{sub}_j(M) \to M \to C_j(M) \to 0.$$

We define recursively that M is a *crystal module* if $\mathrm{fac}_j(M)$ and $\mathrm{sub}_j(M)$ are locally free for all $j \in I$, and $K_j(M)$ as well as $C_j(M)$ are crystal modules for all $j \in I$. Clearly, if M is a crystal module, for all $j \in I$ there exist $\varphi_j(M), \varphi_j^*(M) \in \mathbb{N}$ such that

$$\mathrm{sub}_j(M) \cong E_j^{\varphi_j(M)} \text{and} \quad \mathrm{fac}_j(M) \cong E_j^{\varphi_j^*(M)}. \tag{4.1}$$

Note moreover, that crystal modules are by construction $\mathbf{E}$-filtered. It is now easy to see that for all projective S-modules $\mathbf{M}$ the set

$$\Pi(\mathbf{M})^{\mathrm{cr}} := \{M \in \Pi(\mathbf{M}) \mid M \text{ is a crystal representation}\}$$

is a constructible subset of $\Pi(\mathbf{M})$. The following result from Geiß, Leclerc, and Schröer [2017c, Sec. 4] is crucial for the proof of Theorem 4.2 (b). It has no counterpart for the case of trivial symmetrizers.

Proposition 4.5. *For each projective S-module $\mathbf{M}$ the set $\Pi(\mathbf{M})^{\mathrm{cr}}$ is a dense and equidimensional subset of the union of all top dimensional irreducible components of $\Pi(\mathbf{M})$.*

This allows us in particular to define for all $Z \in \mathrm{Irr}(\Pi(\mathbf{M}))^{\max}$ and $i \in I$ the value $\varphi_i(Z)$, see (4.1), such that for a dense open subset $U \subset Z$ we have $\varphi_i(M) = \varphi_i(Z)$ for all $M \in U$. Similarly, we can define $\varphi_i^*(Z)$.

Next we set

$$\mathrm{Irr}(\Pi(\mathbf{r})^{i,p})^{\max} := \{Z \in \mathrm{Irr}(\Pi(\mathbf{r})^{i,p}) \mid \dim Z = \dim H(\mathbf{r})\}$$

for $i \in I$ and $p \in \mathbb{N}_0$, and similarly $\mathrm{Irr}(\Pi(\mathbf{r})_{i,p}$. By Lemma 4.3 we get a bijection

$$e_i^*(\mathbf{r}, p)\colon \ \mathrm{Irr}(\Pi(\mathbf{r})^{i,p})^{\max} \to \mathrm{Irr}(\Pi(\mathbf{r} + \alpha_i)^{i,p+1})^{\max}, Z \mapsto p''(p'^{-1}(Z \times J_0))$$

Similarly we obtain a bijection

$$e_i(\mathbf{r}, p)\colon \ \mathrm{Irr}(\Pi(\mathbf{r})_{i,p})^{\max} \to \mathrm{Irr}(\Pi(\mathbf{r} + \alpha_i)_{i,p+1})^{\max}.$$

This allows us to define for all $\mathbf{r} \in \mathbb{N}^I$ the operators

$$\tilde{e}_i\colon \ \mathrm{Irr}(\Pi(\mathbf{r}))^{\max} \to \mathrm{Irr}(\Pi(\mathbf{r} + \alpha_i)), Z \mapsto \overline{e_i(\mathbf{r}, \varphi_i(Z))(Z^\circ)},$$

where $Z^\circ \in \mathrm{Irr}(\Pi(\mathbf{r})_{i,\varphi_i(Z)})^{\max}$ is the unique irreducible component with $\overline{Z^\circ} = Z$. Similarly, we can define the operators $\tilde{e}_i^*$ in terms of the bijections $e_i^*(\mathbf{r}, p)$. We define now

$$\mathfrak{B} := \coprod_{\mathbf{r} \in \mathbb{N}_0} \mathrm{Irr}(\Pi(\mathbf{r}))^{\max} \text{ and } \mathrm{wt}\colon \mathfrak{B} \to \mathbb{Z}^I, \ Z \mapsto \underline{\mathrm{rank}}(Z). \tag{4.2}$$

It is easy to see that $(\mathfrak{B}, \mathrm{wt}, (\tilde{e}_i, \varphi_i)_{i \in I})$ is special case of a lowest weight crystal in the sense of Kashiwara [1995, Sec. 7.2], namely we have

- $\varphi_i(\tilde{e}_i(b)) = \varphi_i(b) + 1, \ \mathrm{wt}(\tilde{e}_i(b)) = \mathrm{wt}(b) + \alpha_i$,
- with $\{b_-\} := \mathrm{Irr}(\Pi(0))^{\max}$, for each $b \in \mathcal{B}$ there exists a sequence $i_1, \dots, i_l$ of elements of I with $\tilde{e}_{i_1}\tilde{e}_{i_2}\cdots\tilde{e}_{i_l}(b_-) = b$,
- $\varphi_i(b) = 0$ implies $b \notin \mathrm{Im}(\tilde{e}_i)$.

Similarly $(\mathcal{B}, \mathrm{wt}, (\tilde{e}_i^*, \varphi_i^*)_{i\in I})$ is a lowest weight crystal with the same lowest weight element b_-.

Lemma 4.6. *The above defined operators and functions on $\mathcal{B}$ fulfill additionally the following conditions:*

(a) If $i \neq j$, then $\tilde{e}_i^*\tilde{e}_j(b) = \tilde{e}_j\tilde{e}_i^*(b)$.

(b) For all $b \in B$ we have $\varphi_i(b) + \varphi_i^*(b) - \langle \mathrm{wt}(b), \alpha_i\rangle \geq 0$.

(c) If $\varphi_i(b) + \varphi_i^*(b) - \langle \mathrm{wt}(b), \alpha_i\rangle = 0$, then $\tilde{e}_i(b) = \tilde{e}_i^*(b)$.

(d) If $\varphi_i(b) + \varphi_i^*(b) - \langle \mathrm{wt}(b), \alpha_i\rangle \geq 1$, then $\varphi_i(\tilde{e}_i^*(b)) = \varphi_i(b)$ and $\varphi_i^*(\tilde{e}_i(b)) = \varphi_i^*(b)$.

(e) If $\varphi_i(b) + \varphi_i^*(b) - \langle \mathrm{wt}(b), \alpha_i\rangle \geq 2$, then $\tilde{e}_i\tilde{e}_i^*(b) = \tilde{e}_i^*\tilde{e}_i(b)$.

The proof of this Lemma in Geiß, Leclerc, and Schröer [2017c, Sec. 5.6] uses the homological features of locally free Π-modules from Corollary 3.15 in an essential way. Note that here, by definition, $\langle \mathbf{r}, \alpha_i\rangle = (C\cdot\mathbf{r})_i$.

Altogether this means, by a criterion of Kashiwara and Saito [1997, Prop. 3.2.3], which we use here in a reformulation due to Tingley and Webster [2016, Prop. 1.4], that $(\mathcal{B}, \mathrm{wt}, (\tilde{e}_i, \varphi_i)_{i\in I}$ $(\mathcal{B}, \mathrm{wt}, (\tilde{e}_i^*, \varphi_i^*)_{i\in I}) \cong B_C(-\infty)$. Here, $B_C(-\infty)$ is the crystal graph of the quantum group $U_q(\mathfrak{n}(C))$. This implies part (b) of Theorem 4.2.

Remark 4.7. We did not give here Kashiwara's general definition of a crystal graph, or that of a lowest weight crystal associated to a dominant integral weight. The reason is that, due to limitations of space, we can not to set up the, somehow unwieldy, notations for the integral weights of a Kac-Moody Lie algebra. The interested reader can look up the relevant definitions, in a form which is compatible with these notes, in Geiß, Leclerc, and Schröer [2017c, Sec. 5.1, 5.2].

5 Algebras of constructible functions

5.1 Constructible functions and Euler characteristic. Recall that the topological Euler characteristic, defined in terms of singular cohomology with compact support and rational coefficients, defines a ring homomorphism from the Grothendieck ring of complex varieties to the integers.

By definition, a constructible function $f: X \to \mathbb{C}$ on a complex algebraic variety X has finite image, and $f^{-1}(c) \subset C$ is a constructible set for all $c \in \mathbb{C}$. By the above remark it makes sense to define

$$\int_{x \in X} f d\chi := \sum_{c \in \mathbb{C}} c\, \chi(f^{-1}(c)).$$

If $\varphi\colon X \to Y$ is a morphism of varieties, we can define the *push forward* of constructible functions via $(\varphi_*(f))(y) := \int_{x\in\varphi^{-1}(y)} f d\chi$. This is functorial in the sense that $(\psi \circ \varphi)_*(f) = \psi_*(\varphi_*(f))$ for $\psi\colon Y \to Z$ an other morphism, by result of MacPherson [1974, Prop. 1]. See also Joyce [2006, Sec. 3] for a careful discussion.

5.2 Convolution algebras as enveloping algebras. Let $A = \mathbb{C}Q$ as in Section 4.1. We consider for a dimension vector $\mathbf{d} \in \mathbb{N}^I$ the vector space $\mathfrak{F}(A)_{\mathbf{d}}$ of constructible functions $f\colon \operatorname{Rep}(A, \mathbf{d}) \to \mathbb{C}$ which are constant on $\mathrm{GL}_{\mathbf{d}}(\mathbb{C})$-orbits and set

$$\mathfrak{F}(A) := \bigoplus_{\mathbf{d}\in\mathbb{N}^i} \mathfrak{F}(A)_{\mathbf{d}}.$$

Following Lusztig [1991] $\mathfrak{F}(A)$ has the structure of a unitary, graded associative algebra. The multiplication is defined by

$$(f * g)(X) = \int_{U \in \mathrm{Gr}_{\mathbf{d}}^A(X)} f(U) g(X/U) d\chi,$$

where $f \in \mathfrak{F}(A)_{\mathbf{d}}$, $g \in \mathfrak{F}(A)_{\mathbf{e}}$, $X \in \operatorname{Rep}(A, \mathbf{d}+\mathbf{e})$, and $\mathrm{Gr}_{\mathbf{d}}^A(X)$ denotes the quiver Grassmannian of $\mathbf{d}$-dimensional subrepresentations of X. The associativity of the multiplication follows easily from the functoriality of the push-forward of constructible functions. We have an algebra homomorphism

$$c\colon \mathfrak{F}(A) \to \mathfrak{F}(A \times A), \text{ with } (c(f))(X, Y) = f(X \oplus Y), \tag{5.1}$$

see for example Geiß, Leclerc, and Schröer [2016, Sec. 4.3]. The proof depends crucially on the Białynicki-Birula result about the fixpoints of algebraic torus actions Białynicki-Birula [1973, Cor. 2]. This fails for example over the real numbers.

Remark 5.1. If $\mathbf{X} = (X_j)_{j\in J}$ is a family of indecomposable representations of A, we define the characteristic functions $\theta_j \in \mathfrak{F}_{\underline{\dim} X_j}(A)$ of the $\mathrm{GL}_{\underline{\dim} X_j}$-orbit $\mathcal{O}(X_j) \subset \operatorname{Rep}(A, \underline{\dim} X_j)$ and consider the graded subalgebra $\mathfrak{M}(A) = \mathfrak{M}_{\mathbf{X}}(A)$ of $\mathfrak{F}(A)$, which is generated by the θ_j. Clearly, the homogeneous components of $\mathfrak{M}$ are finite dimensional. If $\mathbf{j}$ =

$(j_1, j_2, \ldots, j_l)$ is a sequence of elements of j we have by the definition of the multiplication

$$\theta_{j_1} * \theta_{j_l} * \cdots * \theta_{j_l}(X) = \chi(\mathrm{Fl}^A_{\mathbf{X},\mathbf{j}}(M)),$$

where $\mathrm{Fl}^A_{\mathbf{X},\mathbf{j}}(M)$ denotes the variety of all flags of submodules

$$0 = M^{(0)} \subset M^{(1)} \subset \cdots \subset M^{(l)} = M$$

with $M^{(k)}/M^{(k-1)} \cong X_{j_k}$ for $k = 1, 2, \ldots, l$. In particular, if M has no filtration with all factors isomorphic to some X_j, we have $f(M) = 0$ for all $f \in \mathfrak{M}(A)_{\underline{\dim} M}$. See Geiß, Leclerc, and Schröer [2016, Lemma 4.2].

Lemma 5.2. *The morphism c from (5.1) induces a comultiplication $\Delta\colon \mathfrak{M}(A) \to \mathfrak{M}(A) \otimes \mathfrak{M}(A)$ with $\Delta(\theta_j) = \theta_j \otimes 1 + 1 \otimes \theta_j$ for all j. With this structure $\mathfrak{M}$ is a cocommutative Hopf algebra, which is isomorphic to the enveloping algebra $U(\mathcal{P}(\mathfrak{M}))$ of the Lie algebra of its primitive elements $\mathcal{P}(\mathfrak{M})$.*

See Geiß, Leclerc, and Schröer [ibid., Prop. 4.5] for a proof. Recall, that an element x of a Hopf algebra is called *primitive* iff $\Delta(x) = x \otimes 1 + 1 \otimes x$. It is straightforward to check that the primitive elements of a Hopf algebra form a Lie algebra under the usual commutator $[x, y] = xy - yx$.

Remark 5.3. It is important to observe that, by the definition of the comultiplication, the support of any primitive element of $\mathfrak{M}$ consists of indecomposable, $\mathbf{X}$-filtered modules. In fact, for $f \in \mathcal{P}(\mathfrak{M})$ and $M, N \in \mathrm{rep}(A)$ we have $f(M \oplus N) = cf(M, N) = (f \otimes 1 + 1 \otimes f)(M, N)$. See Geiß, Leclerc, and Schröer [ibid., Lem. 4.6].

We are here interested in the two special cases when $A = H_{\mathbb{C}}(C, D, \Omega)$ or $A = \Pi_{\mathbb{C}}(C, D)$ and $\mathbf{X} = \mathbf{E} = (E_i)_{i \in I}$. Note that by Remark 5.1 only locally free modules can appear in the support of any $f \in \mathfrak{M}_{\mathbf{E}}(H)$. Similarly, the support of any $f \in \mathfrak{M}_{\mathbf{E}}(\Pi)$ consists only of $\mathbf{E}$-filtered modules. For this reason we will consider in what follows, both $\mathfrak{M}_{\mathbf{E}}(H)$ and $\mathfrak{M}_{\mathbf{E}}(\Pi)$ as graded by *rank vectors*. In other words, from now on

$$\mathfrak{M}(H) := \mathfrak{M}_{\mathbf{E}}(H) = \bigoplus_{\mathbf{r} \in \mathbb{N}^I} \mathfrak{M}_{\mathbf{r}}(H) \quad \text{and} \quad \mathfrak{M}(\Pi) = \mathfrak{M}_{\mathbf{E}}(\Pi) = \bigoplus_{\mathbf{r} \in \mathbb{N}^I} \mathfrak{M}_{\mathbf{r}}(\Pi),$$

where we may consider the the elements of $\mathfrak{M}_{\mathbf{r}}(H) := \mathfrak{M}_{\mathbf{E}}(H)_{D \cdot \mathbf{r}}$ as constructible functions on $H(\mathbf{r})$. Similarly we may consider the elements of $\mathfrak{M}_{\mathbf{r}}(\Pi) := \mathfrak{M}_{\mathbf{E}}(\Pi)_{D \cdot \mathbf{r}}$ as constructible functions on $\Pi(\mathbf{r})$.

5.3 $\mathfrak{M}_{\mathbf{E}}(H)$ and a dual PBW-basis in the Dynkin case. We have the following basic result from Geiß, Leclerc, and Schröer [ibid., Cor. 4.10].

Proposition 5.4. *Let C be a symmetrizable Cartan matrix, D a symmetrizer and Ω an orientation for C. With $H = H_{\mathbb{C}}(C, D, \Omega)$ we have an surjective Hopf algebra homomorphism*

$$\eta_H \colon U(\mathfrak{n}(C)) \to \mathcal{M}_{\mathbf{E}}(H) \text{ defined by } \quad e_i \mapsto \theta_i (i \in I).$$

The main point is to show that for the θ_i $(i \in I)$ fulfill the Serre relations (2.4). More precisely we need that the primitive elements

$$\theta_{ij} := (\operatorname{ad} \theta_i)^{1-c_{ij}}(\theta_j) \in \mathcal{P}(\mathcal{M}(H))_{(1-c_{ij})\alpha_i+\alpha_j} \quad (i \neq j)$$

actually vanish. For this it is enough, by Remark 5.3, to show that there exists no *indecomposable*, locally free H-module M with $\underline{\operatorname{rank}}(M) = (1-c_{ij})\alpha_i + \alpha_j$. This is carried out in the proof of Geiß, Leclerc, and Schröer [2016, Prop. 4.9].

The proof of the following result, which is Geiß, Leclerc, and Schröer [ibid., Thm. 6.1], occupies the major part of that paper.

Proposition 5.5. *Let C be a symmetrizable Cartan matrix of Dynkin type, D a symmetrizer and Ω an orientation for C and $H = H_{\mathbb{C}}(C, D, \Omega)$. Then for each positive root $\beta \in \Delta^+$ there exists a primitive element $\theta_\beta \in \mathcal{P}(\mathcal{M}(H))_\beta$ with $\theta_\beta(M(\beta)) = 1$.*

The idea of the proof is as follows: By Geiß, Leclerc, and Schröer [2017b, Cor. 1.3] for any $\beta \in \Delta^+(C)$ and any sequence $\mathbf{i}$ in I, the Euler characteristic $\chi(\mathrm{Fl}^H_{\mathbf{E},\mathbf{i}}(M(\beta)))$ is independent of the choice of the symmetrizer D. So, we may assume that C is connected and D minimal. In the symmetric (quiver) case, our claim follows now by Schofield's result Schofield [n.d.], who showed that in this case $\mathcal{P}(\mathcal{M}(H))$ can be identified with $\mathfrak{n}(C)$. By Gabriel's theorem in this case the θ_β are the characteristic function of the GL_β-orbit of $M(\beta)$.

In the remaining cases, we construct the θ_β by induction on the height of β in terms of (iterated) commutators of "smaller" θ_γ. Note however that in this case this construction is delicate since the support of the θ_β may contain several indecomposable, locally free modules. See for example Geiß, Leclerc, and Schröer [2017d, Sec. 13.2(d)].

Since in the Dynkin case all weight spaces of $\mathfrak{n}(C)$ are one-dimensional, the main result of Geiß, Leclerc, and Schröer [2016], Theorem 1.1 (ii), follows easily:

Theorem 5.6. *If C is of Dynkin type, the Hopf algebra homomorphism η_H is an isomorphism.*

Recall the notation used in Proposition 3.11. In particular, $\mathbf{i}$ is a reduced expression for the longest element $w_0 \in W(C)$, which is $+$-adapted to Ω, and $\beta_k = \beta_{\mathbf{i},k}$ for $k = 1, 2, \ldots, r$. Let us abbreviate

$$\theta_{\mathbf{m}} := \frac{1}{m_r! \cdots m_1!} \theta_{\beta_r}^{m_r} * \cdots * \theta_{\beta_1}^{m_1} \quad \text{and} \quad M(\mathbf{m}) := \oplus_{k=1}^r M(\beta_k)^{m_k}$$

for $\mathbf{m} = (m_1, m_2, \dots, m_r) \in \mathbb{N}^r$. By the above results $(\theta_{\mathbf{m}})_{\mathbf{m}\in\mathbb{N}^r}$ is a normalized PBW-basis of $\mathfrak{M}(H) \cong U(\mathfrak{n}(C))$ in the Dynkin case.

Moreover we consider the graded dual $\mathfrak{M}(H)^*$ of $\mathfrak{M}(H)$, and the evaluation form $\delta_{M(\mathbf{m})} \in \mathfrak{M}(H)^*$ with $\delta_{\mathbf{m}}(f) := f(M(\mathbf{m}))$. By the definition of the comultiplication in $\mathfrak{M}(H)$, the graded dual is a commutative Hopf algebra, and $\delta_{M(\mathbf{m})} \cdot \delta_{M(\mathbf{n})} = \delta_{M(\mathbf{m}+\mathbf{n})}$. Our next result is essentially Geiß, Leclerc, and Schröer [2017d, Thm. 1.3].

Proposition 5.7. *With the above notation we have*

$$\delta_{M(\mathbf{m})}(\theta_{\mathbf{n}}) = \delta_{\mathbf{m},\mathbf{n}} \textit{ for all } \mathbf{m}, \mathbf{n} \in \mathbb{N}^r.$$

Thus $(\delta_{M(\mathbf{m})})_{\mathbf{m}\in\mathbb{N}^r}$ is a basis of $\mathfrak{M}(H)^*$ which is dual to the PBW-basis $(\theta_{\mathbf{m}})_{\mathbf{m}\in\mathbb{N}^r}$, and $\mathfrak{M}(H)^* = \mathbb{C}[\delta_{M(\beta_1)}, \dots, \delta_{M(\beta_r)}]$.

In the quiver case (with trivial symmetrizer) this result is easy to prove, since with Gabriel's theorem and Proposition 3.11 follows quickly that $\theta_{\mathbf{r}}$ is the characteristic function of the orbit of $M(\mathbf{r})$. However, in our more general setting, already the θ_{β_k} are usually not the characteristic function of $M(\beta_k)$, as we observed above. The more sophisticated Proposition 3.12 implies, by the definition of the multiplication in $\mathfrak{M}_{\mathbf{E}}(H)$, that $\theta_{\mathbf{m}}(M(\beta_k)) = 0$ if $\mathbf{m} \neq \mathbf{e}_k$, the k-th unit vector. The remaining claims follow now by formal arguments, see the proof of Geiß, Leclerc, and Schröer [ibid., Thm. 6.1].

Remark 5.8. For $M \in \operatorname{rep}_{\mathrm{l.f.}}(H)$ and $\mathbf{e} \in \mathbb{N}^I$ we we introduce the quasi-projective variety

$$\operatorname{Grlf}^H_{\mathbf{e}}(M) := \{U \subset M \mid U \text{ locally free submodule and } \underline{\operatorname{rank}}(U) = \mathbf{e}\},$$

which is an open subset of the usual quiver Grassmannian $\operatorname{Gr}^H_{D\cdot\mathbf{e}}(M)$. With this notation we can define

$$F_M := \sum_{\mathbf{e}\in\mathbb{N}^I} \chi(\operatorname{Grlf}^H_{\mathbf{e}}(M)) Y^{\mathbf{e}} \in \mathbb{Z}[Y_1, \dots, Y_n] \text{ and } \mathbf{g}_M := -R \cdot \underline{\operatorname{rank}}(M),$$

where R is the matrix introduced in Corollary 3.4. By the main result of Geiß, Leclerc, and Schröer [ibid.] this yields for $M = M(\beta)$ with $\beta \in \Delta^+(C)$ the F-polynomial and g-vector, in the sense of Fomin and Zelevinsky [2007], for all cluster variables of a finite type cluster algebra Fomin and Zelevinsky [2003] of type C with respect to an acyclic seed defined by Ω. The proof is based on Proposition 5.7, and on the description by Yang and Zelevinsky [2008] of the F-polynomial of a cluster variable in terms of generalized minors.

5.4 Semicanonical functions and the support conjecture for $\mathcal{M}_{\mathbf{E}}(\Pi)$. Recall, that we abbreviate $\Pi = \Pi_{\mathbb{C}}(C, D)$ for a symmetrizable Cartan matrix C with symmetrizer D. By definition $\mathcal{M}(\Pi) = \mathcal{M}_{\mathbf{E}}(\Pi) \subset \mathcal{F}(\Pi)$ is generated by the functions $\tilde{\theta}_i \in \mathcal{M}_{\alpha_i}(\Pi)$ for $i \in I$, where $\tilde{\theta}_i$ is the characteristic function of the orbit of E_i, viewed as a Π-module. We use here the notation $\tilde{\theta}_i$ rather than θ_i to remind us that the multiplication is now defined in terms of constructible functions on a larger space. More precisely, we have for each $\mathbf{r} \in \mathbb{N}^I$ an injective $\mathrm{Aut}_S(\mathbf{E}^{\mathbf{r}})$-equivariant, injective morphism of varieties

$$\iota_{\mathbf{r}}\colon H(\mathbf{r}) \to \Pi(\mathbf{d}).$$

These morphisms induce, via restriction, a surjective morphism of graded Hopf algebras

$$\iota_{\Omega}^*\colon \mathcal{M}(\Pi) \to \mathcal{M}(H), \quad \tilde{\theta}_i \mapsto \theta_i \text{ for } i \in I.$$

The proof of the following result is, almost verbatim, the same induction argument as the one used by Lusztig [2000], see Geiß, Leclerc, and Schröer [2017c, Lem. 7.1].

Lemma 5.9. *Let $\mathbf{r} \in \mathbb{N}^I$. For each $Z \in \mathrm{Irr}(\Pi(\mathbf{r}))^{\max}$ there exists an open dense subset $U_Z \subset Z$ and a function $f_Z \in \mathcal{M}_{\mathbf{r}}(\Pi)$ such that for $Z, Z' \in \mathrm{Irr}(\Pi(\mathbf{r}))^{\max}$ and any $u' \in U_{Z'}$ we have*

$$f_Z(u') = \delta_{Z,Z'}.$$

In particular, the functions $(f_Z)_{Z\in\mathrm{Irr}(\Pi(\mathbf{r}))^{\max}}$ are linearly independent in $\mathcal{M}_{\mathbf{r}}(\Pi)$.

Note however, that the result is not trivial since we claim that the $f_Z \in \mathcal{M}_{\mathbf{e}}(\Pi)$ and not in the much bigger space $\mathcal{F}(\Pi)_{C\cdot\mathbf{r}}$. On the other hand, it is important to observe that the inductive construction of the *semicanonical functions* f_Z involves some choices.

As in Section 5.3, we define now for each $i \neq j$ in I the primitive element

$$\tilde{\theta}_{ij} = (\mathrm{ad}\,\tilde{\theta}_i)^{1-c_{ij}}(\tilde{\theta}_j) \in \mathcal{P}(\mathcal{M}(\Pi)).$$

Unfortunately, we have the following result, which is a combination of Lemma 6.1, Proposition 6.2 and Lemma 6.3 from Geiß, Leclerc, and Schröer [ibid.].

Lemma 5.10. *Suppose with the above notations that $c_{ij} < 0$.*

(a) If $c_i \geq 2$ then there exists an indecomposable, $\Pi = \Pi(C, D)$-module $X = X_{(ij)}$ with $\underline{\mathrm{rank}}(X_{(ij)}) = (1 - c_{ij})\alpha_i + \alpha_j$ and $\tilde{\theta}_{ij}(X_{(ij)}) \neq 0$.

(b) If M is crystal module with $\underline{\mathrm{rank}}(M) = (1 - c_{ij})\alpha_i + \alpha_j$ we have $\tilde{\theta}_{ij}(M) = 0$.

This leads us to define in $\mathcal{M}(\Pi)$ the ideal $\mathcal{J}$, which is generated by the homogeneous elements $\tilde{\theta}_{ij}$ for $i, j \in I$ with $i \neq j$. We set moreover

$$\overline{\mathcal{M}}(\Pi) = \mathcal{M}(\Pi)/\mathcal{J} \text{ and } \bar{f} := f + \mathcal{J} \quad (f \in \mathcal{M}(\Pi)).$$

Thus, by Proposition 5.4, the morphism ι_Ω^* induces a surjective algebra homomorphism $\overline{\iota}_\Omega^*\colon \overline{\mathfrak{M}}(\Pi) \to \mathfrak{M}(H)$. On the other hand, we can define for each $\mathbf{r} \in \mathbb{N}^I$ the space of functions with non maximal support

$$\mathcal{S}_\mathbf{r} := \{f \in \mathfrak{M}_\mathbf{r}(\Pi) \mid \dim \operatorname{supp}(f) < \dim H(\mathbf{r})\} \text{ and } \mathcal{S} := \oplus_{\mathbf{r}\in\mathbb{N}^I} \mathcal{S}_\mathbf{r}.$$

Recall that $\dim \Pi(\mathbf{r}) = \dim H(\mathbf{r})$. Proposition 4.5 and Lemma 5.10 imply at least that $\tilde{\theta}_{ij} \in \mathcal{S}$. In view of Lemma 5.9 and Theorem 4.2 it is easy to show the following result:

Proposition 5.11. *The following three conditions are equivalent:*

$$(1)\ \mathcal{I} \subset \mathcal{S}, \qquad (2)\ \mathcal{I} = \mathcal{S}, \qquad (3)\ \mathcal{S} \text{ is an ideal.}$$

In this case the surjective algebra homomorphism

$$\eta\colon U(\mathfrak{n}) \to \overline{\mathfrak{M}}(\Pi), e_i \mapsto \tilde{\theta}_i + \mathcal{I}$$

would be an isomorphism, and the $(\eta^{-1}(\bar{f}_Z))_{\mathfrak{B}}$ would form a basis of $U(\mathfrak{n})$ which is independent of the possible choices for the $(f_Z)_{Z\in\mathfrak{B}}$.

Thus we call the equivalent conditions of the above proposition our *Support conjecture*.

Remark 5.12. Our semicanonical basis would yield, similarly to Lusztig [2000, Sec. 3], in a natural way a basis for each integrable highest weight representation $L(\lambda)$ of $\mathfrak{g}(C)$, if the support conjecture is true. See Geiß, Leclerc, and Schröer [2017c, Se. 7.3] for more details.

Acknowledgments. I wish to thank Bernard Leclerc and Jan Schröer for their very precious collaboration and friendship over the years. I also should like to acknowledge hospitality from the MPIM-Bonn, where this manuscript was prepared.

TILTING COHEN–MACAULAY REPRESENTATIONS

OSAMU IYAMA

Dedicated to the memory of Ragnar-Olaf Buchweitz

Abstract

This is a survey on recent developments in Cohen-Macaulay representations via tilting and cluster tilting theory. We explain triangle equivalences between the singularity categories of Gorenstein rings and the derived (or cluster) categories of finite dimensional algebras.

1 Introduction

The study of Cohen-Macaulay (CM) representations (Curtis and Reiner [1981], Yoshino [1990], Simson [1992], and Leuschke and Wiegand [2012]) is one of the active subjects in representation theory and commutative algebra. It has fruitful connections to singularity theory, algebraic geometry and physics. This article is a survey on recent developments in this subject.

The first half of this article is spent for background materials, which were never written in one place. In Section 2, we recall the notion of CM modules over Gorenstein rings, and put them into the standard framework of triangulated categories. This gives us powerful tools including Buchweitz's equivalence between the stable category $\underline{\mathrm{CM}}R$ and the singularity category, and Orlov's realization of the graded singularity category in the derived category, giving a surprising connection between CM modules and algebraic geometry. We also explain basic results including Auslander-Reiten duality stating that $\underline{\mathrm{CM}}R$ is a Calabi-Yau triangulated category for a Gorenstein isolated singularity R, and Gabriel's Theorem on quiver representations and its commutative counterpart due to Buchweitz-Greuel-Schreyer.

In Section 3, we give a brief introduction to tilting and cluster tilting. Tilting theory controls equivalences of derived categories, and played a central role in Cohen-Macaulay

approximation theory around 1990 (Auslander and Buchweitz [1989] and Auslander and Reiten [1991]). The first main problem of this article is to find a tilting object in the stable category $\underline{\mathrm{CM}}^G R$ of a G-graded Gorenstein ring R. This is equivalent to find a triangle equivalence

$$\underline{\mathrm{CM}}^G R \simeq \mathrm{K}^{\mathrm{b}}(\mathrm{proj}\,\Lambda) \tag{1-1}$$

with some ring Λ. It reveals a deep connection between rings R and Λ.

The notion of d-cluster tilting was introduced in higher Auslander-Reiten theory. A Gorenstein ring R is called d-CM-finite if there exists a d-cluster tilting object in CM R. This property is a natural generalization of CM-finiteness, and closely related to the existence of non-commutative crepant resolutions of Van den Bergh. On the other hand, the d-cluster category $\mathrm{C}_d(\Lambda)$ of a finite dimensional algebra Λ is a d-Calabi-Yau triangulated category containing a d-cluster tilting object, introduced in categorification of Fomin-Zelevinsky cluster algebras. The second main problem of this article is to find a triangle equivalence

$$\underline{\mathrm{CM}} R \simeq \mathrm{C}_d(\Lambda) \tag{1-2}$$

with some finite dimensional algebra Λ. This implies that R is d-CM-finite.

In the latter half of this article, we construct various triangle equivalences of the form (1-1) or (1-2). In Section 4, we explain results in Yamaura [2013] and Buchweitz, Iyama, and Yamaura [2018]. They assert that, for a large class of $\mathbb{Z}$-graded Gorenstein rings R in dimension 0 or 1, there exist triangle equivalences (1-1) for some algebras Λ.

There are no such general results in dimension greater than 1. Therefore in the main Sections 5 and 6 of this article, we concentrate on special classes of Gorenstein rings. In Section 5, we explain results on Gorenstein rings obtained from classical and higher preprojective algebras (Amiot, Iyama, and Reiten [2015], Iyama and Oppermann [2013], and Kimura [2018, 2016]). A crucial observation is that certain Calabi-Yau algebras are higher preprojective algebras and higher Auslander algebras at the same time. In Section 6, we explain results on CM modules on Geigle-Lenzing complete intersections and the derived categories of coherent sheaves on the associated stacks (Herschend, Iyama, Minamoto, and Oppermann [2014]). They are higher dimensional generalizations of weighted projective lines of Geigle-Lenzing.

Acknowledgements The author would like to thank Claire Amiot, Bernhard Keller and Idun Reiten for valuable comments on this article.

2 Preliminaries

2.1 Notations. We fix some conventions in this paper. All modules are right modules. The composition of $f: X \to Y$ and $g: Y \to Z$ is denoted by gf. For a ring Λ, we denote by $\operatorname{mod}\Lambda$ the category of finitely generated Λ-modules, by $\operatorname{proj}\Lambda$ the category of finitely generated projective Λ-modules, and by $\operatorname{gl.dim}\Lambda$ the global dimension of Λ. When Λ is G-graded, we denote by $\operatorname{mod}^G\Lambda$ and $\operatorname{proj}^G\Lambda$ the G-graded version, whose morphisms are degree preserving. We denote by k an arbitrary field unless otherwise specified, and by D the k-dual or Matlis dual over a base commutative ring.

2.2 Cohen-Macaulay modules. We start with the classical notion of Cohen-Macaulay modules over commutative rings (Bruns and Herzog [1993] and Matsumura [1989]).

Let R be a commutative noetherian ring. The *dimension* $\dim R$ of R is the supremum of integers $n \geq 0$ such that there exists a chain $\mathfrak{p}_0 \subsetneq \mathfrak{p}_1 \subsetneq \cdots \subsetneq \mathfrak{p}_n$ of prime ideals of R. The *dimension* $\dim M$ of $M \in \operatorname{mod} R$ is the dimension $\dim(R/\operatorname{ann} M)$ of the factor ring $R/\operatorname{ann} M$, where $\operatorname{ann} M$ is the annihilator of M.

The notion of depth is defined locally. Assume that R is a local ring with maximal ideal $\mathfrak{m}$ and $M \in \operatorname{mod} R$ is non-zero. An element $r \in \mathfrak{m}$ is called *M-regular* if the multiplication map $r: M \to M$ is injective. A sequence $r_1, \ldots, r_n$ of elements in $\mathfrak{m}$ is called an *M-regular sequence* of length n if r_i is $(M/(r_1, \ldots, r_{i-1})M)$-regular for all $1 \leq i \leq n$. The *depth* $\operatorname{depth} M$ of M is the supremum of the length of M-regular sequences. This is given by the simple formula

$$\operatorname{depth} M = \inf\{i \geq 0 \mid \operatorname{Ext}^i_R(R/\mathfrak{m}, M) \neq 0\}.$$

The inequalities $\operatorname{depth} M \leq \dim M \leq \dim R$ hold. We call M (maximal) *Cohen-Macaulay* (or *CM*) if the equality $\operatorname{depth} M = \dim R$ holds or $M = 0$.

When R is not necessarily local, $M \in \operatorname{mod} R$ is called *CM* if $M_{\mathfrak{m}}$ is a CM $R_{\mathfrak{m}}$-module for all maximal ideals $\mathfrak{m}$ of R. The ring R is called *CM* if it is CM as an R-module. The ring R is called *Gorenstein* (resp. *regular*) if $R_{\mathfrak{m}}$ has finite injective dimension as an $R_{\mathfrak{m}}$-module (resp. $\operatorname{gl.dim} R_{\mathfrak{m}} < \infty$) for all maximal ideals $\mathfrak{m}$ of R. In this case, the injective (resp. global) dimension coincides with $\dim R_{\mathfrak{m}}$, but this is not true in the more general setting below. The following hierarchy is basic.

$$\text{Regular rings} \Longrightarrow \text{Gorenstein rings} \Longrightarrow \text{Cohen-Macaulay rings}$$

We will study CM modules over Gorenstein rings. Since we apply methods in representation theory, it is more reasonable to work in the following wider framework.

Definition 2.1 (Iwanaga [1979] and Enochs and Jenda [2000])**.** Let Λ be a (not necessarily commutative) noetherian ring, and $d \geq 0$ an integer. We call Λ (d-)*Iwanaga-Gorenstein* (or *Gorenstein*) if Λ has injective dimension at most d as a Λ-module, and also as a Λ^{op}-module.

Clearly, a commutative noetherian ring R is Iwanaga-Gorenstein if and only if it is Gorenstein and $\dim R < \infty$. Note that there are various definitions of non-commutative Gorenstein rings, e.g. Artin and Schelter [1987], Curtis and Reiner [1981], Fossum, Griffith, and Reiten [1975], Goto and Nishida [2002], and Iyama and Wemyss [2014]. Although Definition 2.1 is much weaker than them, it is sufficient for the aim of this paper.

Noetherian rings with finite global dimension are analogues of regular rings, and form special classes of Iwanaga-Gorenstein rings. The first class consists of *semisimple rings* (i.e. rings Λ with $\operatorname{gl.dim} \Lambda = 0$), which are products of matrix rings over division rings by Artin-Wedderburn Theorem. The next class consists of *hereditary rings* (i.e. rings Λ with $\operatorname{gl.dim} \Lambda \leq 1$), which are obtained from quivers.

Definition 2.2 (Assem, Simson, and Skowroński [2006])**.** A *quiver* is a quadruple $Q = (Q_0, Q_1, s, t)$ consisting of sets Q_0, Q_1 and maps $s, t \colon Q_1 \to Q_0$. We regard each element in Q_0 as a vertex, and $a \in Q_1$ as an arrow with source $s(a)$ and target $t(a)$. A *path* of length 0 is a vertex, and a *path* of length $\ell (\geq 1)$ is a sequence $a_1 a_2 \cdots a_\ell$ of arrows satisfying $t(a_i) = s(a_{i+1})$ for each $1 \leq i < \ell$.

For a field k, the *path algebra* kQ is defined as follows: It is a k-vector space with basis consisting of all paths on Q. For paths $p = a_1 \cdots a_\ell$ and $q = b_1 \cdots b_m$, we define $pq = a_1 \cdots a_\ell b_1 \cdots b_m$ if $t(a_\ell) = s(b_1)$, and $pq = 0$ otherwise.

Clearly $\dim_k(kQ)$ is finite if and only if Q is *acyclic* (that is, there are no paths p of positive length satisfying $s(p) = t(p)$).

Example 2.3. (a) (Assem, Simson, and Skowroński [ibid.]) The path algebra kQ of a finite quiver Q is hereditary. Conversely, any finite dimensional hereditary algebra over an algebraically closed field k is Morita equivalent to kQ for some acyclic quiver Q.

(b) A finite dimensional k-algebra Λ is 0-Iwanaga-Gorenstein if and only if Λ is *self-injective*, that is, $D\Lambda$ is projective as a Λ-module, or equivalently, as a Λ^{op}-module. For example, the group ring kG of a finite group G is self-injective.

(c) (Iyama and Wemyss [2014] and Curtis and Reiner [1981]) Let R be a CM local ring with canonical module ω and dimension d. An R-algebra Λ is called an *R-order* if it is CM as an R-module. Then an R-order Λ is d-Iwanaga-Gorenstein if and only if Λ is a *Gorenstein order*, i.e. $\operatorname{Hom}_R(\Lambda, \omega)$ is projective as a Λ-module, or equivalently, as a Λ^{op}-module.

An R-order Λ is called *non-singular* if $\operatorname{gl.dim} \Lambda = d$. They are classical objects for the case $d = 0, 1$ (Curtis and Reiner [1981]), and studied for $d = 2$ (Reiten and Van den Bergh [1989]). Non-singular orders are closely related to cluster tilting explained in Section 3.2.

2.3 The triangulated category of Cohen-Macaulay modules. CM modules can be defined naturally also for Iwanaga-Gorenstein rings.

Definition 2.4. Let Λ be an Iwanaga-Gorenstein ring. We call $M \in \operatorname{mod}\Lambda$ (maximal) *Cohen-Macaulay* (or *CM*) if $\operatorname{Ext}^i_\Lambda(M,\Lambda) = 0$ holds for all $i > 0$. We denote by $\operatorname{CM}\Lambda$ the category of CM Λ-modules.

We also deal with graded rings and modules. For an abelian group G and a G-graded Iwanaga-Gorenstein ring Λ, we denote by $\operatorname{CM}^G \Lambda$ the full subcategory of $\operatorname{mod}^G \Lambda$ consisting of all X which belong to $\operatorname{CM}\Lambda$ as ungraded Λ-modules.

When Λ is commutative Gorenstein, Definition 2.4 is one of the well-known equivalent conditions of CM modules. Note that, in a context of Gorenstein homological algebra (Auslander and Bridger [1969] and Enochs and Jenda [2000]), CM modules are also called Gorenstein projective, Gorenstein dimension zero, or totally reflexive.

Example 2.5. (a) Let Λ be a noetherian ring with $\operatorname{gl.dim}\Lambda < \infty$. Then $\operatorname{CM}\Lambda = \operatorname{proj}\Lambda$.

(b) Let Λ be a finite dimensional self-injective k-algebra. Then $\operatorname{CM}\Lambda = \operatorname{mod}\Lambda$.

(c) Let Λ be a Gorenstein R-order in Example 2.3(c). Then CM Λ-modules are precisely Λ-modules that are CM as R-modules.

We study the category $\operatorname{CM}^G \Lambda$ from the point of view of triangulated categories. We start with Quillen's exact categories (see Bühler [2010] for a more axiomatic definition).

Definition 2.6 (Happel [1988]). (a) An *exact category* is a full subcategory $\mathcal{F}$ of an abelian category $\mathcal{A}$ such that, for each exact sequence $0 \to X \to Y \to Z \to 0$ in $\mathcal{A}$ with $X, Z \in \mathcal{F}$, we have $Y \in \mathcal{F}$. In this case, we say that $X \in \mathcal{F}$ is *projective* if $\operatorname{Ext}^1_{\mathcal{A}}(X,\mathcal{F}) = 0$ holds. Similarly we define *injective* objects in $\mathcal{F}$.

(b) An exact category $\mathcal{F}$ in $\mathcal{A}$ is called *Frobenius* if:

- an object in $\mathcal{F}$ is projective if and only if it is injective,
- any $X \in \mathcal{F}$ admits exact sequences $0 \to Y \to P \to X \to 0$ and $0 \to X \to I \to Z \to 0$ in $\mathcal{A}$ such that P and I are projective in $\mathcal{F}$ and $Y, Z \in \mathcal{F}$.

(c) The *stable category* $\underline{\mathcal{F}}$ has the same objects as $\mathcal{F}$, and the morphisms are given by $\underline{\operatorname{Hom}}_{\mathcal{F}}(X,Y) = \operatorname{Hom}_{\mathcal{F}}(X,Y)/P(X,Y)$, where $P(X,Y)$ is the subgroup consisting of morphisms which factor through projective objects in $\mathcal{F}$.

Frobenius categories are ubiquitous in algebra. Here we give two examples.

Example 2.7. (a) For a G-graded Iwanaga-Gorenstein ring Λ, the category $\mathrm{CM}^G \Lambda$ of G-graded Cohen-Macaulay Λ-modules is a Frobenius category.

(b) For an additive category $\mathcal{A}$, the category $\mathrm{C}(\mathcal{A})$ of chain complexes in $\mathcal{A}$ is a Frobenius category, whose stable category is the homotopy category $\mathrm{K}(\mathcal{A})$.

A *triangulated category* is a triple of an additive category $\mathcal{T}$, an autoequivalence $[1]\colon \mathcal{T} \to \mathcal{T}$ (called *suspension*) and a class of diagrams $X \xrightarrow{f} Y \xrightarrow{g} Z \xrightarrow{h} X[1]$ (called *triangles*) satisfying a certain set of axioms. There are natural notions of functors and equivalences between triangulated categories, called *triangle functors* and *triangle equivalences*. For details, see e.g. Happel [1988] and Neeman [2001]. Typical examples of triangulated categories are given by the homotopy category $\mathrm{K}(\mathcal{A})$ of an additive category $\mathcal{A}$ and the derived category $\mathrm{D}(\mathcal{A})$ of an abelian category $\mathcal{A}$.

A standard construction of triangulated categories is given by the following.

Theorem 2.8 (Happel [1988]). *The stable category $\underline{\mathcal{F}}$ of a Frobenius category $\mathcal{F}$ has a canonical structure of a triangulated category.*

Such a triangulated category is called *algebraic*. Note that the suspension functor $[1]$ of $\underline{\mathcal{F}}$ is given by the cosyzygy. Thus the i-th suspension $[i]$ is the i-th cosyzygy for $i \geq 0$, and the $(-i)$-th syzygy for $i < 0$. We omit other details.

As a summary, we obtain the following.

Corollary 2.9. *Let G be an abelian group and Λ a G-graded Iwanaga-Gorenstein ring. Then $\mathrm{CM}^G \Lambda$ is a Frobenius category, and therefore the stable category $\underline{\mathrm{CM}}^G \Lambda$ has a canonical structure of a triangulated category.*

We denote by $\mathrm{D}^{\mathrm{b}}(\mathrm{mod}^G \Lambda)$ the bounded derived category of $\mathrm{mod}^G \Lambda$, and by $\mathrm{K}^{\mathrm{b}}(\mathrm{proj}^G \Lambda)$ the bounded homotopy category of $\mathrm{proj}^G \Lambda$. We regard $\mathrm{K}^{\mathrm{b}}(\mathrm{proj}^G \Lambda)$ as a thick subcategory of $\mathrm{D}^{\mathrm{b}}(\mathrm{mod}^G \Lambda)$. The *stable derived category* (Buchweitz [1987]) or the *singularity category* (Orlov [2009]) is defined as the Verdier quotient

$$\mathrm{D}^G_{\mathrm{sg}}(\Lambda) = \mathrm{D}^{\mathrm{b}}(\mathrm{mod}^G \Lambda)/\mathrm{K}^{\mathrm{b}}(\mathrm{proj}^G \Lambda).$$

This is enhanced by the Frobenius category $\mathrm{CM}^G \Lambda$ as the following result shows.

Theorem 2.10 (Buchweitz [1987], Rickard [1989a], and Keller and Vossieck [1987]). *Let G be an abelian group and Λ a G-graded Iwanaga-Gorenstein ring. Then there is a triangle equivalence $\mathrm{D}^G_{\mathrm{sg}}(\Lambda) \simeq \underline{\mathrm{CM}}^G \Lambda$.*

Let us recall the following notion (Bruns and Herzog [1993]).

Definition 2.11. Let G be an abelian group and R a G-graded Gorenstein ring with $\dim R = d$ such that $R_0 = k$ is a field and $\bigoplus_{i \neq 0} R_i$ is an ideal of R. The *a-invariant* $a \in G$ (or *Gorenstein parameter* $-a \in G$) is an element satisfying $\operatorname{Ext}^d_R(k, R(a)) \simeq k$ in $\operatorname{mod}^{\mathbb{Z}} R$.

For a G-graded noetherian ring Λ, let

$$\operatorname{qgr} \Lambda = \operatorname{mod}^G \Lambda / \operatorname{mod}^G_0 \Lambda \tag{2-1}$$

be the Serre quotient of $\operatorname{mod}^G \Lambda$ by the subcategory $\operatorname{mod}^G_0 \Lambda$ of G-graded Λ-modules of finite length (Artin and Zhang [1994]). This is classical in projective geometry. In fact, for a $\mathbb{Z}$-graded commutative noetherian ring R generated in degree 1, $\operatorname{qgr} R$ is the category $\operatorname{coh} X$ of coherent sheaves on the scheme $X = \operatorname{Proj} R$ (Serre [1955]).

The following result realizes $\mathrm{D}^{\mathbb{Z}}_{\mathrm{sg}}(R)$ and $\mathrm{D}^{\mathrm{b}}(\operatorname{qgr} R)$ inside of $\mathrm{D}^{\mathrm{b}}(\operatorname{mod}^{\mathbb{Z}} R)$, where $\operatorname{mod}^{\geq n} R$ is the full subcategory of $\operatorname{mod}^{\mathbb{Z}} R$ consisting of all X satisfying $X = \bigoplus_{i \geq n} X_i$, and $(-)^*$ is the duality $\mathbf{R}\operatorname{Hom}_R(-, R) \colon \mathrm{D}^{\mathrm{b}}(\operatorname{mod}^{\mathbb{Z}} R) \to \mathrm{D}^{\mathrm{b}}(\operatorname{mod}^{\mathbb{Z}} R)$.

Theorem 2.12 (Orlov [2009] and Iyama and Yang [2017])**.** *Let $R = \bigoplus_{i \geq 0} R_i$ be a $\mathbb{Z}$-graded Gorenstein ring such that R_0 is a field, and a the a-invariant of R.*

(a) *There is a triangle equivalence* $\mathrm{D}^{\mathrm{b}}(\operatorname{mod}^{\geq 0} R) \cap \mathrm{D}^{\mathrm{b}}(\operatorname{mod}^{\geq 1} R)^* \simeq \mathrm{D}^{\mathbb{Z}}_{\mathrm{sg}}(R)$.

(b) *There is a triangle equivalence* $\mathrm{D}^{\mathrm{b}}(\operatorname{mod}^{\geq 0} R) \cap \mathrm{D}^{\mathrm{b}}(\operatorname{mod}^{\geq a+1} R)^* \simeq \mathrm{D}^{\mathrm{b}}(\operatorname{qgr} R)$.

Therefore if $a = 0$, then $\mathrm{D}^{\mathbb{Z}}_{\mathrm{sg}}(R) \simeq \mathrm{D}^{\mathrm{b}}(\operatorname{qgr} R)$. If $a < 0$ (resp. $a > 0$), then there is a fully faithful triangle functor $\mathrm{D}^{\mathbb{Z}}_{\mathrm{sg}}(R) \to \mathrm{D}^{\mathrm{b}}(\operatorname{qgr} R)$ (resp. $\mathrm{D}^{\mathrm{b}}(\operatorname{qgr} R) \to \mathrm{D}^{\mathbb{Z}}_{\mathrm{sg}}(R)$). This gives a new connection between CM representations and algebraic geometry.

2.4 Representation theory.

We start with Auslander-Reiten theory.

Let R be a commutative ring, and D the Matlis duality. A triangulated category $\mathcal{T}$ is called *R-linear* if each morphism set $\operatorname{Hom}_{\mathcal{T}}(X, Y)$ has an R-module structure and the composition $\operatorname{Hom}_{\mathcal{T}}(X, Y) \times \operatorname{Hom}_{\mathcal{T}}(Y, Z) \to \operatorname{Hom}_{\mathcal{T}}(X, Z)$ is R-bilinear. It is called *Hom-finite* if each morphism set has finite length as an R-module.

Definition 2.13 (Reiten and Van den Bergh [2002])**.** A *Serre functor* is an R-linear autoequivalence $\mathbb{S} \colon \mathcal{T} \to \mathcal{T}$ such that there exists a functorial isomorphism $\operatorname{Hom}_{\mathcal{T}}(X, Y) \simeq D\operatorname{Hom}_{\mathcal{T}}(Y, \mathbb{S}X)$ for any $X, Y \in \mathcal{T}$ (called *Auslander-Reiten duality* or *Serre duality*). The composition $\tau = \mathbb{S} \circ [-1]$ is called the *AR translation*.

For $d \in \mathbb{Z}$, we say that $\mathcal{T}$ is *d-Calabi-Yau* if $[d]$ gives a Serre functor of $\mathcal{T}$.

A typical example of a Serre functor is given by a smooth projective variety X over a field k. In this case, $\mathrm{D}^{\mathrm{b}}(\operatorname{coh} X)$ has a Serre functor $- \otimes_X \omega[d]$, where ω is the canonical bundle of X and d is the dimension of X (Huybrechts [2006]).

Example 2.14 (Happel [1988] and Buchweitz, Iyama, and Yamaura [2018]). Let Λ be a finite dimensional k-algebra. Then $\mathrm{K}^{\mathrm{b}}(\operatorname{proj}\Lambda)$ has a Serre functor if and only if Λ is Iwanaga-Gorenstein, and $\mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Lambda)$ has a Serre functor if and only if $\operatorname{gl.dim}\Lambda < \infty$. In both cases, the Serre functor is given by $\nu = - \overset{\mathbf{L}}{\otimes}_\Lambda (D\Lambda)$, and the AR translation is given by $\tau = \nu \circ [-1]$.

For AR theory of CM modules, we need the following notion.

Definition 2.15. Let R be a Gorenstein ring with $\dim R = d$. We denote by $\mathrm{CM}_0 R$ the full subcategory of $\mathrm{CM} R$ consisting of all X such that $X_\mathfrak{p} \in \operatorname{proj} R_\mathfrak{p}$ holds for all $\mathfrak{p} \in \operatorname{Spec} R$ with $\dim R_\mathfrak{p} < d$. When R is local, such an X is called *locally free on the punctured spectrum* (Yoshino [1990]). If R is G-graded, we denote by $\mathrm{CM}_0^G R$ the full subcategory of $\mathrm{CM}^G R$ consisting of all X which belong to $\mathrm{CM}_0 R$ as ungraded R-modules.

As before, $\mathrm{CM}_0^G R$ is a Frobenius category, and $\underline{\mathrm{CM}}_0^G R$ is a triangulated category. Note that $\mathrm{CM}_0 R = \mathrm{CM} R$ holds if and only if R satisfies Serre's (R_{d-1}) condition (i.e. $R_\mathfrak{p}$ is regular for all $\mathfrak{p} \in \operatorname{Spec} R$ with $\dim R_\mathfrak{p} < d$). This means that R has at worst an isolated singularity if R is local.

The following is a fundamental theorem of CM representations.

Theorem 2.16 (Auslander [1978] and Auslander and Reiten [1987]). *Let R be a Gorenstein ring with* $\dim R = d$. *Then $\underline{\mathrm{CM}}_0 R$ is a $(d-1)$-Calabi-Yau triangulated category. If R is G-graded and has an a-invariant $a \in G$, then $\underline{\mathrm{CM}}_0^G R$ has a Serre functor $(a)[d-1]$.*

Let us introduce a key notion in Auslander-Reiten theory. We call an additive category $\mathcal{C}$ *Krull-Schmidt* if any object in $\mathcal{C}$ is isomorphic to a finite direct sum of objects whose endomorphism rings are local. We denote by $\operatorname{ind}\mathcal{C}$ the set of isomorphism classes of indecomposable objects in $\mathcal{C}$.

Definition 2.17 (Happel [1988]). Let $\mathcal{T}$ be a Krull-Schmidt triangulated category. We call a triangle $X \xrightarrow{f} Y \xrightarrow{g} Z \xrightarrow{h} X[1]$ in $\mathcal{T}$ an *almost split triangle* if:

- X and Z are indecomposable, and $h \neq 0$ (i.e. the triangle does not split).
- Any morphism $W \to Z$ which is not a split epimorphism factors through g.
- Any morphism $X \to W$ which is not a split monomorphism factors through f.

We say that $\mathcal{T}$ *has almost split triangles* if for any indecomposable object X (resp. Z), there is an almost split triangle $X \to Y \to Z \to X[1]$.

There is a close connection between almost split triangles and Serre functors.

Theorem 2.18 (Reiten and Van den Bergh [2002]). *Let $\mathcal{T}$ be an R-linear Hom-finite Krull-Schmidt triangulated category. Then $\mathcal{T}$ has a Serre functor if and only if $\mathcal{T}$ has almost split triangles. In this case, $X \simeq \tau Z$ holds in each almost split triangle $X \to Y \to Z \to X[1]$ in $\mathcal{T}$.*

When $\mathcal{T}$ has almost split triangles, one can define the *AR quiver* of $\mathcal{T}$, which has $\operatorname{ind}\mathcal{T}$ as the set of vertices. It describes the structure of $\mathcal{T}$ (see Happel [1988]). Similarly, *almost split sequences* and the AR quiver are defined for exact categories (Assem, Simson, and Skowroński [2006] and Leuschke and Wiegand [2012]).

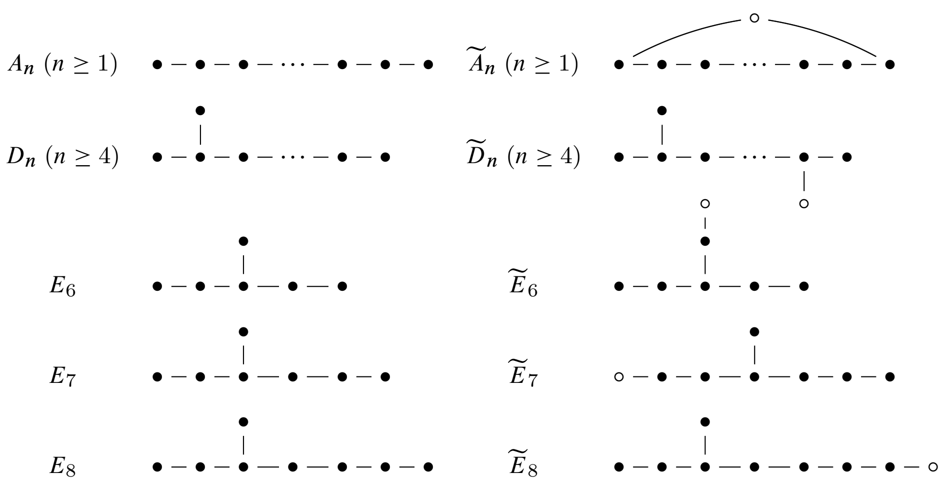
In the rest of this section, we discuss the following notion.

Definition 2.19. A finite dimensional k-algebra Λ is called *representation-finite* if $\operatorname{ind}(\operatorname{mod}\Lambda)$ is a finite set. It is also said to be *of finite representation type*.

The classification of representation-finite algebras was one of the main subjects in the 1980s. Here we recall only one theorem, and refer to Gabriel and Roĭter [1997] for further results.

A *Dynkin quiver* (resp. *extended Dynkin quiver*) is a quiver obtained by orienting each edge of one of the following diagrams A_n, D_n and E_n (resp. $\widetilde{A}_n$, $\widetilde{D}_n$ and $\widetilde{E}_n$).

(2-2)



Now we are able to state Gabriel's Theorem below. For results in non-Dynkin case, we refer to Kac's theorem in Gabriel and Roĭter [ibid.].

Theorem 2.20 (Assem, Simson, and Skowroński [2006]). *Let Q be a connected acyclic quiver and k a field. Then kQ is representation-finite if and only if Q is Dynkin. In this case, there is a bijection between $\operatorname{ind}(\operatorname{mod} kQ)$ and the set Φ_+ of positive roots in the root system of Q.*

For a quiver Q, we define a new quiver $\mathbb{Z}Q$: The set of vertices is $\mathbb{Z} \times Q_0$. The arrows are $(\ell, a)\colon (\ell, s(a)) \to (\ell, t(a))$ and $(\ell, a^*)\colon (\ell, t(a)) \to (\ell+1, s(a))$ for each $\ell \in \mathbb{Z}$ and $a \in Q_1$. For example, if $Q = [1 \xrightarrow{a} 2 \xrightarrow{b} 3]$, then $\mathbb{Z}Q$ is as follows.

$$\begin{array}{ccccccccccccccc}
 & (-2,3) & & (-1,3) & & (0,3) & & (1,3) & & (2,3) & & (3,3) & & & \\
 & & \searrow & \nearrow & \searrow & \nearrow & \searrow & \nearrow & \searrow & \nearrow & \searrow & \nearrow & & & \\
\cdots & & (-1,2) & & (0,2) & & (1,2) & & (2,2) & & (3,2) & & & \cdots & \\
 & \nearrow & \searrow & \nearrow & \searrow & \nearrow & \searrow & \nearrow & \searrow & \nearrow & \searrow & & & & \\
 & (-1,1) & & (0,1) & & (1,1) & & (2,1) & & (3,1) & & (4,1) & & &
\end{array}$$

If the underlying graph Δ of Q is a tree, then $\mathbb{Z}Q$ depends only on Δ. Thus $\mathbb{Z}Q$ is written as $\mathbb{Z}\Delta$.

The AR quiver of $\mathrm{D}^{\mathrm{b}}(\mathrm{mod}\, kQ)$ has a simple description (Happel [1988]).

Proposition 2.21 (Happel [ibid.]). (a) *Let Λ be a finite dimensional hereditary algebra. Then there is a bijection* $\mathrm{ind}(\mathrm{mod}\,\Lambda) \times \mathbb{Z} \to \mathrm{ind}\,\mathrm{D}^{\mathrm{b}}(\mathrm{mod}\,\Lambda)$ *given by* $(X, i) \mapsto X[i]$.

(b) *For each Dynkin quiver Q, the AR quiver of* $\mathrm{D}^{\mathrm{b}}(\mathrm{mod}\, kQ)$ *is* $\mathbb{Z}Q^{\mathrm{op}}$. *Moreover, the category* $\mathrm{D}^{\mathrm{b}}(\mathrm{mod}\, kQ)$ *is presented by the quiver* $\mathbb{Z}Q^{\mathrm{op}}$ *with* mesh relations.

Note that $\mathbb{Z}Q$ has an automorphism τ given by $\tau(\ell, i) = (\ell-1, i)$ for $(\ell, i) \in \mathbb{Z} \times Q_0$, which corresponds to the AR translation.

Now we discuss CM-finiteness. For an additive category $\mathcal{C}$ and an object $M \in \mathcal{C}$, we denote by $\mathrm{add}\, M$ the full subcategory of $\mathcal{C}$ consisting of direct summands of finite direct sum of copies of M. We call M an *additive generator* of $\mathcal{C}$ if $\mathcal{C} = \mathrm{add}\, M$.

Definition 2.22. An Iwanaga-Gorenstein ring Λ is called *CM-finite* if $\mathrm{CM}\,\Lambda$ has an additive generator M. In this case, we call $\mathrm{End}_\Lambda(M)$ the *Auslander algebra*. When $\mathrm{CM}\,\Lambda$ is Krull-Schmidt, Λ is CM-finite if and only if $\mathrm{ind}(\mathrm{CM}\,\Lambda)$ is a finite set. It is also said to be *of finite CM type* or *representation-finite*.

Let us recall the classification of CM-finite Gorenstein rings given in the 1980s. Let k be an algebraically closed field of characteristic zero. A hypersurface $R = k[[x, y, z_2 \dots, z_d]]/(f)$ is called a *simple singularity* if

$$f = \begin{cases} x^{n+1} + y^2 + z_2^2 + \cdots + z_d^2 & A_n \\ x^{n-1} + xy^2 + z_2^2 + \cdots + z_d^2 & D_n \\ x^4 + y^3 + z_2^2 + \cdots + z_d^2 & E_6 \\ x^3 y + y^3 + z_2^2 + \cdots + z_d^2 & E_7 \\ x^5 + y^3 + z_2^2 + \cdots + z_d^2 & E_8. \end{cases} \tag{2-3}$$

We are able to state the following result. We refer to Leuschke and Wiegand [2012] for results in positive characteristic.

Theorem 2.23 (Buchweitz, Greuel, and Schreyer [1987] and Knörrer [1987]). *Let R be a complete local Gorenstein ring containing the residue field k, which is an algebraically closed field of characteristic zero. Then R is CM-finite if and only if it is a simple singularity.*

We will see that tilting theory explains why Dynkin quivers appear in both Theorems 2.20 and 2.23 (see Example 4.5 and Corollary 5.2 below).

Now we describe the AR quivers of simple singularities. Recall that each quiver Q gives a new quiver $\mathbb{Z}Q$. For an automorphism ϕ of $\mathbb{Z}Q$, an orbit quiver $\mathbb{Z}Q/\phi$ is naturally defined. For example, $\mathbb{Z}Q/\tau$ is the *double* $\overline{Q}$ of Q obtained by adding an inverse arrow $a^*: j \to i$ for each arrow $a: i \to j$.

Proposition 2.24 (Yoshino [1990] and Dieterich and Wiedemann [1986]). *Let R be a simple singularity with* $\dim R = d$. *Then the AR quiver of* $\underline{\mathrm{CM}}R$ *is $\mathbb{Z}\Delta/\phi$, where Δ and ϕ are given as follows.*

(a) *If d is even, then Δ is the Dynkin diagram of the same type as R, and $\phi = \tau$.*

(b) *If d is odd, then Δ and ϕ are given as follows.*

R	A_{2n-1}	A_{2n}	D_{2n}	D_{2n+1}	E_6	E_7	E_8
Δ	D_{n+1}	A_{2n}	D_{2n}	A_{4n-1}	E_6	E_7	E_8
ϕ	$\tau\iota$	$\tau^{1/2}$	τ^2	$\tau\iota$	$\tau\iota$	τ^2	τ^2

Here ι is the involution of $\mathbb{Z}\Delta$ induced by the non-trivial involution of Δ, and $\tau^{1/2}$ is the automorphism of $\mathbb{Z}A_{2n}$ satisfying $(\tau^{1/2})^2 = \tau$.

In dimension 2, simple singularities (over a sufficiently large field) have an alternative description as invariant subrings. This enables us to draw the AR quiver of the category CM R systematically.

Example 2.25 (Auslander [1986] and Leuschke and Wiegand [2012]). Let $k[[u,v]]$ be a formal power series ring over a field k and G a finite subgroup of $\mathrm{SL}_2(k)$ such that $\#G$ is non-zero in k. Then CM $S^G = \operatorname{add} S$ holds, and the Auslander algebra $\operatorname{End}_{S^G}(S)$ is isomorphic to the *skew group ring* $S * G$. This is a free S-module with basis G, and the multiplication is given by $(sg)(s'g') = sg(s')gg'$ for $s, s' \in S$ and $g, g' \in G$. Thus the AR quiver of CM S^G coincides with the *Gabriel quiver* of $S * G$, and hence with the *McKay quiver* of G, which is the double of an extended Dynkin quiver. This is called *algebraic McKay correspondence*.

On the other hand, the dual graph of the exceptional curves in the minimal resolution X of the singularity Spec S^G is a Dynkin graph. This is called *geometric McKay correspondence*. There is a geometric construction of CM S^G-modules using X (Artin and Verdier [1985]), which is a prototype of non-commutative crepant resolutions (Van den Bergh [2004b,a]).

3 Tilting and cluster tilting

3.1 Tilting theory. Tilting theory is a Morita theory for triangulated categories. It has an origin in Bernstein-Gelfand-Ponomarev reflection for quiver representations, and established by works of Brenner-Butler, Happel-Ringel, Rickard, Keller and others (see e.g. Angeleri Hügel, Happel, and Krause [2007]). The class of silting objects was introduced to complete the class of tilting objects in the study of t-structures (Keller and Vossieck [1988]) and mutation (Aihara and Iyama [2012]).

Definition 3.1. Let $\mathcal{T}$ be a triangulated category. A full subcategory of $\mathcal{T}$ is *thick* if it is closed under cones, $[\pm 1]$ and direct summands. We call an object $T \in \mathcal{T}$ *tilting* (resp. *silting*) if $\mathrm{Hom}_{\mathcal{T}}(T, T[i]) = 0$ holds for all integers $i \neq 0$ (resp. $i > 0$), and the smallest thick subcategory of $\mathcal{T}$ containing T is $\mathcal{T}$.

The principal example of tilting objects appears in $\mathrm{K}^{\mathrm{b}}(\mathrm{proj}\,\Lambda)$ for a ring Λ. It has a tilting object given by the stalk complex Λ concentrated in degree zero. Conversely, any triangulated category with a tilting object is triangle equivalent to $\mathrm{K}^{\mathrm{b}}(\mathrm{proj}\,\Lambda)$ under mild assumptions (see Kimura [2016] for a detailed proof).

Theorem 3.2 (Keller [1994]). *Let $\mathcal{T}$ be an algebraic triangulated category and $T \in \mathcal{T}$ a tilting object. If $\mathcal{T}$ is idempotent complete, then there is a triangle equivalence $\mathcal{T} \simeq \mathrm{K}^{\mathrm{b}}(\mathrm{proj}\,\mathrm{End}_{\mathcal{T}}(T))$ sending T to $\mathrm{End}_{\mathcal{T}}(T)$.*

As an application, one can deduce Rickard's fundamental Theorem (Rickard [1989b]), characterizing when two rings are derived equivalent in terms of tilting objects. Another application is the following converse of Proposition 2.21(b).

Example 3.3. Let $\mathcal{T}$ be a k-linear Hom-finite Krull-Schmidt algebraic triangulated category over an algebraically closed field k. If the AR quiver of $\mathcal{T}$ is $\mathbb{Z}Q$ for a Dynkin quiver Q, then $\mathcal{T}$ has a tilting object $T = \bigoplus_{i \in Q_0}(0, i)$ for $(0, i) \in \mathbb{Z} \times Q_0 = (\mathbb{Z}Q)_0 = \mathrm{ind}\,\mathcal{T}$. Thus there is a triangle equivalence $\mathcal{T} \simeq \mathrm{D}^{\mathrm{b}}(\mathrm{mod}\,kQ^{\mathrm{op}})$.

The following is the first main problem we will discuss in this paper.

Problem 3.4. *Find a G-graded Iwanaga-Gorenstein ring Λ such that there is a triangle equivalence $\underline{\mathrm{CM}}^G\Lambda \simeq \mathrm{K}^{\mathrm{b}}(\mathrm{proj}\,\Gamma)$ for some ring Γ. Equivalently (by Theorem 3.2), find a G-graded Iwanaga-Gorenstein ring Λ such that there is a tilting object in $\underline{\mathrm{CM}}^G\Lambda$.*

3.2 Cluster tilting and higher Auslander-Reiten theory. The notion of cluster tilting appeared naturally in a context of higher Auslander-Reiten theory (Iyama [2008]). It also played a central role in categorification of cluster algebras (Fomin and Zelevinsky [2002]) by using cluster categories, a new class of triangulated categories introduced in Buan, Marsh, Reineke, Reiten, and Todorov [2006], and preprojective algebras (Geiss, Leclerc, and Schröer [2013]). Here we explain only the minimum necessary background for the aim of this paper.

Let Λ be a finite dimensional k-algebra with $\operatorname{gl.dim}\Lambda \leq d$. Then $\mathrm{D^b}(\operatorname{mod}\Lambda)$ has a Serre functor ν by Example 2.14. Using the *higher AR translation* $\nu_d := \nu \circ [-d]$ of $\mathrm{D^b}(\operatorname{mod}\Lambda)$, the *orbit category* $\mathrm{C}^{\circ}_d(\Lambda) = \mathrm{D^b}(\operatorname{mod}\Lambda)/\nu_d$ is defined. It has the same objects as $\mathrm{D^b}(\operatorname{mod}\Lambda)$, and the morphism space is given by

$$\operatorname{Hom}_{\mathrm{C}^{\circ}_d(\Lambda)}(X,Y) = \bigoplus_{i\in\mathbb{Z}} \operatorname{Hom}_{\mathrm{D^b}(\operatorname{mod}\Lambda)}(X, \nu_d^i(Y)),$$

where the composition is defined naturally. In general, $\mathrm{C}^{\circ}_d(\Lambda)$ does not have a natural structure of a triangulated category. The *d-cluster category* of Λ is a triangulated category $\mathrm{C}_d(\Lambda)$ containing $\mathrm{C}^{\circ}_d(\Lambda)$ as a full subcategory such that the composition $\mathrm{D^b}(\operatorname{mod}\Lambda) \to \mathrm{C}^{\circ}_d(\Lambda) \subset \mathrm{C}_d(\Lambda)$ is a triangle functor. It was constructed in Buan, Marsh, Reineke, Reiten, and Todorov [2006] for hereditary case where $\mathrm{C}_d(\Lambda) = \mathrm{C}^{\circ}_d(\Lambda)$ holds, and in Keller [2005, 2011], Amiot [2009], and Guo [2011] for general case by using a DG enhancement of $\mathrm{D^b}(\operatorname{mod}\Lambda)$.

We say that Λ is ν_d*-finite* if $H^0(\nu_d^{-i}(\Lambda)) = 0$ holds for $i \gg 0$. This is automatic if $\operatorname{gl.dim}\Lambda < d$. In the hereditary case $d = 1$, Λ is ν_1-finite if and only if it is representation-finite. The following is a basic property of d-cluster categories.

Theorem 3.5 (Amiot [2009] and Guo [2011])**.** *Let Λ be a finite dimensional k-algebra with* $\operatorname{gl.dim}\Lambda \leq d$. *Then Λ is ν_d-finite if and only if $\mathrm{C}_d(\Lambda)$ is Hom-finite. In this case, $\mathrm{C}_d(\Lambda)$ is a d-Calabi-Yau triangulated category.*

Thus, if Λ is ν_d-finite, then $\mathrm{C}_d(\Lambda)$ never has a tilting object. But the object Λ in $\mathrm{C}_d(\Lambda)$ still enjoys a similar property to tilting objects. Now we recall the following notion, introduced in Iyama [2007b] as a *maximal* $(d-1)$*-orthogonal* subcategory.

Definition 3.6 (Iyama [ibid.])**.** Let $\mathcal{T}$ be a triangulated or exact category and $d \geq 1$. We call a full subcategory $\mathcal{C}$ of $\mathcal{T}$ *d-cluster tilting* if $\mathcal{C}$ is a functorially finite subcategory of $\mathcal{T}$ such that

$$\begin{aligned}\mathcal{C} &= \{X \in \mathcal{T} \mid \forall i \in \{1,2,\dots,d-1\}\ \operatorname{Ext}^i_{\mathcal{T}}(\mathcal{C}, X) = 0\}\\ &= \{X \in \mathcal{T} \mid \forall i \in \{1,2,\dots,d-1\}\ \operatorname{Ext}^i_{\mathcal{T}}(X, \mathcal{C}) = 0\}.\end{aligned}$$

We call an object $T \in \mathcal{T}$ *d-cluster tilting* if $\operatorname{add} T$ is a d-cluster tilting subcategory.

If $\mathcal{T}$ has a Serre functor $\mathbb{S}$, then it is easy to show $(\mathbb{S}\circ[-d])(\mathcal{C}) = \mathcal{C}$. Thus it is natural in our setting $\mathcal{T} = \mathrm{D^b}(\operatorname{mod}\Lambda)$ to consider the full subcategory

$$\mathrm{U}_d(\Lambda) := \operatorname{add}\{\nu_d^i(\Lambda) \mid i \in \mathbb{Z}\} \subset \mathrm{D^b}(\operatorname{mod}\Lambda). \tag{3-1}$$

Equivalently, $\mathrm{U}_d(\Lambda) = \pi^{-1}(\operatorname{add} \pi\Lambda)$ for the functor $\pi : \mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Lambda) \to \mathrm{C}_d(\Lambda)$. In the hereditary case $d = 1$, $\mathrm{U}_1(\Lambda) = \mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Lambda)$ holds if Λ is representation-finite, and otherwise $\mathrm{U}_1(\Lambda)$ is the connected component of the AR quiver of $\mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Lambda)$ containing Λ. This observation is generalized as follows.

Theorem 3.7 (Amiot [2009] and Iyama [2011]). *Let Λ be a finite dimensional k-algebra with* $\operatorname{gl.dim}\Lambda \leq d$. *If Λ is ν_d-finite, then $\mathrm{C}_d(\Lambda)$ has a d-cluster tilting object Λ, and* $\mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Lambda)$ *has a d-cluster tilting subcategory* $\mathrm{U}_d(\Lambda)$.

We define a full subcategory of $\mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Lambda)$ by

$$\mathrm{D}^{d\mathbb{Z}}(\operatorname{mod}\Lambda) = \{X \in \mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Lambda) \mid \forall i \in \mathbb{Z} \setminus d\mathbb{Z},\ H^i(X) = 0\}.$$

If $\operatorname{gl.dim}\Lambda \leq d$, then any object in $\mathrm{D}^{d\mathbb{Z}}(\operatorname{mod}\Lambda)$ is isomorphic to a finite direct sum of $X[di]$ for some $X \in \operatorname{mod}\Lambda$ and $i \in \mathbb{Z}$. This generalizes Proposition 2.21(a) for hereditary algebras, and motivates the following definition.

Definition 3.8 (Herschend, Iyama, and Oppermann [2014]). Let $d \geq 1$. A finite dimensional k-algebra Λ is called *d-hereditary* if $\operatorname{gl.dim}\Lambda \leq d$ and $\mathrm{U}_d(\Lambda) \subset \mathrm{D}^{d\mathbb{Z}}(\operatorname{mod}\Lambda)$.

It is clear that 1-hereditary algebras are precisely hereditary algebras. We have the following dichotomy of d-hereditary algebras.

Theorem 3.9 (Herschend, Iyama, and Oppermann [ibid.]). *Let Λ be a ring-indecomposable finite dimensional k-algebra with* $\operatorname{gl.dim}\Lambda \leq d$. *Then Λ is d-hereditary if and only if either (i) or (ii) holds:*

(i) *There exists a d-cluster tilting object in* $\operatorname{mod}\Lambda$.

(ii) $\nu_d^{-i}(\Lambda) \in \operatorname{mod}\Lambda$ *holds for any* $i \geq 0$.

When $d = 1$, the above (i) holds if and only if Λ is representation-finite, and the above (ii) holds if and only if Λ is d-representation-infinite.

Definition 3.10. Let Λ be a d-hereditary algebra. We call Λ *d-representation-finite* if the above (i) holds, and *d-representation-infinite* if the above (ii) holds.

Example 3.11. (a) Let $\Lambda = kQ$ for a connected acyclic quiver Q. Then Λ is 1-representation-finite if Q is Dynkin, and 1-representation-infinite otherwise.

(b) Let X be a smooth projective variety with $\dim X = d$, and $T \in \operatorname{coh} X$ a tilting object in $\mathrm{D}^{\mathrm{b}}(\operatorname{coh} X)$. Then $\Lambda = \operatorname{End}_X(T)$ always satisfies $\operatorname{gl.dim}\Lambda \geq d$. If the equality holds, then Λ is d-representation-infinite (Buchweitz and Hille [2014]).

(c) There is a class of finite dimensional k-algebras called *Fano algebras* (Minamoto [2012] and Minamoto and Mori [2011]) in non-commutative algebraic geometry. So-called *extremely Fano algebras* Λ with $\operatorname{gl.dim} \Lambda = d$ are d-representation-infinite.

It is known that d-cluster tilting subcategories of a triangulated (resp. exact) category $\mathcal{T}$ enjoy various properties which should be regarded as higher analogs of those of $\mathcal{T}$. For example, they have *almost split* $(d+2)$*-angles* by Iyama and Yoshino [2008] (resp. d*-almost split sequences* by Iyama [2007b]), and structures of $(d+2)$*-angulated categories* by Geiss, Keller, and Oppermann [2013] (resp. d*-abelian categories* by Jasso [2016]). These motivate the following definition.

Definition 3.12 (cf. Definition 2.22)**.** An Iwanaga-Gorenstein ring Λ is called d*-CM-finite* if there exists a d-cluster tilting object M in $\operatorname{CM} \Lambda$. In this case, we call $\operatorname{End}_\Lambda(M)$ the d*-Auslander algebra* and $\underline{\operatorname{End}}_\Lambda(M)$ the *stable* d*-Auslander algebra*.

1-CM-finiteness coincides with classical CM-finiteness since 1-cluster tilting objects are precisely additive generators. d*-Auslander correspondence* gives a characterization of a certain nice class of algebras with finite global dimension as d-Auslander algebras (Iyama [2007a]). As a special case, it gives a connection with non-commutative crepant resolutions (NCCRs) of Van den Bergh [2004a]. Recall that a reflexive module M over a Gorenstein ring R gives an *NCCR* $\operatorname{End}_R(M)$ of R if $\operatorname{End}_R(M)$ is a non-singular R-order (see Example 2.3(c)).

Theorem 3.13 (Iyama [2007a])**.** *Let R be a Gorenstein ring with* $\dim R = d+1$. *Assume $M \in$* CM R *has R as a direct summand. Then M is a d-cluster tilting object in* CM R *if and only if M gives an NCCR of R and R satisfies Serre's (R_d) condition.*

The following generalizes Example 2.25.

Example 3.14 (Iyama [2007b] and Van den Bergh [2004a])**.** Let $S = k[[x_0, \dots, x_d]]$ be a formal power series ring and G a finite subgroup of $\mathrm{SL}_{d+1}(k)$ such that $\#G$ is non-zero in k. Then the S^G-module S gives an NCCR $\operatorname{End}_{S^G}(S) = S * G$ of S^G. If S^G has at worst an isolated singularity, then S is a d-cluster tilting object in $\operatorname{CM} S^G$, and hence S^G is d-CM-finite with the d-Auslander algebra $S * G$. As in Example 2.25, the quiver of $\operatorname{add} S$ coincides with the Gabriel quiver of $S * G$ and with the McKay quiver of G.

The following is the second main problem we will discuss in this paper.

Problem 3.15. *Find a d-CM-finite Iwanaga-Gorenstein ring. More strongly (by Theorem 3.7), find an Iwanaga-Gorenstein ring Λ such that there is a triangle equivalence* $\underline{\operatorname{CM}}\Lambda \simeq \mathrm{C}_d(\Gamma)$ *for some algebra* Γ.

We refer to Erdmann and Holm [2008] and Bergh [2014] for some necessary conditions for d-CM-finiteness. Besides results in this paper, a number of examples of NCCRs have been found, see e.g. Leuschke [2012], Wemyss [2016], and Špenko and Van den Bergh [2017] and references therein.

It is natural to ask how the notion of d-CM-finiteness is related to CM-tameness (e.g. Burban and Y. Drozd [2008]) and also the representation type of homogeneous coordinate rings of projective varieties (e.g. Faenzi and Malaspina [2017]).

4 Results in dimension 0 and 1

4.1 Dimension zero. In this subsection, we consider finite dimensional Iwanaga-Gorenstein algebras. We start with a classical result due to Happel [1988]. Let Λ be a finite dimensional k-algebra. The *trivial extension algebra* of Λ is $T(\Lambda) = \Lambda \oplus D\Lambda$, where the multiplication is given by $(\lambda, f)(\lambda', f') = (\lambda\lambda', \lambda f' + f\lambda')$ for $(\lambda, f), (\lambda', f') \in T(\Lambda)$. This is clearly a self-injective k-algebra, and has a $\mathbb{Z}$-grading given by $T(\Lambda)_0 = \Lambda$, $T(\Lambda)_1 = D\Lambda$ and $T(\Lambda)_i = 0$ for $i \neq 0, 1$.

Theorem 4.1 (Happel [ibid.]). *Let Λ be a finite dimensional k-algebra with* $\mathrm{gl.dim}\,\Lambda < \infty$. *Then $\underline{\mathrm{mod}}^{\mathbb{Z}}\,T(\Lambda)$ has a tilting object Λ such that $\underline{\mathrm{End}}^{\mathbb{Z}}_{T(\Lambda)}(\Lambda) \simeq \Lambda$, and there is a triangle equivalence*

$$\underline{\mathrm{mod}}^{\mathbb{Z}}\,T(\Lambda) \simeq \mathrm{D^b}(\mathrm{mod}\,\Lambda). \tag{4-1}$$

As an application, it follows from Gabriel's Theorem 2.20 and covering theory that $T(kQ)$ is representation-finite for any Dynkin quiver Q. More generally, a large family of representation-finite self-injective algebras was constructed from Theorem 4.1. See a survey article (Skowroński [2006]).

Recently, Theorem 4.1 was generalized to a large class of $\mathbb{Z}$-graded self-injective algebras Λ. For $X \in \mathrm{mod}^{\mathbb{Z}}\,\Lambda$, let $X_{\geq 0} = \bigoplus_{i \geq 0} X_i$.

Theorem 4.2 (Yamaura [2013]). *Let $\Lambda = \bigoplus_{i\geq 0} \Lambda_i$ be a $\mathbb{Z}$-graded finite dimensional self-injective k-algebra such that* $\mathrm{gl.dim}\,\Lambda_0 < \infty$. *Then $\underline{\mathrm{mod}}^{\mathbb{Z}}\,\Lambda$ has a tilting object $T = \bigoplus_{i>0} \Lambda(i)_{\geq 0}$, and there is a triangle equivalence $\underline{\mathrm{mod}}^{\mathbb{Z}}\,\Lambda \simeq \mathrm{K^b}(\mathrm{proj}\,\underline{\mathrm{End}}^{\mathbb{Z}}_{\Lambda}(T))$.*

If $\mathrm{soc}\,\Lambda \subset \Lambda_a$ for some $a \in \mathbb{Z}$, then $\underline{\mathrm{End}}^{\mathbb{Z}}_{\Lambda}(T)$ has a simple description

$$\underline{\mathrm{End}}^{\mathbb{Z}}_{\Lambda}(T) \simeq \begin{bmatrix} \Lambda_0 & 0 & \cdots & 0 & 0 \\ \Lambda_1 & \Lambda_0 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \Lambda_{a-2} & \Lambda_{a-3} & \cdots & \Lambda_0 & 0 \\ \Lambda_{a-1} & \Lambda_{a-2} & \cdots & \Lambda_1 & \Lambda_0 \end{bmatrix}.$$

For example, if $\Lambda = k[x]/(x^{a+1})$ with $\deg x = 1$, then $\underline{\mathrm{End}}^{\mathbb{Z}}_{\Lambda}(T)$ is the path algebra $k\mathbb{A}_a$ of the quiver of type A_a.

We end this subsection with posing the following open problem.

Problem 4.3. *Let $\Lambda = \bigoplus_{i\geq 0} \Lambda_i$ be a $\mathbb{Z}$-graded finite dimensional Iwanaga-Gorenstein algebra. When does $\underline{\mathrm{CM}}^{\mathbb{Z}}\Lambda$ have a tilting object?*

Recently, it was shown in Lu and Zhu [2017] and Kimura, Minamoto, and Yamaura [n.d.] independently that if $\Lambda = \bigoplus_{i\geq 0} \Lambda_i$ is a $\mathbb{Z}$-graded finite dimensional 1-Iwanaga-Gorenstein algebra satisfying $\mathrm{gl.dim}\,\Lambda_0 < \infty$, then the stable category $\underline{\mathrm{CM}}^{\mathbb{Z}}\Lambda$ has a silting object. We will see some other results in Section 5.4. We refer to Darpö and Iyama [2017] for some results on Problem 3.15.

4.2 Dimension one.

In this subsection, we consider a $\mathbb{Z}$-graded Gorenstein ring $R = \bigoplus_{i\geq 0} R_i$ with $\dim R = 1$ such that R_0 is a field. Let S be the multiplicative set of all homogeneous non-zerodivisors of R, and $K = RS^{-1}$ the $\mathbb{Z}$-graded total quotient ring. Then there exists a positive integer p such that $K(p) \simeq K$ as $\mathbb{Z}$-graded R-modules. In this setting, we have the following result (see Definitions 2.15 and 2.11 for $\mathrm{CM}_0^{\mathbb{Z}} R$ and the a-invariant).

Theorem 4.4 (Buchweitz, Iyama, and Yamaura [2018])**.** *Let $R = \bigoplus_{i\geq 0} R_i$ be a $\mathbb{Z}$-graded Gorenstein ring with $\dim R = 1$ such that R_0 is a field, and a the a-invariant of R.*

(a) *Assume $a \geq 0$. Then $\underline{\mathrm{CM}}_0^{\mathbb{Z}} R$ has a tilting object $T = \bigoplus_{i=1}^{a+p} R(i)_{\geq 0}$, and there is a triangle equivalence $\underline{\mathrm{CM}}_0^{\mathbb{Z}} R \simeq \mathrm{K}^{\mathrm{b}}(\mathrm{proj}\,\underline{\mathrm{End}}_R^{\mathbb{Z}}(T))$.*

(b) *Assume $a < 0$. Then $\underline{\mathrm{CM}}_0^{\mathbb{Z}} R$ has a silting object $\bigoplus_{i=1}^{a+p} R(i)_{\geq 0}$. Moreover, it has a tilting object if and only if R is regular.*

An important tool in the proof is Theorem 2.12. The endomorphism algebra of T above has the following description.

$$\underline{\mathrm{End}}_R^{\mathbb{Z}}(T) = \begin{bmatrix} R_0 & 0 & \cdots & 0 & 0 & 0 & 0 & \cdots & 0 & 0 \\ R_1 & R_0 & \cdots & 0 & 0 & 0 & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \vdots & \cdots & \vdots & \vdots \\ R_{a-2} & R_{a-3} & \cdots & R_0 & 0 & 0 & 0 & \cdots & 0 & 0 \\ R_{a-1} & R_{a-2} & \cdots & R_1 & R_0 & 0 & 0 & \cdots & 0 & 0 \\ K_a & K_{a-1} & \cdots & K_2 & K_1 & K_0 & K_{-1} & \cdots & K_{2-p} & K_{1-p} \\ K_{a+1} & K_a & \cdots & K_3 & K_2 & K_1 & K_0 & \cdots & K_{3-p} & K_{2-p} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ K_{a+p-2} & K_{a+p-3} & \cdots & K_p & K_{p-1} & K_{p-2} & K_{p-3} & \cdots & K_0 & K_{-1} \\ K_{a+p-1} & K_{a+p-2} & \cdots & K_{p+1} & K_p & K_{p-1} & K_{p-2} & \cdots & K_1 & K_0 \end{bmatrix}.$$

As an application, we obtain the following graded version of Proposition 2.24(b).

Example 4.5. Let $R = k[x, y]/(f)$ be a simple singularity (2-3) with $\dim R = 1$ and the grading given by the list below. Then there is a triangle equivalence $\underline{\mathrm{CM}}^{\mathbb{Z}} R \simeq \mathrm{D}^{\mathrm{b}}(\mathrm{mod}\, kQ)$, where Q is the Dynkin quiver in the list below. In particular, the AR quiver of $\underline{\mathrm{CM}}^{\mathbb{Z}} R$ is $\mathbb{Z}Q^{\mathrm{op}}$ (Araya [1999]).

R	A_{2n-1}	A_{2n}	D_{2n}	D_{2n+1}	E_6	E_7	E_8
$(\deg x, \deg y)$	$(1, n)$	$(2, 2n+1)$	$(1, n-1)$	$(2, 2n-1)$	$(3, 4)$	$(2, 3)$	$(3, 5)$
Q	D_{n+1}	A_{2n}	D_{2n}	A_{4n-1}	E_6	E_7	E_8

This gives a conceptual proof of the classical result that simple singularities in dimension 1 are CM-finite (Jacobinski [1967], J. A. Drozd and Roĭter [1967], and Greuel and Knörrer [1985]).

In the following special case, one can construct a different tilting object, whose endomorphism algebra is 2-representation-finite (Definition 3.10). This is closely related to the 2-cluster tilting object constructed in Burban, Iyama, Keller, and Reiten [2008].

Theorem 4.6 (Herschend and Iyama [n.d.]). *Let $R = k[x, y]/(f)$ be a hypersurface singularity with $f = f_1 f_2 \cdots f_n$ for linear forms f_i and* $\deg x = \deg y = 1$. *Assume that R is reduced.*

(a) *$\underline{\mathrm{CM}}^{\mathbb{Z}} R$ has a tilting object*

$$U = \bigoplus_{i=1}^{n} (k[x, y]/(f_1 f_2 \cdots f_i) \oplus k[x, y]/(f_1 f_2 \cdots f_i)(1))$$

(b) *$\underline{\mathrm{End}}_R^{\mathbb{Z}}(U)$ is a 2-representation-finite algebra. It is the Jacobian algebra of a certain quiver with potential.*

We refer to Demonet and Luo [2016], Jensen, King, and Su [2016], and Gelinas [2017] for other results in dimension one.

5 Preprojective algebras

5.1 Classical preprojective algebras. Preprojective algebras are widely studied objects with various applications, e.g. cluster algebras (Geiss, Leclerc, and Schröer [2013]), quantum groups (Kashiwara and Y. Saito [1997] and Lusztig [1991]), quiver varieties (Nakajima [1994]). Here we discuss a connection to CM representations.

Let Q be an acyclic quiver, and $\overline{Q}$ the double of Q obtained by adding an inverse arrow $a^*: j \to i$ for each arrow $a: i \to j$ in Q. The *preprojective algebra* of Q is the factor algebra of the path algebra $k\overline{Q}$ defined by

$$\Pi = k\overline{Q}/(\sum_{a \in Q_1} (aa^* - a^*a)). \tag{5-1}$$

We regard Π as a $\mathbb{Z}$-graded algebra by $\deg a = 0$ and $\deg a^* = 1$ for any $a \in Q_1$. Clearly $\Pi_0 = kQ$ holds. Moreover $\Pi_1 = \mathrm{Ext}^1_{kQ}(D(kQ), kQ)$ as a kQ-bimodule, and Π is isomorphic to the tensor algebra $T_{kQ}\,\mathrm{Ext}^1_{kQ}(D(kQ), kQ)$. Thus the kQ-module Π_i is isomorphic to the *preprojective kQ-module* $H^0(\tau^{-i}(kQ))$, where $\tau = \nu \circ [-1]$ is the AR translation. This is the reason why Π is called the preprojective algebra. Moreover, for the category $\mathrm{U}_1(kQ)$ defined in (3-1), there is an equivalence

$$\mathrm{U}_1(kQ) = \mathrm{add}\{\tau^{-i}(kQ) \mid i \in \mathbb{Z}\} \simeq \mathrm{proj}^{\mathbb{Z}}\,\Pi \tag{5-2}$$

given by $X \mapsto \bigoplus_{i \in \mathbb{Z}} \mathrm{Hom}_{\mathrm{U}_1(kQ)}(kQ, \tau^{-i}(X))$, which gives the following trichotomy.

Q	Dynkin	extended Dynkin	else
kQ	representation-finite	representation-tame	representation-wild
$\dim_k \Pi_i$	$\dim_k \Pi < \infty$	linear growth	exponential growth

It was known in 1980s that, Π in the extended Dynkin case has a close connection to simple singularities.

Theorem 5.1 (Auslander [1978], Geigle and Lenzing [1987, 1991], and Reiten and Van den Bergh [1989]). *Let Π be a preprojective algebra of an extended Dynkin quiver Q, e the vertex $\circ$ in* (2-2)*, and $R = e\Pi e$.*

(a) *R is a simple singularity $k[x, y, z]/(f)$ in dimension 2 with induced $\mathbb{Z}$-grading below, where p in type A_n is the number of clockwise arrows in Q. (Note that f coincides with* (2-3) *after a change of variables if k is sufficiently large.)*

Q, R	f	$(\deg x, \deg y, \deg z)$
A_n	$x^{n+1} - yz$	$(1, p, n+1-p)$
D_n	$x(y^2 + x^{\ell-1}y) + z^2$ if $n = 2\ell$ $x(y^2 + x^{\ell-1}z) + z^2$ if $n = 2\ell+1$	$(2, n-2, n-1)$
E_6	$x^2z + y^3 + z^2$	$(3, 4, 6)$
E_7	$x^3y + y^3 + z^2$	$(4, 6, 9)$
E_8	$x^5 + y^3 + z^2$	$(6, 10, 15)$

(b) *Πe is an additive generator of* CM R *and satisfies* $\mathrm{End}_R(\Pi e) = \Pi$. *Therefore R is CM-finite with an Auslander algebra Π.*

(c) Π *is Morita equivalent to the skew group ring* $k[u,v]*G$ *for a finite subgroup* G *of* $\mathrm{SL}_2(k)$ *if* k *is sufficiently large (cf. Example 2.25).*

By (b) and (5-2) above, there are equivalences $\mathrm{CM}^{\mathbb{Z}} R \simeq \mathrm{proj}^{\mathbb{Z}} \Pi \simeq \mathrm{U}_1(kQ) \subset \mathrm{D}^{\mathrm{b}}(\mathrm{mod}\, kQ)$. Thus the AR quivers of $\mathrm{CM}^{\mathbb{Z}} R$ and $\underline{\mathrm{CM}}^{\mathbb{Z}} R$ are given by $\mathbb{Z}Q^{\mathrm{op}}$ and $\mathbb{Z}(Q^{\mathrm{op}}\backslash\{e\})$ respectively. Now the following result follows from Example 3.3.

Corollary 5.2. *Under the setting in Theorem 5.1, there is a triangle equivalence* $\underline{\mathrm{CM}}^{\mathbb{Z}} R \simeq \mathrm{D}^{\mathrm{b}}(\mathrm{mod}\, kQ/(e))$.

Two other proofs were given in Kajiura, K. Saito, and A. Takahashi [2007], one uses explicit calculations of $\mathbb{Z}$-graded matrix factorizations, and the other uses Theorem 2.12. In Theorem 5.8 below, we deduce Corollary 5.2 from a general result on higher preprojective algebras. We refer to Kajiura, K. Saito, and A. Takahashi [2009] and Lenzing and de la Peña [2011] for results for some other hypersurfaces in dimension 2.

5.2 Higher preprojective algebras. There is a natural analog of preprojective algebras for finite dimensional algebras with finite global dimension.

Definition 5.3 (Iyama and Oppermann [2013])**.** Let Λ be a finite dimensional k-algebra with $\mathrm{gl.dim}\,\Lambda \le d$. We regard the highest extension $\mathrm{Ext}^d_\Lambda(D\Lambda,\Lambda)$ as a Λ-bimodule naturally, and define the $(d+1)$-*preprojective algebra* as the tensor algebra

$$\Pi_{d+1}(\Lambda) = T_\Lambda \mathrm{Ext}^d_\Lambda(D\Lambda,\Lambda).$$

This is the 0-th cohomology of the *Calabi-Yau completion* of Λ (Keller [2011]). For example, for an acyclic quiver Q, $\Pi_2(kQ)$ is the preprojective algebra (5-1).

The algebra $\Pi = \Pi_{d+1}(\Lambda)$ has an alternative description in terms of the higher AR translation $\nu_d = \nu \circ [-d]$ of $\mathrm{D}^{\mathrm{b}}(\mathrm{mod}\,\Lambda)$. The $\mathbb{Z}$-grading on Π is given by

$$\Pi_i = \mathrm{Ext}^d_\Lambda(D\Lambda,\Lambda)^{\otimes_\Lambda i} = \mathrm{Hom}_{\mathrm{D}^{\mathrm{b}}(\mathrm{mod}\,\Lambda)}(\Lambda, \nu_d^{-i}(\Lambda))$$

for $i \ge 0$. Thus there is an isomorphism $\Pi \simeq \mathrm{End}_{\mathrm{C}_d(\Lambda)}(\Lambda)$ and an equivalence

$$\mathrm{U}_d(\Lambda) \simeq \mathrm{proj}^{\mathbb{Z}} \Pi \tag{5-3}$$

given by $X \mapsto \bigoplus_{i\in\mathbb{Z}} \mathrm{Hom}_{\mathrm{U}_d(\Lambda)}(\Lambda, \nu_d^{-i}(X))$. In particular, Π is finite dimensional if and only if Λ is ν_d-finite.

We see below that $\Pi_{d+1}(\Lambda)$ enjoys nice homological properties if Λ is d-hereditary.

Definition 5.4 (cf. Ginzburg [2006])**.** Let $\Gamma = \bigoplus_{i\ge 0}\Gamma_i$ be a $\mathbb{Z}$-graded k-algebra. We denote by $\Gamma^{\mathrm{e}} = \Gamma^{\mathrm{op}} \otimes_k \Gamma$ the enveloping algebra of Γ. We say that Γ is a d-*Calabi-Yau algebra of* a-*invariant* a (or *Gorenstein parameter* $-a$) if Γ belongs to $\mathrm{K}^{\mathrm{b}}(\mathrm{proj}^{\mathbb{Z}}\Gamma^{\mathrm{e}})$ and $\mathbf{R}\mathrm{Hom}_{\Gamma^{\mathrm{e}}}(\Gamma,\Gamma^{\mathrm{e}})(a)[d] \simeq \Gamma$ holds in $\mathrm{D}(\mathrm{Mod}^{\mathbb{Z}}\Gamma^{\mathrm{e}})$.

For example, the $\mathbb{Z}$-graded polynomial algebra $k[x_1, \dots, x_d]$ with $\deg x_i = a_i$ is a d-Calabi-Yau algebra of a-invariant $-\sum_{i=1}^{n} a_i$.

Now we give a homological characterization of the $(d+1)$-preprojective algebras of d-representation-infinite algebras (Definition 3.10) as the explicit correspondence.

Theorem 5.5 (Keller [2011], Minamoto and Mori [2011], and Amiot, Iyama, and Reiten [2015]). *There exists a bijection between the set of isomorphism classes of d-representation-infinite algebras Λ and the set of isomorphism classes of $(d+1)$-Calabi-Yau algebras Γ of a-invariant -1. It is given by $\Lambda \mapsto \Pi_{d+1}(\Lambda)$ and $\Gamma \mapsto \Gamma_0$.*

Note that Γ above is usually non-noetherian. If Γ is right graded coherent, then for the category $\operatorname{qgr}\Gamma$ defined in (2-1), there is a triangle equivalence (Minamoto [2012])

$$\mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Lambda) \simeq \mathrm{D}^{\mathrm{b}}(\operatorname{qgr}\Gamma). \tag{5-4}$$

Applying Theorem 5.5 for $d = 1, 2$, we obtain the following observations (see Van den Bergh [2015] for a structure theorem of (ungraded) Calabi-Yau algebras).

Example 5.6. Let k be an algebraically closed field.

(a) (cf. Bocklandt [2008]) 2-Calabi-Yau algebras of a-invariant -1 are precisely the preprojective algebras of disjoint unions of non-Dynkin quivers.

(b) (cf. Bocklandt [2008] and Herschend and Iyama [2011]) 3-Calabi-Yau algebras of a-invariant -1 are precisely the Jacobian algebras of quivers with 'good' potential with cuts.

The setting of our main result is the following.

Assumption 5.7. Let Γ be a $(d+1)$-Calabi-Yau algebras of a-invariant -1. Equivalently by Theorem 5.5, Γ is a $(d+1)$-preprojective algebra of some d-representation-infinite algebra. We assume that the following conditions hold for $\Lambda = \Gamma_0$.

(i) Γ is a noetherian ring, $e \in \Lambda$ is an idempotent and $\dim_k(\Gamma/(e)) < \infty$.

(ii) $e\Lambda(1-e) = 0$.

For example, let Q be an extended Dynkin quiver. If the vertex $\circ$ in (2-2) is a sink, then $\Gamma = \Pi_2(kQ)$ and $e = \circ$ satisfy Assumption 5.7 by Theorem 5.1.

Under Assumption 5.7(i), let $R = e\Gamma e$. Then R is a $(d+1)$-Iwanaga-Gorenstein ring, and the (Γ, R)-bimodule Γe plays an important role. It is a CM R-module, and gives a d-cluster tilting object in $\mathrm{CM}\, R$. Moreover the natural morphism $\Gamma \to \operatorname{End}_R(\Gamma e)$ is an isomorphism. Thus R is d-CM-finite and has a d-Auslander algebra Γ. The proof of these statements is parallel to Example 3.14.

Regarding Γe as a $\mathbb{Z}$-graded R-module, we consider the composition

$$F\colon \mathrm{D^b}(\operatorname{mod}\Lambda/(e)) \to \mathrm{D^b}(\operatorname{mod}\Lambda) \xrightarrow{-\overset{\mathbf{L}}{\otimes}_\Lambda \Gamma e} \mathrm{D^b}(\operatorname{mod}^{\mathbb{Z}} R) \to \underline{\mathrm{CM}}^{\mathbb{Z}} R,$$

where the first functor is induced from the surjective morphism $\Lambda \to \Lambda/(e)$, and the last functor is given by Theorem 2.10. Under Assumption 5.7(ii), F is shown to be a triangle equivalence. A crucial step is to show that F restricts to an equivalence $\mathrm{U}_d(\Lambda/(e)) \to \operatorname{add}\{\Gamma e(i) \mid i \in \mathbb{Z}\}$, which are d-cluster tilting subcategories of $\mathrm{D^b}(\operatorname{mod}\Lambda/(e))$ and $\underline{\mathrm{CM}}^{\mathbb{Z}} R$ respectively (Theorem 3.7). Similarly, we obtain a triangle equivalence $\mathrm{C}_d(\Lambda/(e)) \simeq \underline{\mathrm{CM}} R$ by using universality of d-cluster categories (Keller [2005]). As a summary, we obtain the following results.

Theorem 5.8 (Amiot, Iyama, and Reiten [2015]). *Under Assumption 5.7(i), let $R = e\Gamma e$ and $\Lambda = \Gamma_0$.*

(a) *R is a $(d+1)$-Iwanaga-Gorenstein algebra, and Γe is a CM R-module.*

(b) *Γe is a d-cluster tilting object in $\mathrm{CM}\,R$ and satisfies $\operatorname{End}_R(\Gamma e) = \Gamma$. Thus R is d-CM-finite and has a d-Auslander algebra Γ*

(c) *If Assumption 5.7(ii) is satisfied, then there exist triangle equivalences*

$$\mathrm{D^b}(\operatorname{mod}\Lambda/(e)) \simeq \underline{\mathrm{CM}}^{\mathbb{Z}} R \quad \text{and} \quad \mathrm{C}_d(\Lambda/(e)) \simeq \underline{\mathrm{CM}} R.$$

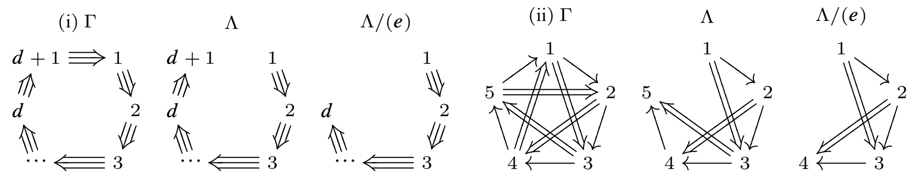
Similar triangle equivalences were given in de Völcsey and Van den Bergh [2016] and Kalck and Yang [2016] using different methods. There is a connection between (c) and (5-4) above via Theorem 2.12, see Amiot [2013].

In the case $d = 1$, the above (c) recovers Corollary 5.2 and a triangle equivalence $\underline{\mathrm{CM}} R \simeq \mathrm{C}_1(kQ/(e))$, which implies algebraic McKay correspondence in Example 2.25. Motivated by Example 3.14 and Theorem 5.1(c), we consider the following.

Example 5.9 (Amiot, Iyama, and Reiten [2015],Ueda [2008]). Let $S = k[x_0, \dots, x_d]$ be a polynomial algebra, and G a finite subgroup of $\mathrm{SL}_{d+1}(k)$. Then the skew group ring $\Gamma = S * G$ is a (ungraded) $(d+1)$-Calabi-Yau algebra. Assume that G is generated by the diagonal matrix $\operatorname{diag}(\zeta^{a_0}, \dots, \zeta^{a_d})$, where ζ is a primitive n-th root of unity and $0 \le a_j \le n-1$ for each j. Then Γ is presented by the McKay quiver of G, which has vertices $\mathbb{Z}/n\mathbb{Z}$, and arrows $x_j\colon i \to i + a_j$ for each i, j. Define a $\mathbb{Z}$-grading on Γ by $\deg(x_j\colon i \to i + a_j) = 0$ if $i < i + a_j$ as integers in $\{1, \dots, n\}$, and 1 otherwise. Then Γ is a $(d+1)$-Calabi-Yau algebra of a-invariant $-\sum_{0 \le j \le d} a_j/n$. Assume that this is -1, and let $e = e_n$. Then Assumption 5.7 is satisfied, and $e\Gamma e = S^G$ holds. Thus Theorem 5.8 gives triangle equivalences

$$\mathrm{D^b}(\operatorname{mod}\Lambda/(e)) \simeq \underline{\mathrm{CM}}^{\mathbb{Z}} S^G \quad \text{and} \quad \mathrm{C}_d(\Lambda/(e)) \simeq \underline{\mathrm{CM}} S^G.$$

Below we draw quivers for two cases (i) $n = d+1$ and $a_0 = \cdots = a_d = 1$, and (ii) $d = 2, n = 5$ and $(a_0, a_1, a_2) = (1, 2, 2)$.



In (i), $\Rrightarrow$ shows $d+1$ arrows, S^G is the Veronese subring $S^{(d+1)}$ and Λ is the Beilinson algebra. For $d = 2$, we recover the triangle equivalence $\mathrm{C}_2(kQ) \simeq \underline{\mathrm{CM}}S^G$ for $Q = [\,1 \Rrightarrow 2\,]$ given in Keller and Reiten [2008] and Keller, Murfet, and Van den Bergh [2011].

Note that similar triangle equivalences are given in Iyama and R. Takahashi [2013], Ueda [2012], and Mori and Ueyama [2016] for the skew group rings $S * G$ whose a-invariants are not equal to -1.

Example 5.10 (Dimer models)**.** Let G be a bipartite graph on a torus, and G_0 (resp. G_1, G_2) the set of vertices (resp. edges, faces) of G. We associate a quiver with potential (Q, W): The underlying graph of Q is the dual of the graph G, and faces of Q dual to white (resp. black) vertices are oriented clockwise (resp. anti-clockwise). Hence any vertex $v \in G_0$ corresponds to a cycle c_v of Q. Let $W = \sum_{v:\text{white}} c_v - \sum_{v:\text{black}} c_v$, and Γ the Jacobian algebra of (Q, W).

Under the assumption that G is *consistent*, Γ is a (ungraded) 3-Calabi-Yau algebra, and for any vertex e, $R = e\Gamma e$ is a Gorenstein toric singularity in dimension 3 (see Broomhead [2012] and Bocklandt [2012] and references therein). Using a perfect matching C on G, define a $\mathbb{Z}$-grading on Γ by $\deg a = 1$ for all $a \in C$ and $\deg a = 0$ otherwise. If both $\Gamma/(e)$ and $\Lambda = \Gamma_0$ are finite dimensional and $e\Lambda(1-e) = 0$ holds, then Theorem 5.8 gives triangle equivalences

$$\mathrm{D^b}(\mathrm{mod}\,\Lambda/(e)) \simeq \underline{\mathrm{CM}}^{\mathbb{Z}} R \quad\text{and}\quad \mathrm{C}_2(\Lambda/(e)) \simeq \underline{\mathrm{CM}} R.$$

5.3 d-representation-finite algebras.

In this subsection, we study the $(d+1)$-preprojective algebras of d-representation-finite algebras. We start with the following basic properties.

Proposition 5.11 (Geiss, Leclerc, and Schröer [2006], Iyama [2011], and Iyama and Oppermann [2013])**.** *Let Λ be a d-representation-finite k-algebra and $\Pi = \Pi_{d+1}(\Lambda)$.*

(a) *Π is a $\mathbb{Z}$-graded finite dimensional self-injective k-algebra.*

(b) *$\underline{\mathrm{mod}}^{\mathbb{Z}}\Pi$ has a Serre functor $(-1)[d+1]$, and $\underline{\mathrm{mod}}\Pi$ is $(d+1)$-Calabi-Yau.*

(c) Π *is a (unique) d-cluster tilting object in* $\operatorname{mod}\Lambda$.

Now we give an explicit characterization of such Π.

Definition 5.12. Let $\Gamma = \bigoplus_{i\geq 0}\Gamma_i$ be a $\mathbb{Z}$-graded finite dimensional self-injective k-algebra. We denote by $\Gamma^{\mathrm{e}} = \Gamma^{\mathrm{op}}\otimes_k\Gamma$ the enveloping algebra of Γ. We say that Γ is a *stably d-Calabi-Yau algebra of a-invariant a* (or *Gorenstein parameter $-a$*) if $\mathbf{R}\mathrm{Hom}_{\Gamma^{\mathrm{e}}}(\Gamma,\Gamma^{\mathrm{e}})(a)[d] \simeq \Gamma$ in $\mathrm{D}^{\mathbb{Z}}_{\mathrm{sg}}(\Gamma^{\mathrm{e}})$.

Now we give a homological characterization of the $(d+1)$-preprojective algebras of d-representation-finite algebras as the explicit correspondence.

Theorem 5.13 (Amiot and Oppermann [2014])**.** *There exists a bijection between the set of isomorphism classes of d-representation-finite algebras Λ and the set of isomorphism classes of stably $(d+1)$-Calabi-Yau self-injective algebras Γ of a-invariant -1. It is given by $\Lambda\mapsto\Pi_{d+1}(\Lambda)$ and $\Gamma\mapsto\Gamma_0$.*

Now let Λ be a d-representation-finite k-algebra, and $\Pi = \Pi_{d+1}(\Lambda)$. Let $\Gamma = \underline{\mathrm{End}}_{\Lambda}(\Pi)$ be the stable d-Auslander algebra of Λ. Then we have an equivalence

$$\mathrm{U}_d(\Lambda) \simeq \mathrm{proj}^{\mathbb{Z}}\, T(\Gamma) \tag{5-5}$$

of additive categories. Thus we have triangle equivalences

$$\underline{\mathrm{mod}}^{\mathbb{Z}}\Pi \overset{(5\text{-}3)}{\simeq} \underline{\mathrm{mod}}\mathrm{U}_d(\Lambda) \overset{(5\text{-}5)}{\simeq} \underline{\mathrm{mod}}^{\mathbb{Z}}T(\Gamma) \overset{(4\text{-}1)}{\simeq} \mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Gamma).$$

By Proposition 5.11(b), the automorphism (-1) on $\underline{\mathrm{mod}}^{\mathbb{Z}}\Pi$ corresponds to ν_{d+1} on $\mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Gamma)$. Using universality of $(d+1)$-cluster categories (Keller [2005]), we obtain a triangle equivalence $\underline{\mathrm{mod}}\Pi \simeq \mathrm{C}_{d+1}(\Gamma)$. As a summary, we obtain the following.

Theorem 5.14 (Iyama and Oppermann [2013])**.** *Let Λ be a d-representation-finite k-algebra, $\Pi = \Pi_{d+1}(\Lambda)$, and $\Gamma = \underline{\mathrm{End}}_{\Lambda}(\Pi)$ the stable d-Auslander algebra of Λ. Then there exist triangle equivalences*

$$\underline{\mathrm{mod}}^{\mathbb{Z}}\Pi \simeq \mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Gamma) \ \textit{and}\ \underline{\mathrm{mod}}\Pi \simeq \mathrm{C}_{d+1}(\Gamma).$$

Applying Theorem 5.14 for $d = 1$, we obtain the following observations.

Example 5.15 (Amiot [2009] and Iyama and Oppermann [2013])**.** Let Π be the preprojective algebra of a Dynkin quiver Q, and Γ the stable Auslander algebra of kQ. Then there exist triangle equivalences

$$\underline{\mathrm{mod}}^{\mathbb{Z}}\Pi \simeq \mathrm{D}^{\mathrm{b}}(\operatorname{mod}\Gamma) \ \text{and}\ \underline{\mathrm{mod}}\Pi \simeq \mathrm{C}_2(\Gamma).$$

As an application, if a quiver Q' has the same underlying graph with Q, then the stable Auslander algebra Γ' of kQ' is derived equivalent to Γ since Π is common.

In the rest of this subsection, we discuss properties of $\Pi_{d+1}(\Lambda)$ for a more general class of Λ. We say that a finite dimensional k-algebra Λ with $\operatorname{gl.dim}\Lambda \le d$ satisfies the *vosnex property* if Λ is ν_d-finite and satisfies $\operatorname{Hom}_{\mathrm{D^b}(\operatorname{mod}\Lambda)}(\mathrm{U}_d(\Lambda)[i], \mathrm{U}_d(\Lambda)) = 0$ for all $1 \le i \le d-2$. This is automatic if $d = 1, 2$ or Λ is d-representation-finite. In this case, the following generalization of Theorem 5.14 holds.

Theorem 5.16 (Iyama and Oppermann [2013]). *Let Λ be a finite dimensional k-algebra with* $\operatorname{gl.dim}\Lambda \le d$ *satisfying the vosnex property. Then $\Pi = \Pi_{d+1}(\Lambda)$ is 1-Iwanaga-Gorenstein, $\Gamma = \underline{\operatorname{End}}_\Lambda(\Pi)$ satisfies* $\operatorname{gl.dim}\Gamma \le d+1$*, and there exist triangle equivalences*

$$\underline{\mathrm{CM}}^{\mathbb{Z}}\Pi \simeq \mathrm{D^b}(\operatorname{mod}\Gamma) \ \textit{and}\ \underline{\mathrm{CM}}\Pi \simeq \mathrm{C}_{d+1}(\Gamma).$$

For more general Λ, we refer to Beligiannis [2015] for some properties of $\Pi_{d+1}(\Lambda)$.

5.4 Preprojective algebras and Coxeter groups. We discuss a family of finite dimensional k-algebras constructed from preprojective algebras and Coxeter groups.

Let Q be an acyclic quiver and Π the preprojective algebra of kQ. The *Coxeter group* of Q is generated by s_i with $i \in Q_0$, and the relations are the following.

- $s_i^2 = 1$ for all $i \in Q_0$.
- $s_i s_j = s_j s_i$ if there is no arrow between i and j in Q.
- $s_i s_j s_i = s_j s_i s_j$ if there is precisely one arrow between i and j in Q.

Let $w \in W$. An expression $w = s_{i_1} s_{i_2} \cdots s_{i_\ell}$ of w is called *reduced* if ℓ is minimal among all expressions of w. For $i \in Q_0$, let I_i be the two-sided ideal of Π generated by the idempotent $1 - e_i$. For a reduced expression $w = s_{i_1} \cdots s_{i_\ell}$, we define a two-sided ideal of Π by

$$I_w := I_{i_1} I_{i_2} \cdots I_{i_\ell}.$$

This is independent of the choice of the reduced expression of w. The corresponding factor algebra $\Pi_w := \Pi/I_w$ is a finite dimensional k-algebra. It enjoys the following remarkable properties.

Theorem 5.17 (Buan, Iyama, Reiten, and Scott [2009], Geiss, Leclerc, and Schröer [2007], and Amiot, Reiten, and Todorov [2011]). *Let $w \in W$.*

(a) *Π_w is a 1-Iwanaga-Gorenstein algebra.*

(b) *$\underline{\mathrm{CM}}\Pi_w$ is a 2-Calabi-Yau triangulated category.*

(c) *There exists a 2-cluster tilting object $\bigoplus_{j=1}^{\ell} e_{i_j}\Pi_{s_{i_j}\cdots s_{i_\ell}}$ in $\mathrm{CM}\,\Pi_w$.*

(d) *There exists a triangle equivalence* $\underline{\mathrm{CM}}\Pi_w \simeq \mathrm{C}_2(\Lambda)$ *for some algebra* Λ.

Therefore it is natural to expect that there exists a triangle equivalence $\underline{\mathrm{CM}}^{\mathbb{Z}}\Pi_w \simeq \mathrm{D}^{\mathrm{b}}(\mathrm{mod}\,\Lambda')$ for some algebra Λ'. In fact, the following results are known, where we refer to Kimura [2018, 2016] for the definitions of *c-sortable*, *c-starting* and *c-ending*.

Theorem 5.18. *Let* $w = s_{i_1} \cdots s_{i_\ell}$ *be a reduced expression of* $w \in W$.

(a) *(Kimura [2018]) If w is c-sortable, then* $\underline{\mathrm{CM}}^{\mathbb{Z}}\Pi_w$ *has a tilting object* $\bigoplus_{i>0} \Pi_w(i)_{\geq 0}$.

(b) *(Kimura [2016])* $\underline{\mathrm{CM}}^{\mathbb{Z}}\Pi_w$ *has a silting object* $\bigoplus_{j=1}^{\ell} e_{i_j}\Pi_{s_{i_j}\cdots s_{i_\ell}}$. *This is a tilting object if the reduced expression is c-starting or c-ending.*

We end this section with posing the following natural question on 'higher cluster combinatorics' (e.g. Oppermann and Thomas [2012]), which will be related to derived equivalences of Calabi-Yau algebras since our I_w is a tilting object in $\mathrm{K}^{\mathrm{b}}(\mathrm{proj}\,\Pi)$ if Q is non-Dynkin.

Problem 5.19. *Are there similar results to Theorems 5.17 and 5.18 for higher preprojective algebras? What kind of combinatorial structure will appear instead of the Coxeter groups?*

6 Geigle-Lenzing complete intersections

Weighted projective lines of Geigle and Lenzing [1987] are one of the basic objects in representation theory. For example, the simplest class of weighted projective lines gives us simple singularities in dimension 2 as certain Veronese subrings. We introduce a higher dimensional generalization of weighted projective lines following Herschend, Iyama, Minamoto, and Oppermann [2014].

6.1 Basic properties. For a field k and an integer $d \geq 1$, we consider a polynomial algebra $C = k[T_0, \dots, T_d]$. For $n \geq 0$, let $\ell_1, \dots, \ell_n$ be linear forms in C and $p_1, \dots, p_n$ positive integers. For simplicity, we assume $p_i \geq 2$ for all i. Let

$$R = C[X_1, \dots, X_n]/(X_i^{p_i} - \ell_i \mid 1 \leq i \leq n)$$

be the factor algebra of the polynomial algebra $C[X_1, \dots, X_n]$, and

$$\mathbb{L} = \langle \vec{x}_1, \dots, \vec{x}_n, \vec{c}\rangle / \langle p_i\vec{x}_i - \vec{c} \mid 1 \leq i \leq n\rangle.$$

the factor group of the free abelian group $\langle \vec{x}_1, \dots, \vec{x}_n, \vec{c}\rangle$. Then $\mathbb{L}$ is an abelian group of rank 1 with torsion elements in general, and R is $\mathbb{L}$-graded by $\deg T_i = \vec{c}$ for all $0 \leq i \leq d$ and $\deg X_i = \vec{x}_i$ for all $1 \leq i \leq n$.

We call the pair $(R, \mathbb{L})$ a *Geigle-Lenzing* (*GL*) *complete intersection* if $\ell_1, \dots, \ell_n$ are in general position in the sense that each set of at most $d+1$ elements from $\ell_1, \dots, \ell_n$ is linearly independent. We give some basic properties.

Proposition 6.1. *Let $(R, \mathbb{L})$ be a GL complete intersection.*

(a) *$X_1^{p_1} - \ell_1, \dots, X_n^{p_n} - \ell_n$ is a $C[X_1, \dots, X_n]$-regular sequence.*

(b) *R is a complete intersection ring with $\dim R = d+1$ and has an a-invariant*

$$\vec{\omega} = (n-d-1)\vec{c} - \sum_{i=1}^{n} \vec{x}_i .$$

(c) *After a suitable linear transformation of variables $T_0, \dots, T_d$, we have*

$$R = \begin{cases} k[X_1, \dots, X_n, T_n, \dots, T_d] & \text{if } n \le d+1, \\ k[X_1, \dots, X_n]/(X_i^{p_i} - \sum_{j=1}^{d+1} \lambda_{i,j-1} X_j^{p_j}) \mid d+2 \le i \le n) & \text{if } n \ge d+2. \end{cases}$$

(d) *R is regular if and only if R is a polynomial algebra if and only if $n \le d+1$.*

(e) *$\mathrm{CM}^{\mathbb{L}} R = \mathrm{CM}_0^{\mathbb{L}} R$ holds, and $\underline{\mathrm{CM}}^{\mathbb{L}} R$ has a Serre functor $(\vec{\omega})[d]$ (Theorem 2.16).*

Let $\delta\colon \mathbb{L} \to \mathbb{Q}$ be a group homomorphism given by $\delta(\vec{x}_i) = \frac{1}{p_i}$ and $\delta(\vec{c}) = 1$. We consider the following trichotomy given by the sign of $\delta(\vec{\omega}) = n - d - 1 - \sum_{i=1}^{n} \frac{1}{p_i}$. For example, $(R, \mathbb{L})$ is Fano if $n \le d+1$.

$\delta(\vec{\omega})$	< 0	$= 0$	> 0
$(R, \mathbb{L})$	Fano	Calabi-Yau	anti-Fano
$d = 1$	domestic	tubular	wild

In the classical case $d = 1$, the ring R has been studied in the context of weighted projective lines. The above trichotomy is given explicitly as follows.

- 5 types for domestic: $n \le 2$, $(2, 2, p)$, $(2, 3, 3)$, $(2, 3, 4)$ and $(2, 3, 5)$.
- 4 types for tubular: $(3, 3, 3)$, $(2, 4, 4)$, $(2, 3, 6)$ and $(2, 2, 2, 2)$.
- All other types are wild.

There is a close connection between domestic type and simple singularities. The following explains Corollary 5.2, where $R^{(\vec{\omega})} = \bigoplus_{i \in \mathbb{Z}} R_{i\vec{\omega}}$ is the Veronese subring.

Theorem 6.2 (Geigle and Lenzing [1991]). *If $(R, \mathbb{L})$ is domestic, then $R^{(\vec{\omega})}$ is a simple singularity $k[x, y, z]/(f)$ in dimension 2, and we have an equivalence $\mathrm{CM}^{\mathbb{L}} R \simeq \mathrm{CM}^{\mathbb{Z}} R^{(\vec{\omega})}$. The AR quiver is $\mathbb{Z}Q$, where Q is given by the following table.*

$(p_1, \dots, p_n)$	x	y	z	f	Q
(p, q)	X_1X_2	X_2^{p+q}	X_1^{p+q}	$x^{p+q} - yz$	$\widetilde{\mathbb{A}}_{p,q}$
$(2, 2, 2p)$	X_3^2	X_1^2	$X_1X_2X_3$	$x(y^2 + x^p y) + z^2$	$\widetilde{\mathbb{D}}_{2p+2}$
$(2, 2, 2p+1)$	X_3^2	X_1X_2	$X_1^2X_3$	$x(y^2 + x^p z) + z^2$	$\widetilde{\mathbb{D}}_{2p+3}$
$(2, 3, 3)$	X_1	X_2X_3	X_2^3	$x^2z + y^3 + z^2$	$\widetilde{\mathbb{E}}_6$
$(2, 3, 4)$	X_2	X_3^2	X_1X_3	$x^3y + y^3 + z^2$	$\widetilde{\mathbb{E}}_7$
$(2, 3, 5)$	X_3	X_2	X_1	$x^5 + y^3 + z^2$	$\widetilde{\mathbb{E}}_8$

6.2 Cohen-Macaulay representations. To study the category $\mathrm{CM}^{\mathbb{L}} R$, certain finite dimensional algebras play an important role. For a finite subset I of $\mathbb{L}$, let

$$A^I = \bigoplus_{\vec{x},\vec{y} \in I} R_{\vec{x}-\vec{y}}.$$

We define the multiplication in A^I by $(r_{\vec{x},\vec{y}})_{\vec{x},\vec{y}\in I} \cdot (r'_{\vec{x},\vec{y}})_{\vec{x},\vec{y}\in I} = (\sum_{\vec{z}\in I} r_{\vec{x},\vec{z}} r'_{\vec{z},\vec{y}})_{\vec{x},\vec{y}\in I}$. Then A^I forms a finite dimensional k-algebra called the *I-canonical algebra*.

We define a partial order $\leq$ on $\mathbb{L}$ by writing $\vec{x} \leq \vec{y}$ if $\vec{y} - \vec{x}$ belongs to $\mathbb{L}_+$, where $\mathbb{L}_+$ is the submonoid of $\mathbb{L}$ generated by $\vec{c}$ and $\vec{x}_i$ for all i. For $\vec{x} \in \mathbb{L}$, let $[0, \vec{x}]$ be the interval in $\mathbb{L}$, and $A^{[0,\vec{x}]}$ the $[0, \vec{x}]$-canonical algebra. We call

$$A^{\mathrm{CM}} = A^{[0, d\vec{c}+2\vec{\omega}]}$$

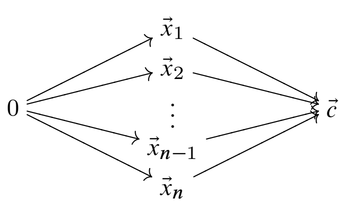
the *CM-canonical algebra*.

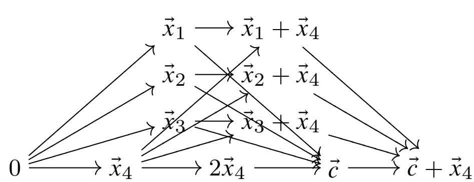
Example 6.3. The equality $d\vec{c} + 2\vec{\omega} = (n - d - 2)\vec{c} + \sum_{i=1}^{n} (p_i - 2)\vec{x}_i$ holds.

(a) If $n \leq d + 1$, then $A^{\mathrm{CM}} = 0$. If $n = d + 2$, then $A^{\mathrm{CM}} = \bigotimes_{i=1}^{n+2} k\mathbb{A}_{p_i-1}$.

(b) If $n = d + 3$ and $p_i = 2$ for all i, then A^{CM} has the left quiver below.

(c) If $d = 1$, $n = 4$ and $(p_i)_{i=1}^4 = (2, 2, 2, 3)$, then A^{CM} has the right quiver below.





The following is a main result in this section.

Theorem 6.4. *Let $(R, \mathbb{L})$ be a GL complete intersection. Then there is a triangle equivalence*

$$\underline{\mathrm{CM}}^{\mathbb{L}} R \simeq \mathrm{D}^{\mathrm{b}}(\mathrm{mod}\, A^{\mathrm{CM}}).$$

In particular, $\underline{\mathrm{CM}}^{\mathbb{L}} R$ has a tilting object.

The case $n = d + 2$ was shown in Kussin, Lenzing, and Meltzer [2013] ($d = 1$) and Futaki and Ueda [2011]. An important tool in the proof is an $\mathbb{L}$-analogue of Theorem 2.12.

As an application, one can immediately obtain the following analogue of Theorem 2.23 by using the knowledge on A^{CM} in representation theory, where we call $(R, \mathbb{L})$ *CM-finite* if there are only finitely many isomorphism classes of indecomposable objects in $\mathrm{CM}^{\mathbb{L}} R$ up to degree shift (cf. Definition 2.22).

Corollary 6.5. *Let $(R, \mathbb{L})$ be a GL complete intersection. Then $(R, \mathbb{L})$ is CM-finite if and only if one of the following conditions hold.*

(i) $n \leq d + 1$.

(ii) $n = d + 2$, *and* $(p_1, \dots, p_n) = (2, \dots, 2, p_n)$, $(2, \dots, 2, 3, 3)$, $(2, \dots, 2, 3, 4)$ *or* $(2, \dots, 2, 3, 5)$ *up to permutation.*

We call a GL complete intersection $(R, \mathbb{L})$ *d-CM-finite* if there exists a d-cluster tilting subcategory $\mathcal{C}$ of $\mathrm{CM}^{\mathbb{L}} R$ such that there are only finitely many isomorphism classes of indecomposable objects in $\mathcal{C}$ up to degree shift (cf. Definition 3.12). Now we discuss which GL complete intersections are d-CM-finite. Our Theorem 3.7 gives the following sufficient condition, where a tilting object is called *d-tilting* if the endomorphism algebra has global dimension at most d.

Proposition 6.6. *If $\underline{\mathrm{CM}}^{\mathbb{L}} R$ has a d-tilting object U, then $(R, \mathbb{L})$ is d-CM-finite and $\mathrm{CM}^{\mathbb{L}} R$ has the d-cluster tilting subcategory* $\mathrm{add}\{U(\ell\vec{\omega}), R(\vec{x}) \mid \ell \in \mathbb{Z}, \vec{x} \in \mathbb{L}\}$.

Therefore the following problem is of our interest.

Problem 6.7. *When does $\underline{\mathrm{CM}}^{\mathbb{L}} R$ have a d-tilting object? Equivalently, when is A^{CM} derived equivalent to an algebra Λ with* $\mathrm{gl.dim}\, \Lambda \leq d$?

Applying Tate's DG algebra resolutions (Tate [1957]), we can calculate $\mathrm{gl.dim}\, A^{\mathrm{CM}}$. Note that any element $\vec{x} \in \mathbb{L}$ can be written uniquely as $\vec{x} = a\vec{c} + \sum_{i=1}^{n} a_i \vec{x}_i$ for $a \in \mathbb{Z}$ and $0 \leq a_i \leq p_i - 1$, which is called the *normal form* of $\vec{x}$.

Theorem 6.8. (a) *Write $\vec{x} \in \mathbb{L}_+$ in normal form $\vec{x} = a\vec{c} + \sum_{i=1}^{n} a_i \vec{x}_i$. Then*

$$\mathrm{gl.dim}\, A^{[0,\vec{x}]} = \begin{cases} \min\{d + 1, a + \#\{i \mid a_i \neq 0\}\} & \text{if } n \leq d + 1, \\ 2a + \#\{i \mid a_i \neq 0\} & \text{if } n \geq d + 2. \end{cases}$$

(b) *If* $n \geq d+2$, *then* A^{CM} *has global dimension* $2(n-d-2)+\#\{i \mid p_i \geq 3\}$.

We obtain the following examples from Theorem 6.8 and the fact that $k\mathbb{A}_2 \otimes_k k\mathbb{A}_m$ is derived equivalent to $k\mathbb{D}_4$ if $m=2$, $k\mathbb{E}_6$ if $m=3$, and $k\mathbb{E}_8$ if $m=4$.

Example 6.9. In the following cases, $\underline{\mathrm{CM}}^{\mathbb{L}} R$ has a d-tilting object.

(i) $n \leq d+1$.

(ii) $n = d+2 \geq 3$ and $(p_1, p_2, p_3) = (2,2,p_3)$, $(2,3,3)$, $(2,3,4)$ or $(2,3,5)$.

(iii) $n = d+2 \geq 4$ and $(p_1,p_2,p_3,p_4) = (3,3,p_3,p_4)$ with $p_3, p_4 \in \{3,4,5\}$.

(iv) $\#\{i \mid p_i = 2\} \geq 3(n-d)-4$.

The following gives a necessary condition for the existence of d-tilting object.

Proposition 6.10. *If* $\underline{\mathrm{CM}}^{\mathbb{L}} R$ *has a* d*-tilting object, then* $(R, \mathbb{L})$ *is Fano.*

Note that the converse is not true. For example, let $d=2$ and $(2,5,5,5)$. Then $(R,\mathbb{L})$ is Fano since $\delta(\vec{\omega}) = -\frac{1}{10}$. On the other hand, $A^{\mathrm{CM}} = \bigotimes_{i=1}^{3} k\mathbb{A}_4$ satisfies $\nu^5 = [9]$. One can show that A^{CM} is not derived equivalent to an algebra Λ with $\mathrm{gl.dim}\,\Lambda \leq 2$ by using the inequality $2(5-1) < 9$.

6.3 Geigle-Lenzing projective spaces. Let $(R,\mathbb{L})$ be a GL complete intersection. Recall that $\mathrm{mod}_0^{\mathbb{L}} R$ is the Serre subcategory of $\mathrm{mod}^{\mathbb{L}} R$ consisting of finite dimensional modules. We consider the quotient category

$$\mathrm{coh}\,\mathbb{X} = \mathrm{qgr}\,R = \mathrm{mod}^{\mathbb{L}} R / \mathrm{mod}_0^{\mathbb{L}} R.$$

We call objects in $\mathrm{coh}\,\mathbb{X}$ *coherent sheaves* on the *GL projective space* $\mathbb{X}$. We can regard $\mathbb{X}$ as the quotient stack $[(\mathrm{Spec}\,R \setminus \{R_+\}) / \mathrm{Spec}\,k[\mathbb{L}]]$ for $R_+ = \bigoplus_{\vec{x}>0} R_{\vec{x}}$. For example, if $n=0$, then $\mathbb{X}$ is the projective space $\mathbb{P}^d$.

We study the bounded derived category $\mathrm{D^b}(\mathrm{coh}\,\mathbb{X})$, which is canonically triangle equivalent to the Verdier quotient $\mathrm{D^b}(\mathrm{mod}^{\mathbb{L}} R)/\mathrm{D^b}(\mathrm{mod}_0^{\mathbb{L}} R)$. The duality $(-)^* = \mathbf{R}\mathrm{Hom}_R(-,R)\colon \mathrm{D^b}($ $\mathrm{D^b}(\mathrm{mod}^{\mathbb{L}} R)$ induces a duality $(-)^*\colon \mathrm{D^b}(\mathrm{coh}\,\mathbb{X}) \to \mathrm{D^b}(\mathrm{coh}\,\mathbb{X})$. We define the category of *vector bundles* on $\mathbb{X}$ as

$$\mathrm{vect}\,\mathbb{X} = \mathrm{coh}\,\mathbb{X} \cap (\mathrm{coh}\,\mathbb{X})^*.$$

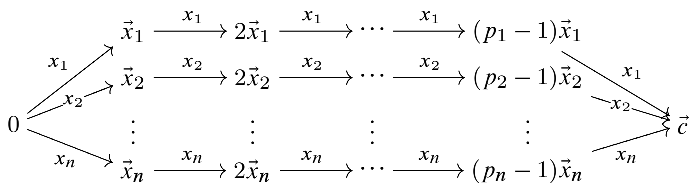
The composition $\mathrm{CM}^{\mathbb{L}} R \subset \mathrm{mod}^{\mathbb{L}} R \to \mathrm{coh}\,\mathbb{X}$ is fully faithful, and we can regard $\mathrm{CM}^{\mathbb{L}} R$ as a full subcategory of $\mathrm{vect}\,\mathbb{X}$. We have $\mathrm{CM}^{\mathbb{L}} R = \mathrm{vect}\,\mathbb{X}$ if $d=1$, but this is not the case if $d \geq 2$. In fact, we have equalities

$$\text{(6-1)} \qquad \mathrm{CM}^{\mathbb{L}} R = \{X \in \operatorname{vect} \mathbb{X} \mid \forall \vec{x} \in \mathbb{L},\ 1 \leq i \leq d-1,\ \operatorname{Ext}^i_{\mathbb{X}}(\mathcal{O}(\vec{x}), X) = 0\}$$
$$= \{X \in \operatorname{vect} \mathbb{X} \mid \forall \vec{x} \in \mathbb{L},\ 1 \leq i \leq d-1,\ \operatorname{Ext}^i_{\mathbb{X}}(X, \mathcal{O}(\vec{x})) = 0\}$$

where $\mathcal{O}(\vec{x}) = R(\vec{x})$. Now we define the *$d$-canonical algebra* by

$$A^{\mathrm{ca}} = A^{[0, d\vec{c}]}.$$

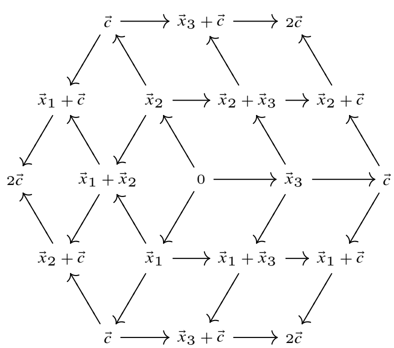
Example 6.11. (a) If $d = 1$, then A^{ca} is precisely the canonical algebra of Ringel [1984]. It is given by the following quiver with relations $x_i^{p_i} = \lambda_{i0} x_1^{p_1} + \lambda_{i1} x_2^{p_2}$ for any i with $3 \leq i \leq n$.

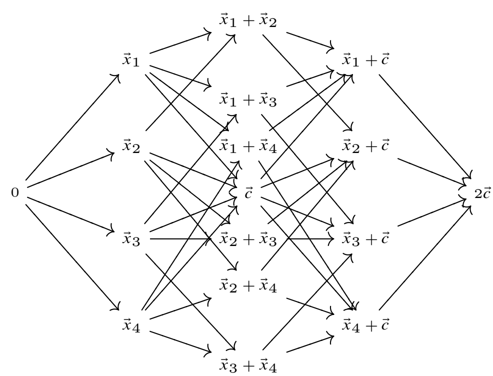


(b) If $n = 0$, then A^{ca} is the Beilinson algebra.

(c) If $d = 2$, $n = 3$ and $(p_i)_{i=1}^3 = (2, 2, 2)$, then A^{ca} has the left quiver below.

(d) If $d = 2$, $n = 4$ and $(p_i)_{i=1}^4 = (2, 2, 2, 2)$, then A^{ca} has the right quiver below.





As in the case of $\underline{\mathrm{CM}}^{\mathbb{L}} R$ and A^{CM}, we obtain the following results.

Theorem 6.12. *Let $\mathbb{X}$ be a GL projective space. Then there is a triangle equivalence*

$$\mathrm{D^b}(\operatorname{coh} \mathbb{X}) \simeq \mathrm{D^b}(\operatorname{mod} A^{\mathrm{ca}}).$$

Moreover $\mathrm{D^b}(\operatorname{coh} \mathbb{X})$ *has a tilting bundle* $\bigoplus_{\vec{x} \in [0, d\vec{c}]} \mathcal{O}(\vec{x})$.

Some cases were known before ($n = 0$ by Beilinson [1978], $d = 1$ by Geigle and Lenzing [1987], $n \leq d+1$ by Baer [1988], $n = d+2$ by Ishii and Ueda [2012]). An important tool in the proof is again an $\mathbb{L}$-analogue of Theorem 2.12.

We call $\mathbb{X}$ *vector bundle finite* (*VB-finite*) if there are only finitely many isomorphism classes of indecomposable objects in $\operatorname{vect}\mathbb{X}$ up to degree shift. There is a complete classification: $\mathbb{X}$ is VB-finite if and only if $d = 1$ and $\mathbb{X}$ is domestic.

We call $\mathbb{X}$ *d-VB-finite* if there exists a d-cluster tilting subcategory $\mathcal{C}$ of $\operatorname{vect}\mathbb{X}$ such that there are only finitely many isomorphism classes of indecomposable objects in $\mathcal{C}$ up to degree shift. In the rest, we discuss which GL projective spaces are d-VB-finite. We start with the following relationship between d-cluster tilting subcategories of $\mathrm{CM}^{\mathbb{L}} R$ and $\operatorname{vect}\mathbb{X}$, which follows from (6-1).

Proposition 6.13. *The d-cluster-tilting subcategories of $\mathrm{CM}^{\mathbb{L}} R$ are precisely the d-cluster-tilting subcategories of $\operatorname{vect}\mathbb{X}$ containing $\mathcal{O}(\vec{x})$ for all $\vec{x} \in \mathbb{L}$. Therefore, if $(R, \mathbb{L})$ is d-CM-finite, then $\mathbb{X}$ is d-VB-finite.*

For example, if $n \leq d+1$, then $\mathrm{CM}^{\mathbb{L}} R = \operatorname{proj}^{\mathbb{L}} R$ is a d-cluster tilting subcategory of itself, and hence $\operatorname{vect}\mathbb{X}$ has a d-cluster tilting subcategory $\operatorname{add}\{\mathcal{O}(\vec{x}) \mid \vec{x} \in \mathbb{L}\}$. This implies Horrocks' splitting criterion for $\operatorname{vect}\mathbb{P}^d$ (Okonek, Schneider, and Spindler [1980]).

We give another sufficient condition for d-VB-finiteness. Recall that we call a tilting object V in $\mathrm{D}^{\mathrm{b}}(\operatorname{coh}\mathbb{X})$ *d-tilting* if $\operatorname{gl.dim}\operatorname{End}_{\mathrm{D}^{\mathrm{b}}(\operatorname{coh}\mathbb{X})}(V) \leq d$.

Proposition 6.14. *Let $\mathbb{X}$ be a GL projective space, and V a d-tilting object in $\mathrm{D}^{\mathrm{b}}(\operatorname{coh}\mathbb{X})$.*

(a) *(cf. Example 3.11(b))* $\operatorname{gl.dim}\operatorname{End}_{\mathrm{D}^{\mathrm{b}}(\operatorname{coh}\mathbb{X})}(V) = d$ *holds. If $V \in \operatorname{coh}\mathbb{X}$, then $\operatorname{End}_{\mathbb{X}}(T)$ is a d-representation-infinite algebra.*

(b) *If $V \in \operatorname{vect}\mathbb{X}$, then $\mathbb{X}$ is d-VB-finite and $\operatorname{vect}\mathbb{X}$ has the d-cluster tilting subcategory* $\operatorname{add}\{V(\ell\vec{\omega}) \mid \ell \in \mathbb{Z}\}$.

Therefore it is natural to ask when $\mathbb{X}$ has a d-tilting bundle, or equivalently, when A^{ca} is derived equivalent to an algebra Λ with $\operatorname{gl.dim}\Lambda = d$. It follows from Theorem 6.8(a) that

$$\operatorname{gl.dim} A^{\mathrm{ca}} = \begin{cases} d & \text{if } n \leq d+1, \\ 2d & \text{if } n \geq d+2. \end{cases}$$

Thus, if $n \leq d+1$, then $\mathbb{X}$ has a d-tilting bundle. Using Example 6.9 and some general results on matrix factorizations, we have more examples.

Theorem 6.15. *In the following cases, $\mathbb{X}$ has a d-tilting bundle.*

(i) $n \leq d+1$.

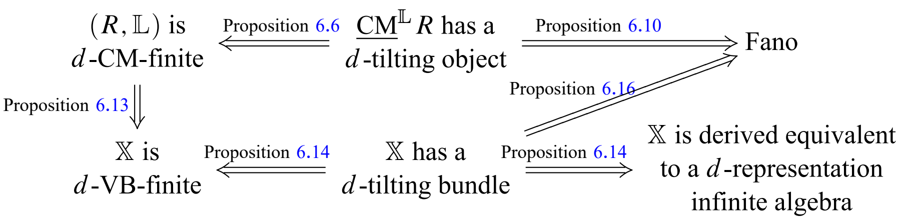
(ii) $n = d + 2 \geq 3$ *and* $(p_1, p_2, p_3) = (2, 2, p_3)$, $(2, 3, 3)$, $(2, 3, 4)$ *or* $(2, 3, 5)$.

(iii) $n = d + 2 \geq 4$ *and* $(p_1, p_2, p_3, p_4) = (3, 3, p_3, p_4)$ *with* $p_3, p_4 \in \{3, 4, 5\}$.

As in the previous subsection, we have the following necessary condition.

Proposition 6.16. *If* $\mathbb{X}$ *has a* d*-tilting bundle, then* $\mathbb{X}$ *is Fano.*

Some of our results in this section can be summarized as follows.



It is important to understand the precise relationship between these conditions. We refer to Chan [2017] and Buchweitz, Hille, and Iyama [n.d.] for results on existence of d-tilting bundles on more general varieties and stacks.

ON NEGATIVE ALGEBRAIC K-GROUPS

MORITZ KERZ

Abstract

We sketch a proof of Weibel's conjecture on the vanishing of negative algebraic K-groups and we explain an analog of this result for continuous K-theory of non-archimedean algebras.

1 Negative K-groups of schemes

For a scheme X Grothendieck introduced the K-group $K_0(X)$ in his study of the generalized Riemann–Roch theorem in Berthelot, Grothendieck, and Illusie [1971, Def. IV.2.2]. In case X has an ample family of line bundles one can describe $K_0(X)$ as the free abelian group generated by the locally free $\mathcal{O}_X$-modules $\mathcal{V}$ of finite type modulo the relation $[\mathcal{V}'] + [\mathcal{V}''] - [\mathcal{V}]$ for any short exact sequence

$$0 \to \mathcal{V}' \to \mathcal{V} \to \mathcal{V}'' \to 0,$$

see Berthelot, Grothendieck, and Illusie [ibid., Sec. IV.2.9]. We denote by $X[t]$ resp. $X[t^{-1}]$ the scheme $X \times \mathbb{A}^1$ with parameter t resp. t^{-1} for the affine line $\mathbb{A}^1$, and we denote by $X[t, t^{-1}]$ the scheme $X \times \mathbb{G}_m$, where $\mathbb{G}_m = \mathbb{A}^1 \setminus \{0\}$. Bass successively defined negative algebraic K-groups of the scheme X (at least in the affine case) in degree $i < 0$ to be

$$K_i(X) = \operatorname{coker}\left[K_{i+1}(X[t]) \times K_{i+1}(X[t^{-1}]) \to K_{i+1}(X[t, t^{-1}])\right].$$

The two classical key properties, essentially due to Bass [1968], satisfied by these algebraic K-groups are the *Fundamental Theorem* and *Excision*.

The author is supported by the DFG through CRC 1085 *Higher Invariants* (Universität Regensburg).
MSC2010: primary 19D35; secondary 13D15.

Proposition 1 (Fundamental Theorem)**.** *For a quasi-compact, quasi-separated scheme X and $i \leq 0$ there exists an exact sequence*

$$0 \to K_i(X) \to K_i(X[t]) \times K_i(X[t^{-1}]) \to K_i(X[t,t^{-1}]) \to K_{i-1}(X) \to 0$$

Furthermore, for a noetherian, regular scheme X we have $K_i(X) = 0$ for $i < 0$.

Proposition 2 (Excision)**.** *For a ring homomorphism $A \to A'$ and an ideal $I \subset A$ which maps isomorphically onto an ideal I' of A' the map $K_i(A, I) \to K_i(A', I')$ of relative K-groups is an isomorphism for $i \leq 0$.*

Combining Proposition 2 with the Artin-Rees Lemma we get the following more geometric reformulation:

Corollary 3. *For a finite morphism of affine noetherian schemes $f : X' \to X$ and a closed immersion $Y \hookrightarrow X$ such that f is an isomorphism over $X \backslash Y$ the map $K_i(X, Y) \to K_i(X', Y')$ is an isomorphism for $i < 0$. Here $Y' = Y \times_X X'$.*

In general it is a hard problem to actually calculate the negative K-groups in concrete examples. One of the examples calculated in C. Weibel [2001, Sec. 6] reads:

Example 4. *For a field k and the normal surface $X = \operatorname{Spec} k[x, y, z]/(z^2 - x^3 - y^7)$ we have $K_{-1}(X) = k$ and $K_i(X) = 0$ for $i < -1$.*

In fact it is shown in C. Weibel [ibid.] that for a normal surface X we have $K_{-2}(X) = \mathbb{Z}^\rho$ and $K_i(X) = 0$ for $i < -2$, where ρ is the number of "loops" in the exceptional divisor of a resolution of singularities of X. We extend this calculation in Theorem 8 and Theorem 11 to higher dimensions.

For our results it is essential to understand in which sense we can extend Corollary 3 to global schemes. For this we have to study the non-connective algebraic K-theory spectrum $K(X)$ of a scheme X introduced in Thomason and Trobaugh [1990]. Its homotopy groups $K_i(X) = \pi_i K(X)$ for $i \leq 0$ agree with the K-groups defined above.

As shown in Thomason and Trobaugh [ibid., Sec. 8], the functor K satisfies Zariski descent. More concretely, consider a noetherian scheme X of finite dimension and a closed subscheme $Y \hookrightarrow X$. Let $K(X, Y)$ be the homotopy fibre of $K(X) \to K(Y)$. Let $K_{i,(X,Y)}$ be the Zariski presheaf on X given by $U \mapsto \pi_i K(U, Y \cap U)$ and let $K^{\sim}_{i,(X,Y)}$ be its Zariski sheafification. There exists a convergent descent spectral sequence

$$E_2^{pq} = H^p(X, K^{\sim}_{-q,(X,Y)}) \Rightarrow K_{-p-q}(X, Y). \tag{1}$$

As a direct consequence of Corollary 3 and of Zariski descent we observe:

Corollary 5. *Let X be a noetherian scheme, let $Y \hookrightarrow X$ be a closed subscheme and let d be the dimension of the closure $\overline{X \setminus Y}$. Assume that $Y \hookrightarrow X$ is an isomorphism away from $\overline{X \setminus Y}$. Let $f : \tilde{X} \to X$ be a finite morphism which is an isomorphism over $X \setminus Y$. Set $E = f^{-1}(Y)$. Then the map $f^* : K_i(X, Y) \to K_i(\tilde{X}, E)$ is an isomorphism for $i < -d$.*

Remark 6. For $\tilde{X} = X_{\text{red}}$ and $Y = \varnothing$ Corollary 5 can be refined to an isomorphism $K_i(X) \xrightarrow{\simeq} K_i(X_{\text{red}})$ for $i \leq -\dim(X)$.

Proof. In order to prove Corollary 5 one compares the descent spectral sequence (1) with the corresponding descent spectral sequence

$$E_2^{pq} = H^p(X, (f_* K_{-q,(\tilde{X},E)})^\sim) \Rightarrow K_{-p-q}(\tilde{X}, E).$$

and one uses that

(i) $K^\sim_{i,(X,Y)} \to (f_* K_{i,(\tilde{X},E)})^\sim$ is an isomorphism for $i \leq 0$ by Corollary 3,

(ii) the sheaves $K^\sim_{i,(X,Y)}$ and $(f_* K_{i,(\tilde{X},E)})^\sim$ vanish away from $\overline{X \setminus Y}$.

Note that (ii) implies that $E_2^{pq} = 0$ for $p > d$ in both spectral sequences. □

2 Platification par éclatement

In this section we explain an application of *platification par éclatement* Raynaud and Gruson [1971, Sec. 5], which generalizes the vanishing result Kerz and Strunk [2017, Prop. 5]. The motivating picture one should keep in mind is that negative K-groups of Zariski-Riemann spaces vanish, since all coherent sheaves on Zariski-Riemann spaces have Tor-dimension ≤ 1.

Let X be a quasi-compact and quasi-separated scheme, let $Y \hookrightarrow X$ be a closed subscheme defined by an invertible ideal sheaf. Recall that an admissible blow-up of X (with respect to Y) is a blow up $\mathbf{Bl}_Z X \to X$ with center $Z \hookrightarrow X$ of finite presentation and set theoretically contained in Y, see Raynaud and Gruson [1971, Def. 5.1.3]. Also recall that the composition of admissible blow-ups is admissible Raynaud and Gruson [ibid., Lem. 5.1.4]. Let $X' \to X$ be a smooth morphism of finite presentation and set $Y' = Y \times_X X'$.

The following proposition is clear in case there exists a suitable resolution of singularities for X, in view of Proposition 1. We denote by $K_i(X \text{ on } Y)$ the K-theory of X with support on Y as in Thomason and Trobaugh [1990, Def. 6.4].

Proposition 7. *Assume that X' has an ample family of line bundles and assume that X is reduced. For $i < 0$ and $\gamma \in K_i(X' \text{ on } Y')$ there exists an admissible blow-up $\tilde{X} \to X$ such that the pullback of γ to $K_i(X' \times_X \tilde{X} \text{ on } Y' \times_X \tilde{X})$ vanishes.*

Proof. For simplicity of notation we assume that $X = X'$ throughout the proof.

By noetherian approximation, see Thomason and Trobaugh [1990, App. C], there exists a directed inverse system $(X_\alpha)_\alpha$ of schemes of finite type over $\mathbb{Z}$ with affine transition maps such that $X = \varprojlim_\alpha X_\alpha$. We may further assume that Y descends to a system of closed subschemes $Y_\alpha \hookrightarrow X_\alpha$ and that there exists $\gamma_\alpha \in K_i(X_\alpha \text{ on } Y_\alpha)$ pulling back to γ.

Under the assumption that we know Proposition 7 for noetherian schemes we can, for some fixed α, find a closed subscheme Z_α which is set theoretically contained in Y_α and such that the pullback of γ_α to $K_i(\mathbf{Bl}_{Z_\alpha} X_\alpha \text{ on } Y_\alpha \times_{X_\alpha} \mathbf{Bl}_{Z_\alpha} X)$ vanishes. Let $\tilde{X}$ be $\mathbf{Bl}_Z X$, where Z is the pullback of Z_α to X. In view of the commutative diagram

$$\begin{array}{ccc} \tilde{X} & \longrightarrow & \mathbf{Bl}_{Y_\alpha} X_\alpha \\ \downarrow & & \downarrow \\ X & \longrightarrow & X_\alpha \end{array}$$

the scheme $\tilde{X}$ satisfies the requested property of Proposition 7.

By what has been explained, we can assume without loss of generality that all schemes in Proposition 7 are noetherian. In view of Bass' definition of negative K-theory, discussed in Section 1, we see that $K_{-k}(X \text{ on } Y)$ is a quotient of $K_0(\mathbb{G}^k_{m,X} \text{ on } \mathbb{G}^k_{m,Y})$ for $k > 0$ in which elements induced from $K_0(\mathbb{A}^k_X \text{ on } \mathbb{A}^k_Y)$ vanish. However, combining Kerz and Strunk [2017, Lem. 6] and Thomason and Trobaugh [1990, Ex. 5.7] we see that the latter groups are generated by coherent $\mathcal{O}$-modules on $\mathbb{G}^k_{m,X}$ resp. $\mathbb{A}^k_X$ which have support over Y and have Tor-dimension ≤ 1 over X. So without loss of generality the given element γ is induced by such an $\mathcal{O}_{\mathbb{G}^k_{m,X}}$-module $\mathcal{V}$ (here $k = -i$).

Extend $\mathcal{V}$ to a coherent $\mathcal{O}_{\mathbb{A}^k_X}$-module $\overline{\mathcal{V}}$ with support over Y. Because of the existence of an ample family of line bundles there exists an exact sequence of coherent $\mathcal{O}_{\mathbb{A}^k_X}$-modules

$$0 \to \mathcal{V}_1 \to \mathcal{V}_2 \to \overline{\mathcal{V}} \to 0$$

with $\mathcal{V}_2$ locally free. By Raynaud and Gruson [1971, Thm. 5.2.2] there exists an admissible blow-up $f : \tilde{X} \to X$ such that the strict transform of $\mathcal{V}_1$ along f is flat over X. This implies that the pullback $f^*\overline{\mathcal{V}}$ has Tor-dimension ≤ 1 over X. So the latter induces an element in $K_0(\mathbb{A}^k_{\tilde{X}})$ which induces $f^*(\gamma) \in K_i(\tilde{X})$ via the Bass construction. This shows the requested vanishing of $f^*(\gamma)$.

□

3 Weibel's conjecture

In C. A. Weibel [1980, p. 2.9] Weibel conjectured that the following Theorem 8 holds.

Theorem 8. *For a noetherian scheme X of dimension $d < \infty$ we have:*

(i) $K_i(X) = 0$ *for* $i < -d$,

(ii) $K_i(X) \xrightarrow{\simeq} K_i(X[t_1, \dots, t_r])$ *is an isomorphism for* $i \leq -d$ *and any number of variables* r.

There have been various partial results on Weibel's conjecture during the past twenty years, in particular it was shown for varieties X in characteristic zero Cortiñas, Haesemeyer, Schlichting, and C. Weibel [2008]. A complete proof of Theorem 8 was first given in Kerz, Strunk, and Tamme [2018, Thm. B] based on a pro-descent result for algebraic K-theory of blow-ups. In this section we sketch a simplified and more direct version of that proof which does not use the excision theory for K-theory of simplicial rings, as developed in Kerz, Strunk, and Tamme [ibid., Sec. 4]. For simplicity we will stick to part (i) of Theorem 8 in the proof.

Remark 9. Almost verbatim the same argument as in the proof of Theorem 8 shows that the conclusion remains true with X replaced by a scheme X' which is smooth of finite type over a noetherian scheme of dimension $d < \infty$. This was observed in Sadhu [2017].

The essential observation is that using *derived schemes* and *derived blow-ups* one can show that the analog of Corollary 5 holds for blow-ups, see Proposition 10 below.

For the convenience of the reader we summarize some properties of derived schemes in the following. A derived scheme $\mathcal{X}$ is roughly speaking given by a topological space $|\mathcal{X}|$ together with a 'derived' sheaf of commutative simplicial rings $\mathcal{O}_{\mathcal{X}}$ on $|\mathcal{X}|$, see Lurie [2016, Sec. 1.1.5]. For a derived scheme $\mathcal{X}$ its topological space together with its sheaf of homotopy groups $\pi_0 \mathcal{O}_{\mathcal{X}}$ defines an ordinary scheme, which we denote $t\mathcal{X}$. The ∞-category of derived schemes has finite limits and t preserves finite limits.

For a quasi-compact, quasi-separated derived scheme $\mathcal{X}$ one can construct its associated stable ∞-category of perfect $\mathcal{O}_{\mathcal{X}}$-modules $\mathrm{Perf}(\mathcal{X})$, see Lurie [ibid., Sec. 9.6], and one can define the K-theory spectrum $K(\mathcal{X})$ as the non-connective K-theory spectrum of $\mathrm{Perf}(\mathcal{X})$ in the sense of Blumberg, Gepner, and Tabuada [2013, Sec. 9.1].

The two key properties about the K-theory of a derived scheme $\mathcal{X}$ that we need — and that are well-known to the experts — are:

(DK1) For a quasi-compact, quasi-separated derived scheme $\mathcal{X}$ and a finite covering $\mathcal{U}$ of $\mathcal{X}$ by quasi-compact open subschemes there is a descent spectral sequence

$$E_2^{pq} = \check{H}^p(\mathcal{U}, K_{-q,\mathcal{X}}) \Rightarrow K_{-p-q}(\mathcal{X}),$$

compare Clausen, Mathew, Naumann, and Noel [2016, App. A] and Thomason and Trobaugh [1990, Prop. 8.3].

(DK2) For $\mathcal{X}$ affine, that is $\mathcal{X}$ is the spectrum of a simplicial ring, the map $K_i(\mathcal{X}) \xrightarrow{\simeq} K_i(t\mathcal{X})$ is an isomorphism for $i \leq 1$, compare Blumberg, Gepner, and Tabuada [2013, Thm. 9.53] and Kerz, Strunk, and Tamme [2018, Thm. 2.16].

Putting properties (DK1) and (DK2) together yields:

(DK3) For a quasi-compact, separated derived scheme $\mathcal{X}$ which has a covering by $d+1$ affine open subschemes the maps $K_i(\mathcal{X}) \xrightarrow{\simeq} K_i(t\mathcal{X}) \xrightarrow{\simeq} K_i((t\mathcal{X})_{\mathrm{red}})$ are isomorphisms for $i \leq -d$.

Proposition 10. *Let $X = \operatorname{Spec} A$ be a noetherian local scheme, let $Y \hookrightarrow X$ be a closed subscheme. Set $d = \dim(X)$, $\tilde{X} = \mathbf{Bl}_Y X$ and $E = f^{-1}(Y)$. Then the map $f^* : K_i(X,Y) \to K_i(\tilde{X},E)$ is an isomorphism for $i < -d$.*

Proof. Let $I \subset A$ be the ideal corresponding to Y. After replacing I by some power, we can assume that there exists a reduction of I generated by elements $a_0, \dots, a_r$ with $r < d$, see Huneke and Swanson [2006, Prop. 8.3.8]. Choose a noetherian ring A' together with a regular sequence $a'_0, \dots, a'_r \in A'$ whose image under a ring homomorphism $A' \to A$ is the sequence $a_0, \dots, a_r$. Set $X' = \operatorname{Spec} A'$ and $Y'(n) = \operatorname{Spec} A'/((a'_0)^{2^n}, \dots, (a'_r)^{2^n})$ for $n \geq 0$. The derived blow-up square

$$(2)\qquad \begin{array}{ccc} \tilde{\mathcal{X}}(m) & \longleftarrow & \mathcal{E}(m,n) \\ \downarrow & & \downarrow \\ X & \longleftarrow & \mathcal{Y}(n) \end{array}$$

is defined as the derived pullback of the usual cartesian blow-up square

$$\begin{array}{ccc} \mathbf{Bl}_{Y'(m)} X' & \longleftarrow & E'(m,n) \\ \downarrow & & \downarrow \\ X' & \longleftarrow & Y'(n) \end{array}$$

According to a derived generalization Kerz, Strunk, and Tamme [2018, Thm. 3.7] of a descent result of Thomason [1993], the square (2) gives rise to an equivalence of relative K-theory spectra $K(X, \mathcal{Y}(n)) \xrightarrow{\simeq} K(\tilde{\mathcal{X}}(n), \mathcal{E}(n,n))$ for any $n \geq 0$.

By property (DK2) above, we know that

$$K_i(X, \mathcal{Y}(n)) \xrightarrow{\simeq} K_i(X,Y)$$

is an isomorphism for $i \le 0$, $n \ge 0$ and by property (DK3) we know that

$$K_i(\tilde{\mathcal{X}}(n), \mathcal{E}(n,n)) \xrightarrow{\simeq} K_i(t\tilde{\mathcal{X}}(n), t\mathcal{E}(n,n))$$

is an isomorphism for $i < -d$, $n \ge 0$. Note that $\tilde{\mathcal{X}}$ and $\mathcal{E}$ have affine coverings by $r+1 \le d$ open subschemes.

Finally, we apply Corollary 5 to the cartesian square

$$\begin{array}{ccc} \tilde{X} & \longleftarrow & E(n) \\ \downarrow & & \downarrow \\ t\tilde{\mathcal{X}}(m) & \longleftarrow & t\mathcal{E}(m,n) \end{array}$$

for n large depending on m, in which the vertical maps are finite by Huneke and Swanson [2006, Thm. 8.2.1]. We deduce that

$$\lim_n K_i(t\tilde{\mathcal{X}}(m), t\mathcal{E}(m,n)) \xrightarrow{\simeq} \lim_n K_i(\tilde{X}, E(n))$$

is an isomorphism for $i < -d$ and $m \ge 0$. For $i < -d$ composing the isomorphisms

$$K_i(X,Y) \xrightarrow{\simeq} \lim_n K_i(X, \mathcal{Y}(n)) \xrightarrow{\simeq} \lim_n K_i(\tilde{\mathcal{X}}(n), \mathcal{E}(n,n)) \xrightarrow{\simeq} \lim_n K_i(t\tilde{\mathcal{X}}(n), t\mathcal{E}(n,n)) \xrightarrow{\simeq} \lim_m \lim_n K_i(t\tilde{\mathcal{X}}(m), t\mathcal{E}(m,n)) \xrightarrow{\simeq} \lim_n K_i(\tilde{X}, E(n)) \xrightarrow{\simeq} K_i(\tilde{X}, E)$$

finishes the proof of Proposition 10. □

Proof of Theorem 8(i). For the proof we make an induction on $d = \dim(X)$. The case $d = 0$ is clear as then $K_i(X) \xrightarrow{\simeq} K_i(X_{\mathrm{red}})$ vanishes for $i < 0$ by Proposition 1. For the induction step we use the descent spectral sequence (1) in order to reduce to the case of a local scheme $X = \operatorname{Spec} A$, see Kerz, Strunk, and Tamme [2018, Prop. 6.1] for details. Since in the affine case $K_i(X) \xrightarrow{\simeq} K_i(X_{\mathrm{red}})$ is an isomorphism for $i \le 0$, we can assume without loss of generality that X is reduced.

Fix $\gamma \in K_i(X)$ for some $i < -d$. Let $Y \hookrightarrow X$ be a closed subscheme defined by an invertible ideal sheaf such that $\gamma|_{X\setminus Y} = 0$. This means that γ can be lifted to an element $\gamma' \in K_i(X \text{ on } Y)$. By Proposition 7 there exists a blow-up $f : \tilde{X} \to X$ in a center $Z \hookrightarrow X$ which is set theoretically contained in Y such that the pullback of γ' along f vanishes, in particular $f^*(\gamma) = 0 \in K_i(\tilde{X})$.

Set $E = f^{-1}(Z)$ and consider the commutative diagram with exact rows

$$\begin{array}{ccccccc} K_{i+1}(E) & \longrightarrow & K_i(\tilde{X}, E) & \longrightarrow & K_i(\tilde{X}) & \longrightarrow & K_i(E) \\ \uparrow & & \uparrow & & \uparrow f^* & & \uparrow \\ K_{i+1}(Z) & \longrightarrow & K_i(X, Z) & \longrightarrow & K_i(X) & \longrightarrow & K_i(Z) \end{array} \tag{3}$$

As $\dim(Z), \dim(E) < d$ the K-groups in the outer corners of diagram (3) vanish by our induction assumption. The second vertical arrow in (3) is an isomorphism by Proposition 10. So the third vertical arrow is an isomorphism as well, which implies that $\gamma = 0$. □

While the negative K-groups $K_i(X)$ for $-d = -\dim(X) < i < 0$ can be quite hard to calculate, there is nice formula for $K_{-d}(X)$, which was shown in complete generality in Kerz, Strunk, and Tamme [2018, Cor. D] and previously for varieties in characteristic zero Cortiñas, Haesemeyer, Schlichting, and C. Weibel [2008].

Theorem 11. *For a noetherian scheme of dimension $d < \infty$ there is a canonical isomorphism*

$$K_{-d}(X) = H^d_{\mathrm{cdh}}(X, \mathbb{Z}),$$

where on the right we take sheaf cohomology with respect to the cdh-topology on X.

4 Negative K-groups of affinoid algebras

In this section let k be a (non-discrete) non-archimedean complete field with ring of integers k°. By π we denote an element with absolute value $0 < |\pi| < 1$. For an affinoid algebra A over k, see Bosch [2014, Sec. 3.1], we write $A\langle t\rangle$ for the Tate algebra over A, which consists of those formal power series $a_0 + a_1 t + \cdots \in A[\![t]\!]$ with $\lim_{i\to\infty} a_i = 0$, similarly for $A\langle t^{-1}\rangle$ and $A\langle t, t^{-1}\rangle$. One defines non-positive continuous K-groups of A successively by $K_0^{\mathrm{cont}}(A) = K_0(A)$ and

$$K_i^{\mathrm{cont}}(A) = \operatorname{coker}\left[K_{i+1}^{\mathrm{cont}}(A\langle t\rangle) \times K_{i+1}^{\mathrm{cont}}(A\langle t^{-1}\rangle) \to K_{i+1}^{\mathrm{cont}}(A\langle t, t^{-1}\rangle)\right]$$

for $i < 0$. These negative continuous K-groups were defined and studied in Karoubi and Villamayor [1971, Sec. 7] and Calvo [1985]. They also coincide with the continuous pro-groups defined in Morrow [2016, Sec. 3] as is shown in Kerz, Saito, and Tamme [2018, Sec. 5].

We are about to show that the analog of Weibel's conjecture, i.e. Theorem 8, holds in the non-archimedean situation:

Theorem 12. *Assume that k is discretely valued. For an affinoid k-algebra A of dimension d we have:*

(i) $K_i^{\mathrm{cont}}(A) = 0$ *for* $i < -d$,

(ii) $K_i^{\mathrm{cont}}(A) \xrightarrow{\simeq} K_i^{\mathrm{cont}}(A\langle t_1, \dots, t_r\rangle)$ *is an isomorphism for* $i \le -d$ *and any number of variables* r.

I expect that the condition that k is discretely valued in Theorem 12 can be removed. Note that even for smooth affinoid algebras A the negative continuous K-groups do not necessarily vanish, as the following example shows.

Example 13. *Assume that the residue field of* k *has characteristic zero and let* $\pi \in k$ *be an element of absolute value* $0 < |\pi| < 1$. *For the affinoid algebra* $A = k\langle s,t\rangle/(t^2 - s^3 + s^2 - \pi)$ *we have* $K_{-1}^{\mathrm{cont}}(A) = \mathbb{Z}$.

The key fact for us is that for an admissible k°-algebra A_0 in the sense of Bosch [2014, Def. 7.3.3] with $A = A_0[1/\pi]$ we obtain an exact sequence, see Kerz, Saito, and Tamme [2018, Sec. 5],

$$K_0(A_0 \text{ on } (\pi)) \to K_0((A_0/(\pi))_{\mathrm{red}}) \to K_0^{\mathrm{cont}}(A) \to K_{-1}(A_0 \text{ on } (\pi)) \to \cdots . \tag{4}$$

Recall that an admissible k°-algebra A_0 is π-adically complete, topologically of finite type and π-torsion free.

The claim made in Example 13 follows from the exact sequence (4) by setting $A_0 = k^\circ\langle s,t\rangle/(t^2 - s^3 + s^2 - \pi)$ and using that in this case $K_i(A_0 \text{ on } (\pi)) = 0$ for $i < 0$ and that $K_{-1}((A_0/(\pi))_{\mathrm{red}}) = \mathbb{Z}$.

Proof of Theorem 12(i). We can assume without loss of generality that A is reduced. An admissible blow-up of $X = \operatorname{Spec} A_0$, where A_0 is an admissible k°-algebra as above, is defined as a blow-up in a center $Y \hookrightarrow X$ which is set theoretically contained in $\operatorname{Spec} A_0/(\pi)$. Let now $\tilde{X} = \mathbf{Bl}_Y X$ be such an admissible blow-up, $X_0 = (X \otimes_{A_0} A_0/(\pi))_{\mathrm{red}}$ and $\tilde{X}_0 = (\tilde{X} \otimes_{A_0} A_0/(\pi))_{\mathrm{red}}$. For $i < -d$ we obtain from Kerz, Saito, and Tamme [ibid., Prop. 5.8] the upper exact sequence in the commutative diagram

$$\begin{array}{ccccc} K_i(\tilde{X}_0) & \longrightarrow & K_i^{\mathrm{cont}}(A) & \longrightarrow & K_{i-1}(\tilde{X} \text{ on } (\pi)) \\ \uparrow & & \| & & \uparrow \\ K_i(X_0) & \longrightarrow & K_i^{\mathrm{cont}}(A) & \longrightarrow & K_{i-1}(X \text{ on } (\pi)) \end{array} \tag{5}$$

while the lower exact sequence is just part of (4). Both groups on the left of (5) vanish by Theorem 8 since $i < -d = -\dim(X_0) = -\dim(\tilde{X}_0)$. Consider an element $\alpha \in K_i^{\mathrm{cont}}(A)$. For its image $\alpha' \in K_{i-1}(X \text{ on } (\pi))$ we can use Proposition 7 in order to choose the admissible blow-up $\tilde{X}$ such that the pullback of α' to $K_{i-1}(\tilde{X}$ on $(\pi))$ vanishes. A diagram chase in (5) shows that α vanishes. □

The forthcoming PhD thesis of C. Dahlhausen will discuss the following conjecture, which is the non-archimedean analytic variant of Theorem 11.

Conjecture 14. *For an affinoid k-algebra A of dimension d there is an isomorphism*

$$K_{-d}^{\mathrm{cont}}(A) \cong H^d(\mathfrak{M}(A), \mathbb{Z}).$$

Here $\mathfrak{M}(A)$ is the Berkovich spectrum of multiplicative seminorms Berkovich [1990, Ch. 1].

Acknowledgments. I would like to thank H. Esnault, O. Gabber, M. Groechenig, M. Morrow, S. Saito, F. Strunk, G. Tamme and C. Weibel for helpful discussions.

ON THE CLASSIFICATION OF FUSION CATEGORIES

Sonia Natale

Abstract

We report, from an algebraic point of view, on some methods and results on the classification problem of fusion categories over an algebraically closed field of characteristic zero.

For I could not count or name the multitude who came to Troy, though I had ten tongues and a tireless voice, and lungs of bronze as well...

Homer, *Iliad, Book II (The catalogue of ships)*

1 Introduction

Fusion categories arise from many areas of mathematics and mathematical physics encoding symmetries of structures of different nature and in this sense they can be regarded as a generalization of (finite) groups. This makes the problem of classifying fusion categories both an exciting and at the same time a colossal task. Some classes of examples of fusion categories with distinct features come from such structures like finite groups themselves, quantum groups at roots of 1, subfactors, vertex algebras... A unifying systematic approach to the theory of fusion categories was initiated in the paper Etingof, Nikshych, and Ostrik [2005]. The classification is still in an early age and perhaps awaiting for its monsters to wake up. Some progress has been made however towards the classification of fusion categories in certain classes. What we want to present here is an overview of some constructions, results and open questions related to the classification problem that we think are interesting. The world of fusion categories is a vast one and there are also important constructions, results and questions that we are not going to discuss here, mainly due to space constraints. Our approach concerns the algebraic aspect of fusion categories

2000 *Mathematics Subject Classification:* primary 18D10; secondary 16T05.
Keywords: tensor category, fusion category, braided fusion category.

and it is for the most part motivated by different notions of extensions. The perspectives we present are the fruit of the efforts of many and the list of references at the end of the paper is not exhaustive.

We shall work over an algebraically closed base field k. Except in Sections 2.1, 2.2 and Section 4, we assume that k is of characteristic zero. We refer the reader to the book Etingof, Gelaki, Nikshych, and Ostrik [2015] and references therein for most notions on tensor and fusion categories appearing throughout.

2 Fusion categories

We start by recalling some basic definitions and notation regarding monoidal and tensor categories and the relevant functors between them. A detailed study can be found in the books Bakalov and Kirillov [2001], Etingof, Gelaki, Nikshych, and Ostrik [2015], Kassel [1995], Majid [1995], V. G. Turaev [1994].

2.1 Basic notions. A *monoidal category* is a collection $(\mathcal{C}, \otimes, \mathbf{1}, a, l, r)$, where $\mathcal{C}$ is a category, $\otimes : \mathcal{C} \times \mathcal{C} \to \mathcal{C}$ is a functor, $\mathbf{1}$ is an object of $\mathcal{C}$, called the *unit object*,

$$a : \otimes \circ (\otimes \times \mathrm{id}_{\mathcal{C}}) \to \otimes \circ (\mathrm{id}_{\mathcal{C}} \times \otimes), \quad l : \mathbf{1} \otimes \mathrm{id}_{\mathcal{C}} \to \mathrm{id}_{\mathcal{C}}, \quad r : \mathrm{id}_{\mathcal{C}} \otimes \mathbf{1} \to \mathrm{id}_{\mathcal{C}},$$

are natural isomorphisms called, respectively, the associativity and left and right unit constraints, subject to the so-called *pentagon* and *triangle* axioms. For the sake of brevity, we shall simply speak of 'the monoidal category $\mathcal{C}$'.

Let $\mathcal{C}$, $\mathcal{D}$ be monoidal categories. A *monoidal functor* $\mathcal{C} \to \mathcal{D}$ is a triple (F, F^2, F^0)[1], where $F : \mathcal{C} \to \mathcal{D}$ is a functor, $F^0 : \mathbf{1} \to F(\mathbf{1})$ is an isomorphism compatible with the unit constraints, and $F^2 : \otimes \circ (F \times F) \to F \circ \otimes$ is a natural isomorphism such that, for all objects X, Y, Z of $\mathcal{C}$,

$$(F^2_{X,Y\otimes Z})(\mathrm{id}_{F(X)} \otimes F^2_{Y,Z}) a_{F(X),F(Y),F(Z)} = F(a_{X,Y,Z}) F^2_{X\otimes Y,Z}(F^2_{X,Y} \otimes \mathrm{id}_{F(Z)}).$$

An *equivalence of monoidal categories* is a monoidal functor (F, F^2, F^0) such that F is an equivalence of categories.

A monoidal category $\mathcal{C}$ is called *strict* if the associativity and unit constraints of $\mathcal{C}$ are identities. A famous result of Mac Lane states that every monoidal category is monoidally equivalent to a strict monoidal category. This allows us in (most of) what follows to suppress the associativity and unit isomorphisms.

[1] The explicit mention of F^2 and F^0 will be often omitted in what follows.

A *braiding* in a monoidal category $\mathcal{C}$ is a natural isomorphism $c_{X,Y} : X \otimes Y \to Y \otimes X$, $X, Y \in \mathcal{C}$, subject to the so-called hexagon axioms. A *braided monoidal category* is a monoidal category endowed with a braiding Joyal and Street [1993]. Braided monoidal categories such that $c_{Y,X} c_{X,Y} = \mathrm{id}_{X \otimes Y}$, for all objects $X, Y \in \mathcal{C}$, are called *symmetric*.

Let $\mathcal{C}$ be a monoidal category. Then the *Drinfeld center* $\mathcal{Z}(\mathcal{C})$ of $\mathcal{C}$ is the braided monoidal category whose objects are pairs (Z, σ_Z), where Z is an object of $\mathcal{C}$ and $\sigma_Z : Z \otimes - \to - \otimes Z$ is a natural isomorphism satisfying appropriate compatibility conditions. The tensor product of $\mathcal{Z}(\mathcal{C})$ is induced from that of $\mathcal{C}$.

Let $\mathcal{C}$ be a monoidal category. A *left dual* of an object X of $\mathcal{C}$ is a triple $(X^*, \mathrm{ev}_X, \mathrm{coev}_X)$, where X^* is an object of $\mathcal{C}$ and $\mathrm{ev}_X : X^* \otimes X \to \mathbf{1}$, $\mathrm{coev}_X : \mathbf{1} \to X \otimes X^*$, are morphisms in $\mathcal{C}$ called, respectively, evaluation and coevaluation morphisms such that the following compositions are identities:

$$X \xrightarrow{\mathrm{coev}_X \otimes \mathrm{id}_X} X \otimes X^* \otimes X \xrightarrow{\mathrm{id}_X \otimes \mathrm{ev}_X} X, \quad X^* \xrightarrow{\mathrm{id}_{X^*} \otimes \mathrm{coev}_X} X^* \otimes X \otimes X^* \xrightarrow{\mathrm{ev}_X \otimes \mathrm{id}_{X^*}} X^*,$$

A *right dual* of X is defined as a triple $({}^*X, \mathrm{ev}'_X, \mathrm{coev}'_X)$, where $\mathrm{ev}'_X : X \otimes {}^*X \to \mathbf{1}$, $\mathrm{coev}'_X : \mathbf{1} \to {}^*X \otimes X$ are morphisms satisfying similar axioms. The monoidal category $\mathcal{C}$ is called *rigid* if every object X has left and right duals X^*, ${}^*X$.

A *tensor category* over the field k is a k-linear abelian category with finite dimensional Hom spaces and objects of finite length, endowed with a rigid monoidal category structure, such that the monoidal product is k-linear in each variable and the unit object is simple. In a tensor category the monoidal product is exact in each variable. A *tensor functor* between tensor categories is a k-linear exact monoidal functor. Every tensor functor preserves duals and it is automatically faithful. A tensor functor $F : \mathcal{C} \to \mathfrak{D}$ between tensor categories $\mathcal{C}$ and $\mathfrak{D}$ is *dominant* if every object of $\mathfrak{D}$ is a subobject of $F(X)$, for some $X \in \mathcal{C}$.

A tensor category over k is called *finite* if it is equivalent as a k-linear category to the category of finite dimensional left modules over a finite dimensional k-algebra. A *fusion category over k* is a semisimple finite tensor category.

Example 2.1. Examples of tensor categories over k are given by the categories of finite dimensional left (resp. right) modules and finite dimensional left (resp. right) comodules over a *Hopf algebra* over k with bijective antipode. The tensor product in these examples is $\otimes_k$ and the associativity and unit constraints are the canonical vector space isomorphisms. These categories will be denoted, respectively, by H-mod, mod-H, H-comod, comod-H. Finite tensor categories $\mathcal{C}$ equivalent to H-mod, for some finite-dimensional Hopf algebra H, are exactly those that admit a *fiber functor*, that is, a tensor functor $\mathcal{C} \to \mathrm{Vect}_k$, where Vect_k is the tensor category of finite dimensional k-vector spaces.

More generally, if H is a *quasi-Hopf algebra* over k, then the category H-mod of finite dimensional H-modules is a tensor category over k; here the tensor product is $\otimes_k$ but the associativity constraint is induced by the associator $\Phi \in H^{\otimes 3}$ V. G. Drinfeld

[1989b]. Let H_1, H_2 be finite dimensional quasi-Hopf algebras. The tensor categories H_1-mod and H_2-mod are equivalent if and only if H_1 and H_2 are *gauge equivalent*, that is, $H_2 \cong (H_1)_F$ as quasi-Hopf algebras, where $(H_1)_F$ is certain quasi-Hopf algebra such that $(H_1)_F = H_1$ as an algebra with comultiplication $\Delta_F(h) = F\Delta(h)F^{-1}$, $h \in H_1$, and associator $\Phi_F = (1 \otimes F)(\mathrm{id} \otimes \Delta)(F)\Phi(\Delta \otimes \mathrm{id})(F^{-1})(F^{-1} \otimes 1)$.

When $\mathcal{C}$ is the representation category of a finite dimensional (quasi-)Hopf algebra H, then the Drinfeld center $\mathcal{Z}(\mathcal{C})$ is equivalent to the category $D(H)$-mod, where $D(H)$ is the quantum double of H V. G. Drinfeld [1989a], Hausser and Nill [1999], Majid [1998].

The previous example admits several generalizations. In the next example we give an outline of a construction from Hopf monads Bruguières and Virelizier [2007], Bruguières, Lack, and Virelizier [2011].

Example 2.2. A *monad* on a category $\mathcal{C}$ is an algebra in the monoidal category of endofunctors of $\mathcal{C}$. We refer the reader to Mac Lane [1998] for a study of this notion and its relation with adjunctions of functors. A *bimonad* on $\mathcal{C}$ (introduced previously by Moerdijk under the name 'Hopf monad') is a monad T endowed with a structure of a (lax) comonoidal endofunctor, that is, a natural transformation $T_2 : T \circ \otimes \to \otimes \circ (T \times T)$ and a morphism $T_0 : T(\mathbf{1}) \to \mathbf{1}$ satisfying certain compatibility conditions. A *Hopf monad* on a rigid monoidal category $\mathcal{C}$ is a bimonad equipped with a left and a right antipode Bruguières and Virelizier [2007]. If T is a Hopf monad on a rigid monoidal category $\mathcal{C}$, then the category $\mathcal{C}^T$ of T-modules in $\mathcal{C}$ is a rigid monoidal category and the forgetful functor $U : \mathcal{C}^T \to \mathcal{C}$ is a strict monoidal functor. Furthermore, suppose that $\mathcal{C}$ is a tensor category over k, and let T be a k-linear right exact Hopf monad on $\mathcal{C}$. Then $\mathcal{C}^T$ is a tensor category over k, and the forgetful functor $U : \mathcal{C}^T \to \mathcal{C}$ is a tensor functor Bruguières and Natale [2011]. Further, $\mathcal{C}^T$ is a fusion category if and only if $\mathcal{C}$ is a fusion category and T is a semisimple Hopf monad in the sense of Bruguières and Virelizier [2007].

Let $F : \mathcal{C} \to \mathfrak{D}$ be a tensor functor between tensor categories. Suppose F admits a left adjoint (which is always the case if $\mathcal{C}$ and $\mathfrak{D}$ are finite tensor categories). Since F is faithful exact, as a consequence of results of Beck on monadicity of adjunctions (see Mac Lane [1998]), there exists a Hopf monad T on $\mathfrak{D}$ such that $\mathcal{C} \cong \mathfrak{D}^T$ as tensor categories.

Let G be a finite group. The next two basic examples are special cases of those in Example 2.1.

Example 2.3. The category $\operatorname{Rep} G$ of finite dimensional k-linear representations of G is a finite tensor category over k with the usual tensor product of representations and whose unit object is the trivial representation. Thus $\operatorname{Rep} G = kG$-mod, where kG is the group (Hopf) algebra of G. By Maschke theorem, $\operatorname{Rep} G$ is a fusion category if and only if the order of G is coprime to the characteristic of k.

Two finite groups G_1 and G_2 are called *isocategorical* if the categories $\operatorname{Rep} G_1$ and $\operatorname{Rep} G_2$ are equivalent as tensor categories. This notion was introduced in Etingof and Gelaki [2001], where necessary and sufficient conditions for two finite groups to be isocategorical were given. In particular, isocategorical groups need not be isomorphic when their (common) order is divisible by 4.

Example 2.4. Let $\omega : G \times G \times G \to k$ be a 3-cocycle on G. The category Vect_G^ω of finite dimensional G-graded k-vector spaces is a fusion category with tensor product $\otimes_k$, unit object $\mathbf{1} = k$ (graded in degree $1 \in G$), and associativity constraint induced by ω. Indeed, $\mathrm{Vect}_G^\omega = H$-mod, where H is the quasi-Hopf algebra k^G of k-valued functions on G with the usual comultiplication and associator $\omega \in k^{G\times G\times G} \cong (k^G)^{\otimes 3}$. The category Vect_G^ω admits a fiber functor if and only if the class of ω is trivial in $H^3(G, k^\times)$. Equivalence classes of fusion categories of the form Vect_G^ω are in bijection with the orbit space $H^3(G, k^\times)/\operatorname{Out} G$ with respect to the natural action of the group $\operatorname{Out} G$ of outer automorphisms of G in the third cohomology group $H^3(G, k^\times)$.

Suppose that $\mathcal{C}$ is a tensor category. An object X of $\mathcal{C}$ is called *invertible* if the evaluation ev_X and the coevaluation coev_X are isomorphisms. The set G of isomorphism classes of invertible objects of $\mathcal{C}$ is a group with multiplication induced by the tensor product of $\mathcal{C}$. The tensor category $\mathcal{C}$ is called *pointed* if every simple object of $\mathcal{C}$ is invertible. Every pointed fusion category is equivalent to a category Vect_G^ω, for some 3-cocycle ω, where G is the group of invertible objects of $\mathcal{C}$.

2.2 Quantum groupoids. A *weak Hopf algebra* (or *quantum groupoid*) over k is an associative algebra H endowed with a coassociative coalgebra structure (H, Δ, ϵ) such that Δ is multiplicative, that is, $\Delta(ab) = \Delta(a)\Delta(b)$, for all $a, b \in H$, and

$$(\Delta \otimes \mathrm{id})\Delta(1) = (\Delta(1) \otimes 1)(1 \otimes \Delta(1)) = (1 \otimes \Delta(1))(\Delta(1) \otimes 1).$$
$$\epsilon(abc) = \epsilon(ab_{(1)})\epsilon(b_{(2)}c) = \epsilon(ab_{(2)})\epsilon(b_{(1)}c), \qquad \forall a, b, c \in H,$$

where $b_{(1)} \otimes b_{(2)} = \Delta(b)$. The existence of an *antipode* is also required: this is a linear map $S : H \to H$ satisfying appropriate conditions. See Böhm, Nill, and Szlachányi [1999], Bòhm and Szlachónyi [1996], Nikshych and Vainerman [2002].

A quantum groupoid H gives rise to the tensor category H-mod of its finite dimensional representations. Here, the tensor product $\otimes$ is defined as

$$V \otimes W = \Delta(1)\ V \otimes_k W,$$

for objects $V, W \in H$-mod, and by restriction of the tensor product on morphisms. The unit object is the so-called *base* subalgebra of H, and the left and right duals of an object

$V \in H$-mod are defined using the antipode. Examples of quantum groupoids from certain so-called *double groupoids* were constructed in Andruskiewitsch and Natale [2006]. Semisimple finite dimensional quantum groupoids give rise to fusion categories. The key fact about them is that every fusion category is the representation category of a quantum groupoid, in view of results of Hayashi and Ostrik:

Theorem 2.5. *Hayashi [2000], Ostrik [2003a]. Let $\mathcal{C}$ be a (multi-)fusion[2] category over k. Then there exists a finite semisimple quantum groupoid H over k such that $\mathcal{C}$ is equivalent to H-mod. Moreover, it is always possible to choose H such that its base is a commutative algebra.*

Theorem 2.5 can be generalized to finite tensor categories; in this case the result states that every finite tensor category is equivalent to H-mod for some finite dimensional left *Hopf algebroid* (a more complicated structure than a quantum groupoid that will not be discussed here). This is proved in Bruguières, Lack, and Virelizier [2011] using Hopf monads.

For the rest of this section we assume that k is the field of complex numbers.

2.3 Fusion categories from quantum groups at roots of 1. Let $\mathfrak{g}$ be a simple complex Lie algebra. Let $h^\vee$ be the dual Coxeter number of $\mathfrak{g}$ and let $q \in \mathbb{C}$ such that q^2 is a primitive root of unity of order $\ell \geq h^\vee$. We sketch here a celebrated construction, due to Andersen and Paradowski Andersen and Paradowski [1995], of a fusion category, called *Verlinde category*, associated to the pair $(\mathfrak{g}, q)$.

Let $U_q(\mathfrak{g})$ denote the Lusztig's quantized enveloping algebra specialized at q Lusztig [1993]. A $U_q(\mathfrak{g})$-module T is called a *tilting module* if both T and its dual T^* have composition series whose factors are Weyl modules. The category $\mathcal{T}$ of tilting modules, although not abelian, is a k-linear *ribbon* category (c.f. SubSection 6.1), which allows to define the trace of an endomorphism $f : T \to T$. A morphism $f : T_1 \to T_2$ in $\mathcal{T}$ is called *negligible* if $\mathrm{Tr}(fg) = 0$ for every morphism $g : T_2 \to T_1$. The *Verlinde fusion category* associated to the pair $(\mathfrak{g}, q)$ is defined as the category whose objects are tilting modules and the morphism spaces are defined by modding out negligible morphisms. We refer the reader to Andersen and Paradowski [1995], Bakalov and Kirillov [2001], Sawin [2006], V. G. Turaev [1994] and references therein for a detailed exposition about this construction.

Other celebrated construction of fusion (in fact modular) categories arising from the simple complex Lie algebra $\mathfrak{g}$ are the categories $\mathcal{C}(\mathfrak{g}, k)$ of integrable highest weight modules of level $k \in \mathbb{Z}_+$ over the corresponding affine Lie algebra $\widehat{\mathfrak{g}}$. See Bakalov and Kirillov

[2] The definition of a multi-fusion category is like that of a fusion category, but dropping the assumption of simplicity of the unit object.

[2001, Chapter 7] for a proof of this fact as well as for the relevant references and a historical overview. Alternatively, the category $\mathcal{C}(\mathfrak{g}, k)$ can be described as the category of finite length modules over the simple vertex algebra $V(\mathfrak{g}, k)$ associated with the vacuum $\widehat{\mathfrak{g}}$-module of level k Huang and Lepowsky [1999]. The relation between these categories and Verlinde categories is given by a theorem of Finkelberg [1996] that asserts that $\mathcal{C}(\mathfrak{g}, k)$ is equivalent as a modular category to the Verlinde category associated to the pair $(\mathfrak{g}, q)$, where $q = \exp(\pi i / m(k + h^\vee))$, such that $m := \langle\langle \alpha, \alpha \rangle\rangle / 2$ for a long root α of $\mathfrak{g}$, $\langle\langle\ ,\ \rangle\rangle$ being an invariant bilinear form on $\mathfrak{g}$ normalized so that $\langle\langle \beta, \beta \rangle\rangle = 2$ for short roots β. See Huang [2008].

2.4 Fusion categories from subfactors. A *subfactor* is an inclusion $A \subseteq B$ of von Neumann algebras with trivial centers. A subfactor $A \subseteq B$ is called of *finite depth* if the tensor powers of the A-bimodule B contain a finite number of isomorphism classes of simple bimodules. A subfactor $A \subseteq B$ of finite index Jones [1983] and finite depth gives rise to a (unitary) fusion category $\mathcal{C}$, called its *principal even part*: this is the full subcategory of the category of A-bimodules generated by the tensor powers of the A-bimodule B. The full subcategory of the category of B-bimodules generated by the tensor powers of the B-bimodule $B \otimes_A B$ is also a fusion category, called the *dual even part* of $A \subseteq B$, which is categorically Morita equivalent to the principal even part (c.f. SubSection 3.3).

Certain examples of fusion categories associated to subfactors do not arise from quantum groups or finite groups by means of any known contruction. Such exotic examples appear related to the Haagerup subfactor, the Asaeda-Haagerup subfactor Asaeda and Haagerup [1999], Haagerup [1994] and the extended Haagerup subfactor Bigelow, Peters, Morrison, and Snyder [2012] and have been intesively studied in the literature; see Grossman, Izumi, and Snyder [2015], Izumi [2001], Jones, Morrison, and Snyder [2014], Peters [2010], and references therein.

The Haagerup and the extended Haagerup subfactors give rise to examples of fusion categories that cannot be defined over a cyclotomic field Morrison and Snyder [2012]. Nevertheless, a result of Etingof, Nikshych, and Ostrik [2005] known as *Ocneanu rigidity* implies that every fusion category can always be defined over an algebraic number field.

3 Some invariants of a fusion category

3.1 Grothendieck ring. Let $\mathcal{C}$ be a fusion category over k and let $\mathrm{Irr}(\mathcal{C})$ denote the set of isomorphism classes of simple objects of $\mathcal{C}$. The Grothendieck group $\mathrm{Gr}(\mathcal{C})$ is the free abelian group with basis $\mathrm{Irr}(\mathcal{C})$. The cardinality of $\mathrm{Irr}(\mathcal{C})$ is called the *rank* of $\mathcal{C}$. The tensor product of $\mathcal{C}$ endows $\mathrm{Gr}(\mathcal{C})$ with a ring structure with unit element $[\mathbf{1}]$ such that, for all objects X and Y, $[X][Y] = [X \otimes Y]$, where $[X]$ denotes the isomorphism class of the object X.[3] For all $X, Y \in \operatorname{Irr}(\mathcal{C})$ we have decompositions

$$XY = \sum_{Z \in \operatorname{Irr}(\mathcal{C})} N_{X,Y}^{Z}\, Z,$$

called the *fusion rules* of $\mathcal{C}$, where the *fusion coefficients* $N_{X,Y}^{Z}$ of $\mathcal{C}$ are the non-negative integers given by $N_{X,Y}^{Z} = \dim_k \operatorname{Hom}_{\mathcal{C}}(Z, X \otimes Y)$, for all $X, Y, Z \in \operatorname{Irr}(\mathcal{C})$.

The duality of $\mathcal{C}$ induces an anti-involution of the Grothendieck ring $\operatorname{Gr}(\mathcal{C})$ that makes it into a *fusion ring* Etingof, Gelaki, Nikshych, and Ostrik [2015, Definition 3.1.3]. In particular, the fusion coefficients satisfy the relations

$$N_{X,Y}^{\mathbf{1}} = \delta_{Y,X^*}, \quad N_{X,Y}^{Z^*} = N_{Z,X}^{Y^*} = N_{Y,Z}^{X^*}, \quad \text{for all } X, Y, Z \in \operatorname{Irr}(\mathcal{C}).$$

Two fusion categories $\mathcal{C}$ and $\mathfrak{D}$ are *Grothendieck equivalent* (or *have the same fusion rules*) if there is a bijection between $\operatorname{Irr}(\mathcal{C})$ and $\operatorname{Irr}(\mathfrak{D})$ that induces a unit preserving ring isomorphism $\operatorname{Gr}(\mathcal{C}) \cong \operatorname{Gr}(\mathfrak{D})$. Non-equivalent fusion categories may share the same fusion rules: examples are the fusion categories of finite dimensional representations of the non-isomorphic non-abelian groups of order 8 Tambara and Yamagami [1998].

A *fusion subcategory* of a fusion category $\mathcal{C}$ is a full abelian subcategory closed under subquotients and tensor products. A fusion subcategory is automatically closed under duality, whence it contains the unit object of $\mathcal{C}$, and thus it is a fusion category Etingof, Gelaki, Nikshych, and Ostrik [2015, Corollary 4.11.4]. Fusion subcategories of $\mathcal{C}$ are in bijective correspondence with unital subrings of $\operatorname{Gr}(\mathcal{C})$ spanned by subsets of $\operatorname{Irr}(\mathcal{C})$. In particular, if $\mathcal{C}$ and $\mathfrak{D}$ are Grothendieck equivalent fusion categories, then the lattices of fusion subcategories of $\mathcal{C}$ and $\mathfrak{D}$ are isomorphic.

The following theorem is a consequence of a result known as *Ocneanu rigidity*, which states that fusion categories do not admit nontrivial deformations.

Theorem 3.1. *Etingof, Nikshych, and Ostrik [2005]. Up to equivalence, there is a finite number of fusion categories with a given Grothendieck ring.*

The following question remains open, although it has been established in Bruillard, Ng, E. C. Rowell, and Wang [2016b] for modular categories (see SubSection 6.1 below).

Question 3.2. Ostrik [2003b]. Are there finitely many equivalence classes of fusion categories with a given finite rank?

The answer to this question is known to be affirmative for fusion categories whose Frobenius-Perron dimension (as defined in SubSection 3.2 below) is an integer Etingof, Nikshych, and Ostrik [2005]. A related result of Etingof says that there is a finite number,

[3] By abuse of notation, we shall also write X to indicate the class of X in $\operatorname{Gr}(\mathcal{C})$.

up to Hopf algebra isomorphism, of semisimple Hopf algebras with a given finite number of irreducible representations Ostrik [2003b, Appendix]. The answer is also affirmative in small rank under certain restrictions: this was proved by Ostrik for rank 2 Ostrik [ibid.] and for rank 3 *pivotal* fusion categories Ostrik [2015].

3.2 Frobenius-Perron dimension. Let $\mathcal{C}$ be a fusion category. The *Frobenius-Perron dimension* of a simple object $X \in \mathcal{C}$ is the Frobenius-Perron eigenvalue of the matrix of left multiplication by the class of X in the basis $\operatorname{Irr}(\mathcal{C})$ of the Grothendieck ring of $\mathcal{C}$ consisting of isomorphism classes of simple objects. The *Frobenius-Perron dimension of* $\mathcal{C}$ is the number $\operatorname{FPdim}\mathcal{C} = \sum_{X\in \operatorname{Irr}(\mathcal{C})}(\operatorname{FPdim} X)^2$. The Frobenius-Perron dimension extends to a ring homomorphism $\operatorname{FPdim} : \operatorname{Gr}(\mathcal{C}) \to \mathbb{R}$ which is characterized by the fact that $\operatorname{FPdim} X > 0$, for all $X \in \operatorname{Irr}(\mathcal{C})$.

Let $\mathcal{C}$ and $\mathfrak{D}$ be fusion categories. Suppose that $F : \mathcal{C} \to \mathfrak{D}$ is a dominant tensor functor. Then the number $\operatorname{FPdim}\mathcal{C}/\operatorname{FPdim}\mathfrak{D}$ is an algebraic integer. This is also true if $\mathfrak{D}$ is a fusion subcategory of $\mathcal{C}$. See Etingof, Nikshych, and Ostrik [2005]. In particular, if $\mathcal{C}$ is integral, then $\operatorname{FPdim}\mathfrak{D}$ divides $\operatorname{FPdim}\mathcal{C}$.

Let $\mathcal{C}$ be any fusion category. For every object X of $\mathcal{C}$, $\operatorname{FPdim} X$ is a cyclotomic integer ≥ 1. Furthermore, it is known that if $\operatorname{FPdim}(X) < 2$, for some $X \in \operatorname{Irr}(\mathcal{C})$, then $\operatorname{FPdim}(X) = 2\cos(\pi/n)$, for some integer $n \geq 3$. See Etingof, Nikshych, and Ostrik [ibid.]. We have the following result on small dimensions of objects in a fusion category:

Theorem 3.3. *Calegari, Morrison, and Snyder [2011]. Let X be an object in a fusion category such that* $\operatorname{FPdim} X$ *belongs to the interval* $(2, 76/33]$. *Then* $\operatorname{FPdim} X$ *is equal to one of the following:*

$$\frac{\sqrt{7}+\sqrt{3}}{2}, \quad \sqrt{5}, \quad 1+2\cos(\frac{2\pi}{7}), \quad \frac{1+\sqrt{5}}{\sqrt{2}}, \quad \frac{1+\sqrt{13}}{2}.$$

Moreover, each of these numbers occurs as the Frobenius-Perron dimension of an object of a fusion category.

A fusion category $\mathcal{C}$ is called *integral* if $\operatorname{FPdim} X \in \mathbb{Z}$, for all simple object $X \in \mathcal{C}$. A fusion category over k is integral if and only if it is equivalent to the category of finite dimensional representations of a finite dimensional semisimple quasi-Hopf algebra over k. If this is the case, then for every H-module V we have $\operatorname{FPdim} V = \dim_k V$. Every fusion category of odd integer Frobenius-Perron dimension is integral Gelaki and Nikshych [2008].

Let $\mathcal{C}$ be an integral fusion category. One can attach some graphs to the set $\operatorname{cd}(\mathcal{C})$ of Frobenius-Perron dimensions of simple objects in the category $\mathcal{C}$: the *prime graph* $\Delta(\mathcal{C})$, whose vertices are the prime divisors of elements of $\operatorname{cd}(\mathcal{C})$ such that two vertices p and q

are joined by an edge if and only if the product pq divides some element of $\mathrm{cd}(\mathcal{C})$, and the *common divisor* graph $\Gamma(\mathcal{C})$, whose vertices are the elements of $\mathrm{cd}(\mathcal{C})-\{1\}$ such that two vertices are joined by an edge if and only if they are not coprime. These graphs extend the corresponding graphs associated to the irreducible character degrees and the conjugacy class sizes of a finite group. Some generalizations of known results on the number of connected components of these graphs for finite groups hold as well in the context of fusion categories Natale and Pacheco Rodríguez [2016].

Remark 3.4. The *categorical* or *global dimension* of a fusion category $\mathcal{C}$ is defined as $\dim \mathcal{C} = \sum_{X\in \mathrm{Irr}(\mathcal{C})} |X|^2$ where, for each simple object X of $\mathcal{C}$, $|X|^2 = \mathrm{Tr}_L(a_X)\mathrm{Tr}_L((a_X^{-1})^*)$, $a_X : X \to X^{**}$ being a fixed isomorphism (which necessarily exists in a fusion category), and $\mathrm{Tr}_L(a_X) = \mathrm{ev}_{X^*}(a_X \otimes \mathrm{id}_{X^*})\mathrm{coev}_X$ Müger [2003a]. A *spherical* structure on $\mathcal{C}$ is an isomorphism of tensor functors $\tau : \mathrm{id}_{\mathcal{C}} \to (\ )^{**}$ such that $\mathrm{Tr}_L(f) = \mathrm{Tr}_R(f)$, for any endomorphism $f : X \to X$ in $\mathcal{C}$, where Tr_L and Tr_R are certain left and right traces induced by τ. A fusion category $\mathcal{C}$ is called *pseudo-unitary* if $\dim(\mathcal{C}) = \mathrm{FPdim}(\mathcal{C})$; this is always the case if $\mathrm{FPdim}\,\mathcal{C}$ is an integer. Every pseudo-unitary fusion category $\mathcal{C}$ has a unique *spherical* structure whose categorical dimensions coincide with the Frobenius-Perron dimensions Etingof, Nikshych, and Ostrik [2005].

In the next examples we discuss some classes of non-pointed fusion categories with distinguished fusion rules.

Example 3.5. *(Near group fusion categories.)* A *near-group* fusion category is a fusion category $\mathcal{C}$ with exactly one non-invertible simple object X up to isomorphism. The fusion rules of $\mathcal{C}$ are determined by the multiplication in the group G of invertible objects of $\mathcal{C}$ and an additional relation

$$X^2 = \sum_{g\in G} g + nX, \tag{3-1}$$

where n is a non-negative integer Siehler [2003]. We say in this case that $\mathcal{C}$ has fusion rules *of type* (G, n). Near-group fusion categories of type $(1, 1)$ are called *Yang-Lee categories*: they fall into two equivalence classes and were classified by Moore and Seiberg [1989a]. Not all pairs (G, n) arise from the fusion rules of a fusion category: Ostrik proved in Ostrik [2003b] that if $n \geq 2$ then there exist no near-group fusion category with fusion rules of type $(1, n)$. Examples and results on near-group fusion categories, including restrictions on the possible values of n and its relation with the structure of G, have been obtained by Evans and Gannon and Izumi. See Evans and Gannon [2014] and references therein.

Example 3.6. *(Tambara-Yamagami fusion categories.)* A fusion category $\mathcal{C}$ is called a *Tambara-Yamagami* fusion category if $\mathcal{C}$ has near-group fusion rules of type $(G, 0)$ for some (necessarily abelian) group G. We have $\operatorname{FPdim} X = \sqrt{|G|}$ and $\operatorname{FPdim} \mathcal{C} = 2|G|$. The classification of these fusion categories was given by Tambara and Yamagami in Tambara and Yamagami [1998]: for each finite abelian group G, they are parameterized, up to equivalence, by isomorphism classes of non-degenerate symmetric bilinear forms $\chi : G \times G \to k$ and elements $\tau \in k$ such that $\tau^2 = |G|^{-1}$.

A Tambara-Yamagami fusion category is integral if and only if the order of G is a square. Tambara-Yamagami fusion categories such that G is of order 2 are called *Ising fusion categories*. These are the only non-pointed fusion categories of Frobenius-Perron dimension 4.

3.3 Categorical Morita equivalence. Let $\mathcal{C}$ be a fusion category over k. A (*right*) $\mathcal{C}$-*module category* is a finite semisimple k-linear abelian category $\mathfrak{M}$ equipped with a k-bilinear functor $\bar{\otimes} : \mathfrak{M} \times \mathcal{C} \to \mathfrak{M}$ and natural isomorphisms $\mu : \bar{\otimes} \circ (\mathrm{id}_{\mathfrak{M}} \times \otimes) \to \bar{\otimes} \circ (\bar{\otimes} \times \mathrm{id}_{\mathcal{C}})$, $r : -\bar{\otimes}\mathbf{1} \to \mathrm{id}_{\mathfrak{M}}$, satisfying certain coherence conditions similar to the pentagon and triangle axioms of a monoidal category.

Let A be an algebra in $\mathcal{C}$. Then the category ${}_A\mathcal{C}$ of left A-modules in $\mathcal{C}$ is a right $\mathcal{C}$-module category with action $\bar{\otimes} :{}_A \mathcal{C} \times \mathcal{C} \to{}_A \mathcal{C}$, given by $M \bar{\otimes} X = M \otimes X$ endowed with the natural left A-module structure. The associativity constraint of ${}_A\mathcal{C}$ is induced from that of $\mathcal{C}$.

Let $(\mathfrak{M}, \bar{\otimes})$ and $(\mathfrak{M}', \bar{\otimes}')$ be right $\mathcal{C}$-module categories. A $\mathcal{C}$-module functor $\mathfrak{M} \to \mathfrak{M}'$ is a pair (F, ζ), where $F : \mathfrak{M} \to \mathfrak{M}'$ is a functor and $\zeta_{M,X} : F(M \bar{\otimes} X) \to F(M)\bar{\otimes}' X$ is a natural isomorphism such that, for all $M \in \mathfrak{M}$, $X, Y \in \mathcal{C}$,

$$(\zeta_{M,X} \otimes \mathrm{id}_Y)\ \zeta_{M\bar{\otimes}X,Y}\ F(\mu_{M,X,Y}) = \mu'_{F(M),X,Y}\ \zeta_{M,X\otimes Y}, \quad r'_{F(M)}\ \zeta_{M,\mathbf{1}} = F(r_M).$$

An *equivalence* of $\mathcal{C}$-module categories $\mathfrak{M} \to \mathfrak{M}'$ is a $\mathcal{C}$-*module functor* $(F, \zeta) : \mathfrak{M} \to \mathfrak{M}'$ such that F is an equivalence of categories. A $\mathcal{C}$-module category is called *indecomposable* if it is not equivalent to a direct sum of two nontrivial $\mathcal{C}$-submodule categories.

Let $\mathfrak{M}, \mathfrak{M}'$ be indecomposable $\mathcal{C}$-module categories. The category $\mathrm{End}_{\mathcal{C}}(\mathfrak{M})$ of $\mathcal{C}$-module endofunctors of $\mathfrak{M}$ is a fusion category with tensor product induced by composition of functors. In particular, this gives a tool for building new examples of fusion categories from 'basic' ones. The category $\mathrm{Fun}_{\mathcal{C}}(\mathfrak{M}, \mathfrak{M}')$ of $\mathcal{C}$-module functors $\mathfrak{M} \to \mathfrak{M}'$ is an indecomposable module category over $\mathrm{End}_{\mathcal{C}}(\mathfrak{M})$ in a natural way. If A and B are indecomposable algebras in $\mathcal{C}$ such that $\mathfrak{M} \cong {}_A\mathcal{C}$ and $\mathfrak{M}' \cong {}_B\mathcal{C}$, then $\mathrm{End}_{\mathcal{C}}(\mathfrak{M})^{op}$ is equivalent to the fusion category ${}_A\mathcal{C}_A$ of (A, A)-bimodules in $\mathcal{C}$ and there is an equivalence of ${}_A\mathcal{C}_A$-module categories ${}_B\mathcal{C}_A \cong \mathrm{Fun}_{\mathcal{C}}(\mathfrak{M}, \mathfrak{M}')$, where ${}_B\mathcal{C}_A$ is the category of (B, A)-bimodules in $\mathcal{C}$.

Two fusion categories $\mathcal{C}$ and $\mathfrak{D}$ are called *categorically Morita equivalent* if $\mathfrak{D} \cong \mathrm{End}_{\mathcal{C}}(\mathfrak{M})^{op}$ for some indecomposable module category $\mathfrak{M}$. If $\mathcal{C}$ and $\mathfrak{D}$ are categorically

Morita equivalent fusion categories, then $\operatorname{FPdim} \mathcal{C} = \operatorname{FPdim} \mathcal{D}$. In addition the class of integral fusion categories is closed under categorical Morita equivalence. See Müger [2003a], Etingof, Nikshych, and Ostrik [2005]. An important characterization of the notion of categorical Morita equivalence is given by the following theorem.

Theorem 3.7. *Etingof, Nikshych, and Ostrik [2011]. Two fusion categories $\mathcal{C}$ and $\mathcal{D}$ are categorically Morita equivalent if and only if $\mathcal{Z}(\mathcal{C})$ and $\mathcal{Z}(\mathcal{D})$ are equivalent as braided fusion categories.*

4 Extensions of tensor categories

4.1 Exact sequences of tensor categories. Let $\mathcal{C}, \mathcal{D}$ be tensor categories and let $F : \mathcal{C} \to \mathcal{D}$ be a tensor functor. Let $\mathfrak{Ker}_F \subset \mathcal{C}$ denote the full subcategory of $\mathcal{C}$ whose objects are those X such that $F(X)$ is a *trivial object* of $\mathcal{D}$, that is, such that $F(X)$ is isomorphic to a direct sum of copies of the unit object $\mathbf{1}$ of $\mathcal{D}$.

A tensor functor $F : \mathcal{C} \to \mathcal{D}$ is called *normal* if for every object X of $\mathcal{C}$ there exists a subobject X_0 such that $F(X_0)$ is the largest trivial subobject of $F(X)$ in $\mathcal{D}$. The notion of normal tensor functor was introduced in Bruguières and Natale [2011] as a generalization of the notion of normal Hopf subalgebra. When $\mathcal{C}$ is a fusion category, the functor F is *normal* if and only if for every simple object $X \in \mathcal{C}$ such that $\operatorname{Hom}_{\mathcal{D}}(\mathbf{1}, F(X)) \neq 0$, we have that $X \in \mathfrak{Ker}_F$.

Definition 4.1. Bruguières and Natale [ibid.]. An *exact sequence of tensor categories* is a sequence of tensor functors

$$\mathcal{C}' \xrightarrow{i} \mathcal{C} \xrightarrow{F} \mathcal{C}'' \tag{4-1}$$

such that the functor F is dominant and normal, and i is a full embedding whose essential image is $\mathfrak{Ker}_F$. In this case we say that $\mathcal{C}$ is an extension of $\mathcal{C}''$ by $\mathcal{C}'$.

Remark 4.2. An exact sequence of tensor categories (4-1) defines a fiber functor $\mathcal{C}' \to \operatorname{Vect}_k$, since the composition $F \circ f$ maps $\mathcal{C}'$ to the trivial subcategory of $\mathcal{C}''$. By Tannaka reconstruction, (4-1) gives rise to a finite dimensional semisimple Hopf algebra H (the induced Hopf algebra of (4-1)), such that $\mathcal{C}' \cong \text{comod-}H$.

Exact sequences of tensor categories (4-1) are classified in terms of algebraic data under suitable conditions. We say that a k-linear right exact Hopf monad T on a tensor category $\mathcal{C}$ is *normal* if $T(\mathbf{1})$ is a trivial object. If T is such a Hopf monad, and if T is faithful, then it gives rise to an exact sequence of tensor categories comod-$H \to \mathcal{C}^T \to \mathcal{C}$, where, roughly, H is the Hopf algebra such that $T|_{\langle \mathbf{1} \rangle} \cong H \otimes -$ (the induced Hopf algebra of T).

Theorem 4.3. *Bruguières and Natale [ibid.]. Let $\mathcal{C}'$, $\mathcal{C}''$ be tensor categories and assume that $\mathcal{C}'$ is finite. Then the following data are equivalent:*

(i) An exact sequence (4-1);

(ii) A normal faithful k-linear right exact Hopf monad T on $\mathcal{C}''$, with induced Hopf algebra H, endowed with a tensor equivalence $K : \mathcal{C}' \cong$ comod-H.

Let $\mathcal{C}$ and $\mathfrak{D}$ be finite tensor categories. In this case exact sequences (4-1) such that F has an exact right adjoint are also classified by commutative algebras (A, σ) in the center $\mathcal{Z}(\mathcal{C})$ Bruguières and Natale [ibid., Section 6] which are *self-trivializing*, that is, such that $A \otimes A \cong A^n$ as right A-modules in $\mathcal{C}$, for some $n \geq 1$.

An exact sequence of finite tensor categories (4-1) is called *central* if, denoting by (A, σ) the corresponding commutative algebra in $\mathcal{Z}(\mathcal{C})$, the tensor functor $i : \mathcal{C}' \to \mathcal{C}$ lifts to a tensor functor $\tilde{i} : \mathcal{C}' \to \mathcal{Z}(\mathcal{C})$ such that $\tilde{i}(A) = (A, \sigma)$ Bruguières and Natale [2014].

4.2 Hopf algebra extensions. Let H, H', H'' be Hopf algebras over the field k. A sequence of Hopf algebra maps

$$k \longrightarrow H' \xrightarrow{i} H \xrightarrow{f} H'' \longrightarrow k, \tag{4-2}$$

is called a (strictly) *exact sequence of Hopf algebras* if i is injective, π is surjective, $i(H') = H^{co\pi} = \{h \in H : (\mathrm{id} \otimes \pi)\Delta(h) = h \otimes 1\}$, and H is right faithfully flat over $i(H')$ (the last condition is automatic in the finite dimensional case). Letting $\iota = i_*$ and $F = f_*$ to be the functors induced by restriction along i and f, respectively, the exact sequence (4-2) induces an exact sequence of tensor categories

$$\text{comod-}H' \xrightarrow{\iota} \text{comod-}H \xrightarrow{F} \text{comod-}H''.$$

Suppose H is finite dimensional. If (4-2) is an exact sequence, then $i(H')$ is a *normal* Hopf subalgebra of H, that is, a Hopf subalgebra stable under the adjoint actions of H. Conversely, every normal Hopf subalgebra H' of H gives rise to an exact sequence (4-2), where $i : H' \longrightarrow H$ is the inclusion and $f : H \longrightarrow H/H(H')^+ =: H''$ is the canonical projection. In this case H can be recovered as a bicrossed product $H' \# H''$ with respect to suitable cohomological data Andruskiewitsch and Devoto [1995]. A Hopf algebra is called *simple* if it contains no proper normal Hopf subalgebra. The following result implies that the simplicity of a Hopf algebra is not a categorical notion.

Theorem 4.4. *Galindo and Natale [2007]. There exists a simple Hopf algebra H such that H-mod $\cong$* Rep G*, where G is a solvable group.*

In fact in the examples of Galindo and Natale [2007], one may take H of dimension p^2q^2, where p and q are distinct prime numbers, thus showing that the analogue of Burnside's p^aq^b-Theorem does not extend to the context of semisimple Hopf algebras with the natural definition of normal Hopf subalgebra. In the (characteristic zero) semisimple case, the only simple examples with dimension ≤ 60 arise in dimensions 36 and 60 and they are twistings of group algebras Natale [2007], Natale [2010].

Composition series of a finite dimensional Hopf algebra H were introduced by Andruskiewitsch and Müller as a sequence of finite dimensional simple Hopf algebras $\mathfrak{H}_1, \dots, \mathfrak{H}_n$ defined recursively as follows: If H is simple, then $n = 1$ and $\mathfrak{H}_1 = H$. If, on the other hand, $k \subsetneq A \subsetneq H$ is a normal Hopf subalgebra, and $\mathfrak{A}_1, \dots, \mathfrak{A}_m$, $\mathfrak{B}_1, \dots, \mathfrak{B}_l$, are composition series of A and $B = H/HA^+$, respectively, then we let $n = m + l$ and $\mathfrak{H}_i = \mathfrak{A}_i$, if $1 \leq i \leq m$, $\mathfrak{H}_i = \mathfrak{B}_{i-m}$, if $m < i \leq m + l$.

The following analogue of the Jordan-Hölder theorem holds for finite dimensional Hopf algebras; see Andruskiewitsch [2002, Question 2.1].

Theorem 4.5. *Natale [2015]. Let $\mathfrak{H}_1, \dots, \mathfrak{H}_n$ and $\mathfrak{H}'_1, \dots, \mathfrak{H}'_m$ be two composition series of H. Then there exists a bijection $f : \{1, \dots, n\} \to \{1, \dots, m\}$ such that $\mathfrak{H}_i \cong \mathfrak{H}'_{f(i)}$ as Hopf algebras.*

4.3 Exact sequences with respect to a module category. The notion of exact sequence of tensor categories was generalized in Etingof and Gelaki [2017] to that of exact sequence of finite tensor categories with respect to a module category.

Let $\mathfrak{C}$ and $\mathfrak{D}$ be finite k-linear abelian categories. Their *Deligne tensor product* is a finite tensor category denoted $\mathfrak{C} \boxtimes \mathfrak{D}$ endowed with a functor $\boxtimes : \mathfrak{C} \times \mathfrak{D} \to \mathfrak{C} \boxtimes \mathfrak{D}$ exact in both variables such that for any k-bilinear right exact functor $F : \mathfrak{C} \times \mathfrak{D} \to \mathfrak{A}$, where $\mathfrak{A}$ is a k-linear abelian category, there exists a unique right exact functor $\tilde{F} : \mathfrak{C} \boxtimes \mathfrak{D} \to \mathfrak{A}$ such that $\tilde{F} \circ \boxtimes = F$. Such a category exists and it is unique up to equivalences. In fact, if $\mathfrak{C} \cong A$-mod and $\mathfrak{D} \cong B$-mod, for some finite dimensional k-algebras A and B, then $\mathfrak{C} \boxtimes \mathfrak{D} \cong (A \otimes B)$-mod. See Deligne [1990]. The tensor product of two finite tensor categories $\mathfrak{C}$ and $\mathfrak{D}$ is again a finite tensor category and if $\mathfrak{C}$ and $\mathfrak{D}$ are fusion categories, then so is $\mathfrak{C} \boxtimes \mathfrak{D}$.

Let $\mathfrak{A} \subseteq \mathfrak{B}$ and $\mathfrak{C}$ be finite tensor categories and let $\mathfrak{M}$ be an exact indecomposable left $\mathfrak{A}$-module category[4]; in particular, $\mathfrak{M}$ is finite. Let $\operatorname{End}(\mathfrak{M})$ denote the category of k-linear right exact endofunctors of $\mathfrak{M}$, which is a monoidal category with tensor product given by composition of functors. Let also $i : \mathfrak{A} \to \mathfrak{B}$ denote the inclusion functor.

[4]Exactness of $\mathfrak{M}$ means that $P \otimes M$ is projective for any projective object $P \in \mathfrak{A}$ and any object $M \in \mathfrak{M}$.

Definition 4.6. Etingof and Gelaki [2017]. An exact sequence of tensor categories *with respect to* $\mathfrak{M}$ is a sequence of tensor functors

$$\mathfrak{A} \xrightarrow{i} \mathfrak{B} \xrightarrow{F} \mathfrak{C} \boxtimes \operatorname{End}(\mathfrak{M}),$$

such that F is dominant, $\mathfrak{A}$ coincides with the subcategory of $\mathfrak{B}$ mapped to $\operatorname{End}(\mathfrak{M})$ under F and, for every object X of $\mathfrak{B}$, there exists a subobject X_0 of X such that $F(X_0)$ is the largest subobject of $F(X)$ contained in $\operatorname{End}(\mathfrak{M})$. In this case $\mathfrak{B}$ is said an extension of $\mathfrak{C}$ by $\mathfrak{A}$ with respect to $\mathfrak{M}$.

It was shown in Etingof and Gelaki [ibid.] that the Deligne tensor product of two tensor categories gives rise to an exact sequence in the sense of the previous definition. The notion of exact sequence with respect to a module category is self-dual in an appropriate sense. In addition, if $\mathfrak{A}$ and $\mathfrak{C}$ are fusion categories and $\mathfrak{M}$ is an indecomposable exact (thus semisimple) module category over $\mathfrak{A}$, then any extension of $\mathfrak{C}$ by $\mathfrak{A}$ with respect to $\mathfrak{M}$ is also a fusion category.

The answers to the following natural questions are at the moment not known:

Question 4.7. Does an analogue of the Jordan-Hölder theorem hold for finite tensor (fusion) categories? Is it possible to classify *simple* tensor (fusion) categories?

5 Fusion categories from finite groups

A fusion category $\mathfrak{C}$ is called *group-theoretical* if it is categorically Morita equivalent to a pointed fusion category. Let $\mathfrak{C}$ be a pointed fusion category, so that there exist a finite group G and a 3-cocycle $\omega : G \times G \times G \to k^\times$ such that $\mathfrak{C} \cong \operatorname{Vect}_G^\omega$, c.f. Example 2.4. Every indecomposable module category over $\operatorname{Vect}_G^\omega$ arises from a pair (F, α), where F is a subgroup of G and $\alpha : F \times F \to k^\times$ is a 2-cochain on F such that $d\alpha = \omega|_{F \times F \times F}$. Thus, the restriction $\omega|_F$ represents the trivial cohomology class in $H^3(F, k^\times)$. The (left) module category associated to such pair (F, α) is the category $\mathfrak{M}_0(F, \alpha) = (\operatorname{Vect}_G^\omega)_{k_\alpha F}$ of (right) $k_\alpha F$-modules in $\operatorname{Vect}_G^\omega$, where $k_\alpha F$ is the twisted group algebra of F. The group-theoretical category $(\operatorname{Vect}_G^\omega)^*_{\mathfrak{M}_0(F,\alpha)}$ is denoted $\mathfrak{C}(G, \omega, F, \alpha)$. Every group-theoretical fusion category is integral. Necessary and sufficient conditions for a group-theoretical category to be equivalent to the representation category of a (semisimple) Hopf algebra were given in Ostrik [2003c].

The class of group-theoretical fusion categories is quite well-understood. It is almost tautologically closed under categorical Morita equivalence, as well as under Deligne tensor products and Drinfeld centers. Moreover, a fusion category $\mathfrak{C}$ is equivalent to a group-theoretical fusion category $\mathfrak{C}(G, \omega, F, \alpha)$ if and only if its Drinfeld center $\mathcal{Z}(\mathfrak{C})$ is equivalent as a braided fusion category to the category of finite-dimensional representations of the *twisted quantum double* $D^\omega G$ Dijkgraaf, Pasquier, and Roche [1991], Majid [1998].

The next theorem illustrates that certain restrictions on the dimension of an integral fusion category force it to be group-theoretical.

Theorem 5.1. *Let p, q, r be distinct prime numbers. Then:*

(i) *V. Drinfeld, Gelaki, Nikshych, and Ostrik [2007]. Every integral fusion category of Frobenius-Perron dimension p^n, $n \geq 0$, is group-theoretical.*

(ii) *Etingof, Gelaki, and Ostrik [2004], Etingof, Nikshych, and Ostrik [2011]. Every integral fusion category of Frobenius-Perron dimension pq or pqr is group-theoretical.*

Example 5.2. *(Abelian extensions of Hopf algebras.)* Exact sequences of finite dimensional Hopf algebras (4-2) such that $H' \cong k^\Gamma$ and $H'' \cong kF$, for some finite groups F and Γ, are called *abelian extensions*. An abelian extension of kF by k^Γ arises from mutual actions by permutations $\Gamma \overset{\triangleleft}{\leftarrow} \Gamma \times F \overset{\triangleright}{\rightarrow} F$ that make (F, Γ) into a *matched pair* of finite groups. This amounts to the existence of a group G together with an exact factorization $G = F\Gamma$: the actions $\triangleleft, \triangleright$ are this case determined by the relations $gx = (g \triangleright x)(g \triangleleft x)$, for all $x \in F$, $g \in \Gamma$.

Let (F, Γ) be a matched pair of finite groups. Let also $\sigma : F \times F \to (k^*)^\Gamma$ and $\tau : \Gamma \times \Gamma \to (k^*)^F$ be normalized 2-cocycles. Under suitable conditions, one can associate a Hopf algebra $H = k^\Gamma {}^\tau\#_\sigma kF$ (with crossed product algebra structure and crossed coproduct coalgebra structure) that fits into an exact sequence of Hopf algebras $k \to k^\Gamma \to H \to kF \to k$. Moreover, every Hopf algebra H fitting into an exact sequence of this form is isomorphic to $k^\Gamma {}^\tau\#_\sigma kF$ for appropriate data $\triangleleft, \triangleright, \sigma, \tau$. Equivalence classes of such extensions associated to a fixed pair $(\triangleleft, \triangleright)$ form an abelian group whose unit element is the class of the *split* extension $k^\Gamma \# kF$.

Abelian extensions are among the first non-commutative and non-cocommutative examples of Hopf algebras in the literature; they were studied by G.I. Kac in the 60's Kac [1962]. We refer to Masuoka [2002] for results on the cohomology underlying an abelian exact sequence and generalizations.

Every abelian extension is group-theoretical. Indeed, if $H \cong k^\Gamma {}^\tau\#_\sigma kF$, then there is equivalence of tensor categories mod-$H \cong \mathcal{C}(G, \omega, F, 1)$, where $\omega : G \times G \times G \to k^\times$ is a 3-cocycle coming from the class of H in an exact sequence due to G. I. Kac. However, group-theoretical Hopf algebras are not closed under taking extensions. Examples of semisimple Hopf algebras H which are not group-theoretical were constructed by Nikshych, answering a question of Etingof, Nikshych, and Ostrik [2005]:

Theorem 5.3. *Nikshych [2008]. There exist semisimple Hopf algebras which are not group-theoretical.*

The examples of Nikshych [ibid.] have dimension $4p^2$, where p is an odd prime number. These Hopf algebras H fit into a central exact sequence $k \to k^{\mathbb{Z}_2} \to H \to A \to k$, where A is certain group-theoretical Hopf algebra of dimension $2p^2$. The 36 dimensional example arising from Nikshych [ibid.] gives the smallest semisimple Hopf algebra which is not group-theoretical.

5.1 Group extensions and equivariantization. Let G be a finite group. A G-grading on a fusion category $\mathcal{C}$ is a decomposition $\mathcal{C} = \oplus_{g \in G} \mathcal{C}_g$, such that $\mathcal{C}_g \otimes \mathcal{C}_h \subseteq \mathcal{C}_{gh}$, for all $g, h \in G$. The fusion category $\mathcal{C}$ is called a *G-extension* of a fusion category $\mathfrak{D}$ if there is a faithful grading $\mathcal{C} = \oplus_{g \in G} \mathcal{C}_g$ with neutral component $\mathcal{C}_1 \cong \mathfrak{D}$. Group extensions of a fusion category were classified in Etingof, Nikshych, and Ostrik [2010] in terms of various data related to some low degree cohomology groups.

If $\mathcal{C}$ is any fusion category, there exist a finite group $U(\mathcal{C})$, called the *universal grading group* of $\mathcal{C}$, and a canonical faithful grading $\mathcal{C} = \oplus_{g \in U(\mathcal{C})} \mathcal{C}_g$, with neutral component $\mathcal{C}_{ad}$, where $\mathcal{C}_{ad}$ is the adjoint subcategory of $\mathcal{C}$, that is, the fusion subcategory generated by $X \otimes X^*$, $X \in \operatorname{Irr}(\mathcal{C})$. In addition, if $\operatorname{FPdim} \mathcal{C} \in \mathbb{Z}$, then $\mathcal{C}$ is faithfully graded by an elementary abelian 2-group E. Moreover, there is a set of distinct square-free integers n_g, $g \in E$, such that $n_1 = 1$ and $\operatorname{FPdim} X \in \mathbb{Z}\sqrt{n_g}$, for every simple object X of $\mathcal{C}_g$. The neutral component of this grading is the unique maximal integral fusion subcategory of $\mathcal{C}$. See Gelaki and Nikshych [2008].

A fusion category $\mathcal{C}$ is (cyclically) *nilpotent* if there exists a sequence of fusion categories $\operatorname{Vect}_k = \mathcal{C}_0 \subseteq \mathcal{C}_1 \cdots \subseteq \mathcal{C}_n = \mathcal{C}$, and finite (cyclic) groups $G_1, \dots, G_n$, such that for all $i = 1, \dots, n$, $\mathcal{C}_i$ is a G_i-extension of $\mathcal{C}_{i-1}$.

Another kind of 'group extension' of a fusion category is provided by the equivariantization under a finite group action. An *action* of a finite group G on a fusion category $\mathcal{C}$ by tensor autoequivalences is a monoidal functor $\rho : \underline{G} \to \operatorname{Aut}_\otimes \mathcal{C}$, where $\underline{G}$ is the strict monoidal category with objects $g \in G$, identities as its only morphisms, and group multiplication as tensor product, and $\operatorname{Aut}_\otimes \mathcal{C}$ is the monoidal category of tensor autoequivalences of $\mathcal{C}$ where morphisms are isomorphisms of tensor functors. The *equivariantization* of $\mathcal{C}$ with respect to the action ρ, denoted $\mathcal{C}^G$, is a fusion category whose objects are pairs (X, μ), such that X is an object of $\mathcal{C}$ and $\mu = (\mu^g)_{g \in G}$, is a collection of isomorphisms $\mu^g : \rho^g X \to X$, $g \in G$, satisfying

$$\mu^g \rho^g(\mu^h) = \mu^{gh} \rho^{g,h}_{2_X}, \quad \mu_1 \rho_{0_X} = \mathrm{id}_X,$$

for all $g, h \in G$, where ρ^2 and ρ^0 denote the monoidal structure of ρ.

Remark 5.4. If $\rho : \underline{G} \to \operatorname{Aut}_\otimes \mathcal{C}$ is an action of a group G by tensor autoequivalences, then the forgetful functor $F : \mathcal{C}^G \to \mathcal{C}$, $F(X, \mu) = X$, is a normal dominant tensor functor and it gives rise to a central exact sequence of fusion categories $\operatorname{Rep} G \to \mathcal{C}^G \to \mathcal{C}$

Bruguières and Natale [2014]. Thus equivariantization provides examples of exact sequences of tensor categories. The notion of equivariantization explained above can be extended to define equivariantization of tensor categories under finite group scheme actions. Some characterizations of an exact sequence of tensor categories arising from equivariantization where given in Bruguières and Natale [ibid.]. In particular, an exact sequence of finite tensor categories arises from an equivariantization if and only if the sequence is central (see SubSection 4.1), which is an alternative formulation of a previous characterization given in Etingof, Nikshych, and Ostrik [2011] in the context of fusion categories.

A generalization of the equivariantization construction was given in Natale [2016b]: the input for this construction is a *crossed action* of a matched pair of finite groups (G, Γ) in a tensor category $\mathcal{C}$, which means a k-linear action of G on $\mathcal{C}$ (not necessarily by tensor autoequivalences) and a Γ-grading on $\mathcal{C}$ satisfying certain compatibility conditions. The resulting tensor category $\mathcal{C}^{(G,\Gamma)}$ also fits into an exact sequence $\operatorname{Rep} G \to \mathcal{C}^{(G,\Gamma)} \to \mathcal{C}$. The representation categories of abelian extensions (c.f. Example 5.2) are also contained in this construction.

Associated to an action of a group on a fusion category, there is another fusion category, called a *crossed product*, and denoted $\mathcal{C} \rtimes G$ Tambara [2001]. As a k-linear abelian category $\mathcal{C} \rtimes G = \mathcal{C} \boxtimes \operatorname{Vect}_G$ with tensor product defined by

$$(X \boxtimes g) \otimes (Y \boxtimes h) = (X \otimes \rho^g(Y)) \boxtimes gh,$$

for all $X, Y \in \mathcal{C}$, $g, h \in G$, unit object $\mathbf{1} \boxtimes k$ and associativity and unit constraints induced from those of $\mathcal{C}$. The category $\mathcal{C} \rtimes G$ is a G-extension of $\mathcal{C}$ with homogeneous components $(\mathcal{C} \rtimes G)_g = \mathcal{C} \boxtimes g$, $g \in G$. The relation with the equivariantized fusion category is given by an equivalence of tensor categories $(\mathcal{C}^G)^*_{\mathcal{C}} \cong \mathcal{C} \rtimes G$ Nikshych [2008]. In particular, every equivariantization is categorically Morita equivalent to a (graded) group extension.

Remark 5.5. The representation category of the non-group-theoretical examples of Nikshych are constructed in Nikshych [ibid.] as an equivariantization of a Tambara-Yamagami category of dimension $2p^2$ under the action of the group $\mathbb{Z}_2$. Thus, *a fortiori*, the class of group-theoretical fusion categories is not closed under group equivariantizations and neither under group extensions. Necessary and sufficient conditions for a group extension of a fusion category to be group-theoretical were given in Nikshych [ibid.].

Example 5.6. (*Equivariantization of pointed fusion categories.*) Let $\mathcal{C} = \operatorname{Vect}_\Gamma^\omega$ be a pointed fusion category, where Γ is a finite group and $\omega : \Gamma\times\Gamma\times\Gamma \to k^\times$ is a normalized 3-cocycle. Let also G be a finite group. An action $\rho : \underline{G} \to \operatorname{Aut}_\otimes \mathcal{C}$ corresponds to an action by group automorphisms of G on Γ, $x \mapsto {}^g x$, $x \in \Gamma$, $g \in G$ and maps $\tau : G\times\Gamma\times\Gamma \to k^\times$,

$\sigma : G \times G \times \Gamma \to k^\times$, obeying, for all $x, y, z \in \Gamma$, $g, h, l \in G$, the following conditions:

$$\sigma(h,l;x)\,\sigma(g,hl;x) = \sigma(gh,l;x)\,\sigma(g,h;{}^{l}x)$$
$$\frac{\omega(x,y,z)}{\omega({}^{g}x,{}^{g}y,{}^{g}z)} = \frac{\tau(g;xy,z)\tau(g;x,y)}{\tau(g;y,z)\,\tau(g;x,yz)}$$
$$\frac{\tau(gh;x,y)}{\tau(g;{}^{h}x,{}^{h}y)\,\tau(h;x,y)} = \frac{\sigma(g,h;x)\,\sigma(g,h;y)}{\sigma(g,h;xy)}$$

In this example, the category $\mathcal{C} \rtimes G$ is pointed: indeed, $\mathcal{C} \rtimes G \cong \mathrm{Vect}^{\tilde{\omega}}_{\Gamma \rtimes G}$, where $\Gamma \rtimes G$ is the semidirect product associated to the given action by group automorphisms of G on Γ and $\tilde{\omega}$ is a certain 3-cocycle on $\Gamma \rtimes G$ Tambara [2001]. In particular, any equivariantization of a pointed fusion category is group-theoretical.

5.2 Weakly group-theoretical fusion categories. A fusion category $\mathcal{C}$ is called *weakly group-theoretical* (respectively, *solvable*) if it is categorically Morita equivalent to a nilpotent (respectively, cyclically nilpotent) fusion category Etingof, Nikshych, and Ostrik [2011]. Weakly group-theoretical fusion categories can be described by means of group-theoretical data. The notion of solvability extends that of finite groups: the fusion categories $\mathrm{Rep}\, G$ and $\mathrm{Vect}^{\omega}_{G}$ are solvable if and only if G is solvable. However, not every nilpotent fusion category is solvable: for instance, Vect_G is always nilpotent.

The class of weakly group-theoretical fusion categories is stable under the operations of taking extensions, equivariantizations, Morita equivalent categories, tensor products, Drinfeld center, fusion subcategories and components of quotient categories. Also, the class of solvable fusion categories is stable under taking extensions and equivariantizations by solvable groups, Morita equivalent categories, tensor products, Drinfeld center, fusion subcategories and components of quotient categories. See Etingof, Nikshych, and Ostrik [ibid.].

Every weakly group-theoretical fusion category has integer Frobenius-Perron dimension. The following is the most important open question regarding the classification of this class of fusion categories:

Question 5.7. Etingof, Nikshych, and Ostrik [ibid.]. Is every fusion category with integer Frobenius-Perron dimension weakly group-theoretical?

A related open question is the following:

Question 5.8. Is the class of weakly group-theoretical fusion categories closed under extensions?

We summarize in the next theorem some results related to Question 5.7. Part (ii) is a generalization of a well-known theorem of Bunrside for finite groups.

Theorem 5.9. *Let $\mathcal{C}$ be a fusion category. Then the following hold:*

(i) *Etingof, Nikshych, and Ostrik [2005]. If* $\operatorname{FPdim} \mathcal{C} = p^n$, *p prime,* $n \geq 0$, *then* $\mathcal{C}$ *is nilpotent.*

(ii) *Etingof, Nikshych, and Ostrik [2011]. If* $\operatorname{FPdim} \mathcal{C} = p^n q^m$, *p, q primes,* $n, m \geq 0$, *then* $\mathcal{C}$ *is solvable.*

(iii) *Natale [2014]. If* $\mathbb{C}$ *is braided non-degenerate and* $\operatorname{FPdim} \mathcal{C} = dq^n$, *p prime,* $n \geq 0$ *and d a square-free integer, then* $\mathcal{C}$ *is solvable.*

It was shown in Etingof, Nikshych, and Ostrik [2011] that a fusion category $\mathcal{C}$ is weakly group-theoretical if and only if there exists a series of fusion categories

$$\text{Vect} = \mathcal{C}_0, \mathcal{C}_1, \dots, \mathcal{C}_n = \mathcal{C}, \tag{5-1}$$

such that for all $1 \leq i \leq n$, the Drinfeld center $\mathcal{Z}(\mathcal{C}_i)$ contains a Tannakian subcategory $\mathcal{E}_i$ and the de-equivariantization of the Müger centralizer $\mathcal{E}_i'$ in $\mathcal{Z}(\mathcal{C}_i)$ by $\mathcal{E}_i$ is equivalent to $\mathcal{Z}(\mathcal{C}_{i-1})$ as braided fusion categories. Since the categories $\mathcal{E}_i$ are Tannakian, then, for all $i = 1, \dots, n$, there exist finite groups $G_1, \dots, G_n$, such that $\mathcal{E}_i \cong \operatorname{Rep} G_i$ as symmetric fusion categories (c.f. Section 6 below). A *composition series* of $\mathcal{C}$ is a series (5-1) whose *factors* $G_1, \dots, G_n$, are simple groups.

The following theorem is an analogue of the Jordan-Hölder theorem. Its proof relies on the structure of a crossed braided fusion category (c.f. SubSection 6.3).

Theorem 5.10. *Natale [2016a]. Let* $\mathcal{C}$ *be a weakly group-theoretical fusion category. Then two composition series of* $\mathcal{C}$ *have, up to isomorphisms, the same factors counted with multiplicities. Thus they are invariants of* $\mathcal{C}$ *under categorical Morita equivalence.*

The solvability of a finite group G is known to be determined by its character table or, equivalently, by the fusion rules of the category $\operatorname{Rep} G$. The answer to the analogous question for fusion categories is not known.

Question 5.11. Escañuela González and Natale [2017]. Is the solvability of a fusion category determined by its fusion rules?

6 Braided fusion categories

Let $\mathcal{C}$ be a braided fusion category and let $\mathfrak{D}$ be a fusion subcategory of $\mathcal{C}$. The *Müger centralizer* of $\mathfrak{D}$ in $\mathcal{C}$, denoted $\mathfrak{D}'$, is the full fusion subcategory generated by all objects $X \in \mathcal{C}$ such that $c_{Y,X} c_{X,Y} = \mathrm{id}_{X \otimes Y}$, for all objects $Y \in \mathfrak{D}$. The category $\mathcal{C}'$ is called the *Müger center* (or *symmetric center*) of $\mathcal{C}$. If $\mathcal{C}$ is any braided fusion category, its Müger center $\mathcal{C}'$ is a symmetric fusion subcategory of $\mathcal{C}$. On the opposite extreme, $\mathcal{C}$ is called *non-degenerate* if $\mathcal{C}' \cong \text{Vect}$. See V. Drinfeld, Gelaki, Nikshych, and Ostrik [2010], Müger [2003b].

For a fusion category $\mathcal{C}$, the Drinfeld center $\mathcal{Z}(\mathcal{C})$ is a non-degenerate braided fusion category of Frobenius-Perron dimension $\operatorname{FPdim} \mathcal{Z}(\mathcal{C}) = (\operatorname{FPdim} \mathcal{C})^2$. Drinfeld centers of fusion categories are characterized as those non-degenerate braided fusion categories $\mathcal{Z}$ containing a Lagrangian algebra, that is, a separable commutative algebra A such that $\operatorname{Hom}_{\mathcal{C}}(\mathbf{1}, A) \cong k$ and $\operatorname{FPdim}(A)^2 = \operatorname{FPdim}(\mathcal{Z})$ Davydov, Müger, Nikshych, and Ostrik [2013].

Example 6.1. (*Group-theoretical braided fusion categories.*) Let G be a finite group and let ω be a normalized 3-cocycle on G. Let also $D^\omega G$-mod be the twisted quantum double Dijkgraaf, Pasquier, and Roche [1991]. Then there is an equivalence of braided fusion categories $D^\omega G\text{-mod} \cong \mathcal{Z}(\operatorname{Vect}_G^\omega)$. Suppose that $\mathcal{C}$ is a braided group-theoretical fusion category. Then there are equivalences of braided fusion categories $\mathcal{Z}(\mathcal{C}) \cong \mathcal{Z}(\operatorname{Vect}_G^\omega) \cong D^\omega G$-mod, for some finite group G and 3-cocycle ω. Thus, every braided group-theoretical fusion category can be embedded in $D^\omega G$-mod. A description of the fusion subcategories of $D^\omega G$-mod was given in Naidu, Nikshych, and Witherspoon [2009] in terms of subgroups of G and certain so-called *ω-bicharacters* on them.

Let G be a finite group. The fusion category $\operatorname{Rep} G$ is a symmetric fusion category with respect to the canonical braiding given by the flip of vector spaces. A braided fusion category $\mathcal{E}$ is called *Tannakian* if $\mathcal{E} \cong \operatorname{Rep} G$ for some finite group G as symmetric fusion categories. More generally, if $u \in G$ is a central element such that $u^2 = 1$, then the category $\operatorname{Rep}(G, u)$ of representations of G on finite dimensional super-vector spaces where u acts as the parity operator is a symmetric fusion category. The category $\operatorname{Rep}(\mathbb{Z}_2, u)$, where $1 \neq u \in \mathbb{Z}_2$ is denoted sVect.

The following result of Deligne is a crucial ingredient in the approach to the classification of braided fusion categories in the literature. Related results in a C^*-context are due to Doplicher and Roberts [1989].

Theorem 6.2. *Deligne [1990], Deligne [2002]. Let $\mathcal{C}$ be a symmetric fusion category. Then $\mathcal{C}$ is equivalent as a braided fusion category to the category* $\operatorname{Rep}(G, u)$ *for some finite group G and central element $u \in G$ such that $u^2 = 1$, which are, up to isomorphism, uniquely determined by* $\mathcal{C}$.

Let $\mathcal{C} \cong \operatorname{Rep}(G, u)$ be a symmetric fusion category. Then $\mathcal{C}$ is a $\mathbb{Z}_2$-extension of the Tannakian subcategory $\mathcal{E} = \operatorname{Rep}(G/(u))$. Thus if $\operatorname{FPdim} \mathcal{C} > 2$, then $\mathcal{C}$ contains a Tannakian subcategory, and a non-Tannakian symmetric fusion category of dimension 2 is equivalent to the category sVect.

Let $\mathcal{C}$ be a fusion category and suppose that $\mathcal{E} \cong \operatorname{Rep} G$ is a Tannakian subcategory of the center $\mathcal{Z}(\mathcal{C})$. The *de-equivariantization* of $\mathcal{C}$ with respect to G (or with respect to $\mathcal{E}$), denoted $\mathcal{C}_G$, is the category $\mathcal{C}_A$ of right A-modules in $\mathcal{C}$, where $A \in \mathcal{E}$ is the (commutative, separable) algebra corresponding to $k^G \in \operatorname{Rep} G$ under an equivalence of braided fusion categories $\operatorname{Rep} G \to \mathcal{E}$. This is a fusion category with tensor product $\otimes_A$ and unit object A. De-equivariantization and equivariantization are inverse processes. Indeed, the natural action by translations of G on A induces an action of G on $\mathcal{C}_G$ by tensor auto-equivalences such that $\mathcal{C} \cong (\mathcal{C}_G)^G$. See Bruguières [2000], Müger [2000], V. Drinfeld, Gelaki, Nikshych, and Ostrik [2010, Section 4].

6.1 Modular categories. A *premodular* category (Bruguières [2000]) is a braided fusion category endowed with a natural isomorphism $\theta : \mathrm{id}_{\mathcal{C}} \to \mathrm{id}_{\mathcal{C}}$, called a *ribbon structure*, satisfying

$$\theta_{X\otimes Y} = (\theta_X \otimes \theta_Y)c_{Y,X}c_{X,Y}, \quad \theta_X^* = \theta_{X^*}, \tag{6-1}$$

for all objects X, Y of $\mathcal{C}$. Equivalently, $\mathcal{C}$ is a braided fusion category endowed with a spherical structure. The ribbon structure of $\mathcal{C}$ allows to consider the *quantum trace* of an endomorphism $f : X \to X$ of an object X of $\mathcal{C}$ and in particular the *quantum dimension* of X defined as $\dim X = \operatorname{Tr}(\mathrm{id}_X)$.

Suppose $\mathcal{C}$ is a premodular category. Let X, Y be simple objects of $\mathcal{C}$ and let $S_{X,Y} \in k$ denote the quantum trace of the squared braiding $c_{Y,X}c_{X,Y} : X \otimes Y \to Y \otimes X$. The S*-matrix* of $\mathcal{C}$ is defined in the form $S = (S_{XY})_{X,Y\in\operatorname{Irr}(\mathcal{C})}$.

A premodular category $\mathcal{C}$ is called *modular* if its S-matrix is invertible. Equivalently, a premodular category $\mathcal{C}$ is modular if and only if it is non-degenerate. Every non-degenerate fusion category with integral Frobenius-Perron dimension is a modular category with its canonical spherical structure (c.f. Remark 3.4).

Let $\mathcal{C}$ be a modular category. The following relation, known as *Verlinde formula*, gives the fusion coefficients of $\mathcal{C}$ in terms of its S-matrix:

$$N_{XY}^Z = \frac{1}{\dim \mathcal{C}} \sum_{T\in\operatorname{Irr}(\mathcal{C})} \frac{S_{XT}\, S_{YT}\, S_{Z^*T}}{d_T},$$

for all $X, Y, Z \in \operatorname{Irr}(\mathcal{C})$, where d_T is the categorical dimension of the object T and $\dim \mathcal{C} = \sum_{T\in\operatorname{Irr}(\mathcal{C})} d_T^2$ is the categorical dimension of $\mathcal{C}$; c.f. Bakalov and Kirillov [2001].

Let $\mathcal{C}$ be a premodular category. A *modularization* of $\mathcal{C}$ is a dominant tensor functor $F : \mathcal{C} \to \mathcal{C}_0$ compatible with the braiding and the ribbon structures, where $\mathcal{C}_0$ is a modular category Bruguières [2000]. If such a modularization exists, then $\mathcal{C}$ is called *modularizable*. In Bruguières [ibid.], Müger [2000], Bruguières and Müger showed that a premodular category is modularizable if and only if its symmetric center $\mathcal{C}'$ is a Tannakian category. In this case, $\mathcal{C}' \cong \operatorname{Rep} G$ for some finite group G and $\mathcal{C}_0$ is the de-equivariantization $\mathcal{C}_G$. In this context, the group G acts on $\mathcal{C}_0$ by braided auto-equivalences and there is an equivalence of braided fusion categories $\mathcal{C} \cong \mathcal{C}_0^G$.

The following theorem was conjectured by Z. Wang. It implies the feasibility of the classification of modular fusion categories of a given rank:

Theorem 6.3. *Bruillard, Ng, E. C. Rowell, and Wang [2016b]. For every natural number r there is, up to equivalence, a finite number of modular categories of rank r.*

As pointed out by Etingof, the number of modular categories of rank r is, however, not bounded by any polynomial in r. Up to monoidal equivalence, the classification of modular categories has been achieved up to rank 5 Bruillard, Ng, E. C. Rowell, and Wang [2016a], E. Rowell, Stong, and Wang [2009].

6.2 Witt group of non-degenerate braided fusion categories. The (abelian) group $\mathcal{W}$ of Witt classes of non-degenerate braided fusion categories was introduced in Davydov, Müger, Nikshych, and Ostrik [2013]. Two non-degenerate braided fusion categories $\mathcal{C}_1$ and $\mathcal{C}_2$ are called *Witt equivalent* if there exist fusion categories $\mathcal{D}_1$ and $\mathcal{D}_2$ such that $\mathcal{C}_1 \boxtimes \mathcal{Z}(\mathcal{D}_1) \cong \mathcal{C}_2 \boxtimes \mathcal{Z}(\mathcal{D}_2)$ as braided tensor categories.

The Witt group $\mathcal{W}$ consists of equivalence classes of non-degenerate braided fusion categories under this equivalence relation with multiplication induced by Deligne's tensor product $\boxtimes$. The unit element is the class of the category Vect of finite-dimensional vector spaces over k and the inverse of the class of a non-degenerate braided fusion category $\mathcal{C}$ is the class of the *reverse* braided fusion category $\mathcal{C}^{rev}$ (this is the fusion category $\mathcal{C}$ with the *reversed* braiding $c^{rev}_{X,Y} = c^{-1}_{Y,X}$). The explicit determination of the relations in $\mathcal{W}$ is a relevant problem in connection with the classification of fusion categories.

Let $\mathcal{W}_{pt}$ and $\mathcal{W}_{Ising}$ denote the subgroups of Witt classes of pointed non-degenerate fusion categories and Ising braided categories, respectively. The subgroups $\mathcal{W}_{pt}$ and $\mathcal{W}_{Ising}$ were described in V. Drinfeld, Gelaki, Nikshych, and Ostrik [2010]. Let $\widetilde{\mathcal{W}}$ be the subgroup of $\mathcal{W}$ generated by the Witt classes of the modular categories $\mathcal{C}(\mathfrak{g}, l)$ of integrable highest weight modules of level $l \in \mathbb{Z}_+$ over the affinization of a simple finite-dimensional Lie algebra $\mathfrak{g}$ (see SubSection 2.3). It was shown in Davydov, Müger, Nikshych, and Ostrik [2013] that $\mathcal{W}_{pt}, \mathcal{W}_{Ising} \subseteq \widetilde{\mathcal{W}}$. The following open question was raised in Davydov, Müger, Nikshych, and Ostrik [ibid.] as a mathematical formulation of a conjecture stated by Moore and Seiberg [1989b]:

Question 6.4. Davydov, Müger, Nikshych, and Ostrik [2013]. Does $\widetilde{\mathcal{W}}$ coincide with be the subgroup $\mathcal{W}_{un}$ of Witt classes of pseudo-unitary non-degenerate braided fusion categories?

In relation with Question 5.7, we have:

Theorem 6.5. *Natale [2014]. The Witt class of a weakly group-theoretical non-degenerate braided fusion category belongs to the subgroup generated by $\mathcal{W}_{Ising}$ and $\mathcal{W}_{pt}$, whence also to $\widetilde{\mathcal{W}}$.*

6.3 Tannakian categories and braided G-crossed fusion categories. Let G be a finite group. A *G-crossed braided fusion category* is a fusion category $\mathfrak{D}$ endowed with a G-grading $\mathfrak{D} = \oplus_{g\in G} \mathfrak{A}_g$ and an action of G by tensor autoequivalences $\rho : \underline{G} \to \mathrm{Aut}_{\otimes}\ \mathfrak{D}$, such that $\rho^g(\mathfrak{D}_h) \subseteq \mathfrak{D}_{ghg^{-1}}$, for all $g, h \in G$, and a *G-braiding* $c : X \otimes Y \to \rho^g(Y) \otimes X$, $g \in G$, $X \in \mathfrak{D}_g$, $Y \in \mathfrak{D}$, subject to certain compatibility conditions. This notion was introduced by Turaev; see V. Turaev [2010].

The equivariantization $\mathfrak{D}^G$ of a G-crossed braided fusion category is a braided fusion category. The canonical embedding $\mathrm{Rep}\, G \to \mathfrak{D}^G$ of fusion categories is fact an embedding of braided fusion categories, with respect to the canonical braiding in $\mathrm{Rep}\, G$. The G-braiding on $\mathfrak{D}$ restricts to a braiding in the neutral component $\mathfrak{D}_1$ of the G-grading. Furthermore, the group G acts by restriction on $\mathfrak{D}_1$ and this action is by braided tensor autoequivalences. This makes the equivariantization $(\mathfrak{D}_1)^G$ into a braided fusion subcategory of $\mathfrak{D}^G$. This fusion subcategory coincides with the centralizer $\mathcal{E}'$ of the Tannakian subcategory $\mathcal{E} \cong \mathrm{Rep}\, G$ in $\mathfrak{D}^G$.

Conversely, if $\mathcal{C}$ is a braided fusion category containing a Tannakian subcategory $\mathcal{E} \cong \mathrm{Rep}\, G$, then the de-equivariantization $\mathcal{C}_G$ of $\mathcal{C}$ with respect to $\mathcal{E}$ is a braided G-crossed fusion category. Thus equivariantization defines a bijective correspondence between equivalence classes of braided fusion categories containing $\mathrm{Rep}\, G$ as a Tannakian subcategory and G-crossed braided fusion categories Jr [2001], Müger [2004].

Let $\mathfrak{D}$ be a G-crossed braided fusion category. The braided fusion category $\mathfrak{D}^G$ is non-degenerate if and only if the neutral component $\mathfrak{D}_1$ is non-degenerate and the G-grading of $\mathfrak{D}$ is faithful. If this is the case, then there is an equivalence of braided fusion categories $\mathcal{Z}(\mathfrak{D}) \cong \mathfrak{D}^G \boxtimes \mathfrak{D}_1^{rev}$ Davydov, Müger, Nikshych, and Ostrik [2013].

An important invariant of a braided fusion category is its *core*, introduced in V. Drinfeld, Gelaki, Nikshych, and Ostrik [2010]. As a braided fusion category, the core of a braided fusion category $\mathcal{C}$ is the neutral homogeneous component $\mathcal{C}_G^0$ of the de-equivariantization of $\mathcal{C}$ by a maximal Tannakian subcategory $\mathcal{E} \cong \mathrm{Rep}\, G$. The core of $\mathcal{C}$ is independent of $\mathcal{E}$. Furthermore, the core of a braided fusion category is *weakly anisotropic*, that is, it contains no Tannakian subcategories stable under all braided auto-equivalences. In addition, the core of $\mathcal{C}$ is non-degenerate if $\mathcal{C}$ is non-degenerate. A complete classification of pointed weakly anisotropic braided fusion categories has been proposed in V. Drinfeld, Gelaki, Nikshych, and Ostrik [ibid.].

A braided fusion category is weakly group-theoretical if and only if it can be obtained from a crossed braided fusion category with pointed neutral component, thus from a pointed category by means of suitable group extensions and equivariantizations:

Theorem 6.6. *Natale [2017]. Let $\mathcal{C}$ be a weakly group-theoretical braided fusion category. Then the core of $\mathcal{C}$ is equivalent to a Deligne tensor product $\mathfrak{B} \boxtimes \mathfrak{D}$, where $\mathfrak{D}$ is a* *pointed weakly anisotropic braided fusion category and* $\mathcal{B} \cong \mathrm{Vect}$ *or* $\mathcal{B}$ *is an Ising category. In particular, if* $\mathcal{C}$ *is integral, then its core is a pointed weakly anisotropic braided fusion category.*

The following theorem summarizes some known results related to Question 5.7 whose proofs rely on the existence of Tannakian subcategories and its relation with G-crossed braided fusion categories outlined above.

Theorem 6.7. *Let* $\mathcal{C}$ *be a braided fusion category. Then the following hold:*

(i) *Bruguières and Natale [2011]. If* $\operatorname{FPdim} \mathcal{C}$ *is an odd square-free integer, then* $\mathcal{C}$ *is equivalent to* $\operatorname{Rep} G$ *as a fusion category for some finite group* G.

(ii) *Natale [2014]. If* $\mathcal{C}$ *is non-degenerate and* $\operatorname{FPdim} \mathcal{C}$ *is a natural number less than* 1800*, or an odd natural number less than* 33075*, then* $\mathcal{C}$ *is weakly group-theoretical.*

(iii) *Natale and Pacheco Rodríguez [2016]. If* $\operatorname{FPdim} \mathcal{C} \in \mathbb{Z}$ *and the Frobenius-Perron dimensions of any simple object of* $\mathcal{C}$ *is a* p_i*-power, for some* $1 \leq i \leq r$*, where let* $p_1, \ldots, p_r$ *be prime numbers, then* $\mathcal{C}$ *is weakly group-theoretical. Moreover, it is solvable is either* $r \leq 2$*, or* $p_i > 7$*, for all* $i = 1, \ldots, r$.

(iv) *Natale [2017]. If* $\mathcal{C}$ *is integral and non-degenerate such that* $\operatorname{FPdim} X \leq 2$*, for every simple object* X*, then* $\mathcal{C}$ *is group-theoretical.*

(v) *Dong and Natale [2017]. If* $\mathcal{C}$ *is a non-degenerate and* $\operatorname{FPdim} \mathcal{C} = dq^n$*, where* $n \geq 0$*,* d *is a square-free natural number and* q *is an odd prime number, then* $\mathcal{C}$ *is group-theoretical.*

ON GROTHENDIECK–SERRE CONJECTURE CONCERNING PRINCIPAL BUNDLES

Ivan Panin

Abstract

Let R be a regular local ring. Let $\mathbf{G}$ be a reductive group scheme over R. A well-known conjecture due to Grothendieck and Serre assertes that a principal $\mathbf{G}$-bundle over R is trivial, if it is trivial over the fraction field of R. In other words, if K is the fraction field of R, then the map of non-abelian cohomology pointed sets

$$\mathrm{H}^1_{\text{ét}}(R, \mathbf{G}) \to \mathrm{H}^1_{\text{ét}}(K, \mathbf{G}),$$

induced by the inclusion of R into K, has a trivial kernel. *The conjecture is solved in positive for all regular local rings contaning a field.* More precisely, if the ring R contains an infinite field, then this conjecture is proved in a joint paper due to R. Fedorov and I. Panin published in 2015 in Publications l'IHES. If the ring R contains a finite field, then this conjecture is proved in 2015 in a preprint due to I. Panin which can be found on preprint server Linear Algebraic Groups and Related Structures. A more structured exposition can be found in Panin's preprint of the year 2017 on arXiv.org.

This and other results concerning the conjecture are discussed in the present paper. We illustrate the exposition by many interesting examples. We begin with couple results for complex algebraic varieties and develop the exposition step by step to its full generality.

1 Introduction

The conjecture was stated by J.-P. Serre in 1958 in so called constant case and by A. Grothendieck in 1968 in the general case. In this introduction we give couple results motivating the conjecture in the constant case. To do that recall some notation. Let X be an affine complex algebraic variety, smooth and irreducible. Let $\mathbb{C}[X]$ be the ring of regular functions on X and $f \in \mathbb{C}[X]$ be a non-zero function. Let $X_f := \{x \in X : f(x) \neq 0\}$. This open subset is called the principal open subset of X corresponding to the function f. This open subset X_f is itself is an affine algebraic variety and its ring of regular functions $\mathbb{C}[X_f]$ is the localization $\mathbb{C}[X]_f$ of the ring $\mathbb{C}[X]$ with respect to the element f. If A is a $\mathbb{C}[X]$-algebra, then we write A_f for the localization of A with respect to $f \in \mathbb{C}[X]$. We are ready now to formulate first result, which is due to Serre [1958].

Let A be a $\mathbb{C}[X]$-algebra, which is a free finitely generated $\mathbb{C}[X]$-module of rank n. Suppose that A is isomorphic to the matrix algebra $M_r(\mathbb{C}[X])$ locally for the complex topology on X. Suppose further that for a non-zero function $f \in \mathbb{C}[X]$ the $\mathbb{C}[X_f]$-algebras A_f and $M_r(\mathbb{C}[X_f])$ are isomorphic. Then for any point $x \in X$ there is a regular function $g \in \mathbb{C}[X]$ such that $g(x) \neq 0$ and the $\mathbb{C}[X_g]$-algebras A_g and $M_r(\mathbb{C}[X_g])$ are isomorphic. In the other words, the $\mathbb{C}[X]$-algebras A and $M_r(\mathbb{C}[X])$ are isomorphic locally for the Zarisky topology on X.

Let us point out that the $\mathbb{C}[X]$-algebras A and $M_r(\mathbb{C}[X])$ are isomorphic locally for the complex topology on X by the assumption of the theorem. The theorem states that these $\mathbb{C}[X]$-algebras are isomorphic *locally for the Zarisky topology on* X provided that they are isomorphic over *a non-empty Zarisky open subset of* X.

It is easy to give many examples of $\mathbb{C}[X]$-algebras A, which are isomorphic to the matrix algebra $M_2(\mathbb{C}[X])$ locally for the complex topology, but which are not isomorphic to the matrix algebra $M_2(\mathbb{C}[X])$ locally for the Zarisky topology. These algebras can be found for instance among generalized quaternion algebras. Second result illustrating the conjecture is due to Ojanguren [1980].

Let X and $\mathbb{C}[X]$ be as above and let $a_i, b_i \in \mathbb{C}[X]$ be invertible functions on X, where $i \in \{1, ..., r\}$. Consider two quadratic spaces $P := \Sigma_{i=1}^r a_i T_i^2$ and $Q := \Sigma_{i=1}^r b_i T_i^2$ over $\mathbb{C}[X]$. Suppose for a non-zero function $f \in \mathbb{C}[X]$ these quadratic spaces are isomorphic over the ring $\mathbb{C}[X_f]$. Then the quadratic spaces P and Q are isomorphic locally for the Zarisky topology on X. In other words, for any point $x \in X$ there is a regular function $g \in \mathbb{C}[X]$ such that $g(x) \neq 0$ and quadratic spaces P and Q are isomorphic as quadratic spaces over $\mathbb{C}[X]_g$.

A very partial case of the above Serre's result can be formulated as follows. Let a and b two invertible regular functions on X. Consider so called generalized quaternion $\mathbb{C}[X]$-algebra A given by two generators u, v subjecting to defining relations $u^2 = a$, $v^2 = b$, $uv = -vu$. Suppose the $\mathbb{C}(X)$-algebra $A \otimes_{\mathbb{C}[X]} \mathbb{C}(X)$ is isomorphic to the matrix algebra $M_2(\mathbb{C}(X))$. Then the $\mathbb{C}[X]$-algebra A is isomorphic to the matrix algebra $M_2(\mathbb{C}[X])$ locally for the Zarisky topology on X.

The indicated results can be restated in terms of principal bundles for groups PGL_r, SO_r and PGL_2 respectively. It is pretty clear now that one can try to state a rather general theorem in terms of principal homogeneous spaces. That will be done in the next section.

2 Principal G-bundles

Recall some notion. Let $\mathbf{G}$ be a linear complex algebraic group, that is a closed subgroup of the general linear group $\mathrm{GL}_n(\mathbb{C})$ with respect to the Zarisky topology. Let X be as above. Let $(E, \nu : \mathbf{G} \times E \to E)$ be a pair such that E is a complex algebraic variety together with a regular map $p : E \to X$ and ν is a $\mathbf{G}$-action on E respecting to the map p, that is $p(\nu(g, e)) = p(e)$ for any $e \in E$ and $g \in \mathbf{G}$. We will write ge for $\nu(g, e)$.

A principal $\mathbf{G}$*-bundle over* X is a pair $(E, \nu : \mathbf{G} \times E \to E)$ above such that
1) the regular map $\mathbf{G} \times E \to E \times_X E$ taking (g, e) to (ge, e) is an isomorphism of algebraic varieties;
2) for any point $x \in X$ there are a neighborhood V of x in the complex topology on X and an isomorphism of complex holomorphic varieties $\varphi : E|_V := p^{-1}(V) \to \mathbf{G} \times V$ such that φ respects to the projection on V and φ respects to obvious $\mathbf{G}$-actions on both sides.

A morphism between two principal $\mathbf{G}$-bundles (E_1, ν_1) and (E_2, ν_2) is a morphism $\psi : E_1 \to E_2$ which respects as to the projections on the base X, so to the $\mathbf{G}$-actions. A trivialized $\mathbf{G}$-bundle is the $\mathbf{G}$-bundle $(\mathbf{G} \times X, \mu)$, where $\mu(g'(g, x)) = (g'g)x$. A trivial $\mathbf{G}$-bundle is a $\mathbf{G}$-bundle isomorphic to the trivialized one. Clearly, a $\mathbf{G}$-bundle (E, ν) over X is trivial if there is a section $s : X \to E$ of the projection $p : E \to X$. For a principal $\mathbf{G}$-bundle (E, ν) over X we often will write just E skipping ν from the notation. We will write often a $\mathbf{G}$-bundle for a principal $\mathbf{G}$-bundle.

Many examples of principal **G**-bundles are obtained by the following simple construction. Consider a closed embedding of algebraic groups $\mathbf{G} \subset \mathrm{GL}_n(\mathbb{C})$ and set $X = \mathbf{G}\backslash\mathrm{GL}_n(\mathbb{C})$ (the orbit variety of right cosets with respect to **G**). Then the pair $(\mathrm{GL}_n(\mathbb{C}), \nu : \mathbf{G} \times \mathrm{GL}_n(\mathbb{C}) \to GL_n(\mathbb{C}))$, where ν takes (g, h) to gh is a principal **G**-bundle over X. The fibres of the projection $p : \mathrm{GL}_n(\mathbb{C}) \to X$ are right cosets of $\mathrm{GL}_n(\mathbb{C})$ with respect to the subgroup **G**. This principal **G**-bundle is very often not trivial locally for the Zarisky topology. For instance, if **G** is the special orthogonal group $\mathrm{SO}_n(\mathbb{C}) \subset \mathrm{GL}_n(\mathbb{C})$, then the above principal G-bundle *is not trivial locally for the Zarisky topology.*

A principal **G**-bundle E over X is not necessary trivial locally for the Zarisky topology on X, *however it is always trivial locally for the étale topology on* X. The latter means the following: there is a regular map $\pi : X' \to X$ of smooth algebraic varieties and a regular map $s' : X' \to E$ such that $p \circ s' = \pi$, π is surjective and for any point $x' \in X'$ the induced map of tangent spaces $T_{X',x'} \to T_{X,\pi(u)}$ is an isomorphism. In the other words, $\pi : X' \to X$ is a surjective étale regular map and the principal **G**-bundle $X' \times_X E$ over X' is trivial. Indeed, the regular map $(id_{X'}, s') : X' \to X' \times_X E$ is a section of the projection $pr_{X'}$.

We are ready now to state a very general result concerning principal **G**-bundles and extending the results from the introduction.

Theorem 2.1. Let **G** be a simple (or a semi-simple, or even a reductive) complex algebraic group. Let X be an affine complex algebraic variety, smooth and irreducible and let E_1, E_2 be two principal **G**-bundles over X. Suppose there is a non-zero regular function $f \in \mathbb{C}[X]$ such that the principal **G**-bundles $E_1|_{X_f}$ and $E_2|_{X_f}$ are isomorphic over X_f. Then the principal **G**-bundles E_1 and E_2 *are isomorphic locally for the Zarisky topology on* X.

In other words, for any point $x \in X$ there is a regular function $g \in \mathbb{C}[X]$ such that $g(x) \neq 0$ and the principal **G**-bundles $E_1|_{X_g}$ and $E_2|_{X_g}$ are isomorphic over X_g.

Remark 2.2. Let E_2 be a trivial principal **G**-bundle, then this theorem states the following. If E_1 is trivial over a non-empty Zarisky open subset of X, then E_1 *is trivial locally for the Zarisky topology on* X.

If E_2 is a trivial , then this theorem is due to Colliot-Thélène and Ojanguren [1992].

The general case of the theorem is due to R. Fedorov and the speaker Fedorov and I. Panin [2015].

Remark 2.3. The case when E_2 is trivial corresponds to the so called ”constant” case of the conjecture. Indeed, in this case one principal **G**-bundle $E = E_1$ is given and the result is a theorem about that principal **G**-bundle. The general case of the theorem can not be reduced to an equivalent statement concerning a principal **G** for the group **G**.

Let us give now few examples illustrating Theorem 2.1. Those examples are partial cases of Theorem 2.1 for the projective linear groups PGL_2,PGL_n, for the exceptional group G_2 and for the special projective orthogonal PSO_{2n} and for the projective simplectic groups PSp_{2n} respectively.
(1) Let A_1, A_2 be two generalized quaternion $\mathbb{C}[X]$-algebras corresponding to pairs a_1, b_1 and a_2, b_2 respectively. Suppose for a non-zero function $f \in \mathbb{C}[X]$ the $\mathbb{C}[X_f]$-algebras $(A_1)_f$ and $(A_2)_f$ are isomorphic. Then the $\mathbb{C}[X]$-algebras A_1 and A_2 are isomorphic locally for the Zarisky topology on X.
(2) Let A_1 and A_2 be two algebras as in the Serre's theorem above. *They are called Azumaya* $\mathbb{C}[X]$*-algebras.* Suppose for a non-zero function $f \in \mathbb{C}[X]$ the $\mathbb{C}[X_f]$-algebras $(A_1)_f$ and $(A_2)_f$ are isomorphic. Then the $\mathbb{C}[X]$-algebras A_1 and A_2 are isomorphic locally for the Zarisky topology on X.
(3) Let a_1, b_1, c_1 be invertible functions in $\mathbb{C}[X]$ and let $\mathbb{O}(a_1, b_1, c_1)$ be a generalized octonion $\mathbb{C}[X]$-algebra. That is as a $\mathbb{C}[X]$-module $\mathbb{O}(a_1, b_1, c_1)$ is a free of rank 8 with a free basis $1, e_1, e_2, ..., e_7$. And the multiplication table is as follows: $e_1^2 = a_1, e_2^2 = b_1, e_3^2 = c_1$

$$e_4 = e_1e_2 = -e_2e_1, e_5 = e_2e_3 = -e_3e_2, e_6 = e_3e_4 = -e_4e_3, e_7 = e_4e_5 = -e_5e_4.$$

Let a_2, b_2, c_2 be invertible functions in $\mathbb{C}[X]$ and let $\mathbb{O}(a_2, b_2, c_2)$ be one more generalized octonion $\mathbb{C}[X]$-algebra. Suppose for a non-zero function $f \in \mathbb{C}[X]$ the $\mathbb{C}[X_f]$-algebras $\mathbb{O}(a_1, b_1, c_1)_f$ and $\mathbb{O}(a_2, b_2, c_2)_f$ are isomorphic. Then the $\mathbb{C}[X]$-algebras $\mathbb{O}(a_1, b_1, c_1)$ and $\mathbb{O}(a_2, b_2, c_2)$ are isomorphic locally for the Zarisky topology on X.
(4) Let (A_1, σ_1) be an Azumaya $\mathbb{C}[X]$-algebra with involution. That is A_1 is an Azumaya algebra and $\sigma_1 : A_1 \to A_1^{op}$ is an $\mathbb{C}[X]$-algebras isomorphism, where A_1^{op} is the opposite $\mathbb{C}[X]$-algebra. Let (A_2, σ_2) be one more Azumaya $\mathbb{C}[X]$-algebra with involution. Suppose for a non-zero function $f \in \mathbb{C}[X]$ the $\mathbb{C}[X_f]$-algebras $(A_1, \sigma_1)_f$ and $(A_2, \sigma_2)_f$ are isomorphic as $\mathbb{C}[X_f]$-algebras with involutions. That is there is a $\mathbb{C}[X_f]$-algebras isomorphism $\varphi : (A_1)_f \to (A_2)_f$ with $\sigma_2 \circ \varphi = \varphi \circ \sigma_1$. Then the $\mathbb{C}[X]$-algebras A_1 and A_2 are isomorphic locally for the Zarisky topology on X as $\mathbb{C}[X]$-algebras with involutions.

3 Non-constant case of the conjecture for complex algebraic varieties

We begin with few examples illustrating the conjecture in the non-constant case. Let X be as above an affine complex algebraic variety, smooth and irreducible.
1) Let a, b be invertible functions in $\mathbb{C}[X]$. Consider an equation

$$T_1^2 - aT_2^2 = b \tag{1}$$

If this equation has a solution over the field $\mathbb{C}(X)$ of rational functions on X, then for any point $x \in X$ there is a function $g \in \mathbb{C}[X]$ such that $g(x) \neq 0$ and the Equation (1) has a solution in $\mathbb{C}[X_g]$.
2) Let $t^n + a_{n-1}t^{n-1} + ... + a_0 = F(t) \in \mathbb{C}[X]$ with $a_i \in \mathbb{C}[X]$ be a monic polinomial such that for any point $x \in X$ the polinomial $F_x(t) = t^n + a_{n-1}(x)t^{n-1} + ... + a_0(x) \in \mathbb{C}[t]$ has no multiple roots. Let $X' \subset X \times \mathbb{A}^1$ be a closed subvariety defined by the equation $\{F = 0\}$. The regular function ring $\mathbb{C}[X']$ is the factor ring $\mathbb{C}[X][t]/(F)$. It is a free rank n module over $\mathbb{C}[X]$. Therefore there is a norm map $N_{\mathbb{C}[X']/\mathbb{C}[X]} : \mathbb{C}[X']^\times \to \mathbb{C}[X]^\times$, which takes an element α to the element $det(m_\alpha)$, where $m_\alpha : \mathbb{C}[X'] \to \mathbb{C}[X']$ is a multiplication by α. Let $a \in \mathbb{C}[X]^\times$ be a unit. Suppose the equation

$$N_{\mathbb{C}(X')/\mathbb{C}(X)}(\alpha) = a \tag{2}$$

has a solution in $\mathbb{C}(X')$, then for any point $x \in X$ there is a function $g \in \mathbb{C}[X]$ such that $g(x) \neq 0$ and the equation $N_{\mathbb{C}[X'_g]/\mathbb{C}[X_g]}(\alpha) = a$ has a solution in $\mathbb{C}[X']_g$.
3) Let $a, b, c \in \mathbb{C}[X]$ be invertible functions. Consider an equation

$$T_1^2 - aT_2^2 - bT_3^2 + abT_4^2 = c \tag{3}$$

Suppose this equation has a solution over the field $\mathbb{C}(X)$. Then for any point $x \in X$ there is a function $g \in \mathbb{C}[X]$ such that $g(x) \neq 0$ and the Equation (3) has a solution in $\mathbb{C}[X_g]$.
4) Let A be an Azumaya $\mathbb{C}[X]$-algebra of rank n from the introduction. Let $Nrd : A \to \mathbb{C}[X]$ be the reduced norm map. It is a map such that for any point $x \in X$ the map $A/m_xA = M_r(\mathbb{C}) \to \mathbb{C}$ is the determinant. Let $a \in \mathbb{C}[X]^\times$. Suppose the equation

$$Nrd(\alpha) = a \tag{4}$$

has a solution in $A \otimes_{\mathbb{C}[X]} \mathbb{C}(X)$. Then for any point $x \in X$ there is a function $g \in \mathbb{C}[X]$ such that $g(x) \neq 0$ and the Equation (4) has a solution in A_g.
5) Let $Q = \Sigma_{i=1}^r b_i T_i^2$ be the quadratic space over $\mathbb{C}[X]$ from the introduction. Let $Q_{\mathbb{C}(X)}$ be the same quadratic space regarded over the field $\mathbb{C}(X)$. Let $a \in \mathbb{C}[X]^\times$ be a unite. Suppose a is a spinor norm over the field $\mathbb{C}(X)$, that is $a = Q(v_1) \cdot ... \cdot Q(v_{2n})$ for some vectors $v_1, ..., v_{2n} \in \mathbb{C}(X)^r$. Then a is a spinor norm locally for the Zarisky topology on X. In the other words, for any point x in X there is a function $g \in \mathbb{C}[X]$ not vanishing at x and there is a non-negative integer s and there are vectors $w_1, \dots, w_{2s} \in \mathbb{C}[X_g]^r$ such that $a = Q(w_1) \cdot \ldots \cdot Q(w_{2s})$.
6) Let (A, σ) be an Azumaya $\mathbb{C}[X]$-algebra with involution and let the involution be orthogonal, that is σ corresponds to a quadratic space locally for the complex topology on X. We use the terminology of Definition 3.1 here. Let $\mathrm{SO}_{A,\sigma} \subset \mathrm{GL}_{1,A}$ be the special orthogonal X-group scheme of the Azumaya $\mathbb{C}[X]$-algebra with involution (A, σ). Let

$\pi : \mathrm{Spin}_{A,\sigma} \to \mathrm{SO}_{A,\sigma}$ be the corresponding spinor X-group scheme. The X-group scheme $\mathrm{SO}_{A,\sigma}$ is the factor of $\mathrm{Spin}_{A,\sigma}$ modulo an inolution ε. Consider an involution τ on the variety $\mathrm{Spin}_{A,\sigma} \times \mathbb{C}^\times$, which takes any point (g, z) to the point $(\varepsilon(g), -z)$. Let Γ^+ be the factor variety of $\mathrm{Spin}_{A,\sigma} \times \mathbb{C}^\times$ modulo the involution τ. It is easy to check that Γ^+ is an X-group scheme. The map $\mathrm{Spin}_{A,\sigma} \times \mathbb{C}^\times \xrightarrow{pr_{\mathbb{C}^\times}} \mathbb{C}^\times \xrightarrow{\uparrow 2} \mathbb{C}^\times$ induces a map $Sn : \Gamma^+ \to \mathbb{C}^\times$ called the spinor norm map. For any section $\alpha : X \to \Gamma^+$ of the projection $\Gamma^+ \to X$ set $Sn(\alpha) = Sn \circ \alpha$. Let $a \in \mathbb{C}[X]^\times$ be a unite. Consider an equation

$$Sn(\alpha) = a. \tag{5}$$

If this equation has a solution over the field $\mathbb{C}(X)$, then it has a solution locally for the Zarisky topology on X. If $A = M_r(\mathbb{C}[X])$ and the involution σ corresponds to the quadratic space Q as above, then this result is equivalent to the result from the previous example.

Definition 3.1. Let X be as above. A smooth X-group scheme consists of the following data $p : \mathbf{G} \to X, \mu : \mathbf{G} \times_X \mathbf{G} \to \mathbf{G}, i : \mathbf{G} \to \mathbf{G}, e : X \to \mathbf{G}$, where p, μ, i, e are a regular maps. The requirements are these ones: p is smooth, μ is associative, e is a two-sided neutral "element" of the composition law μ, i is the inverse "element" for the composition law μ, e is a section of p.

If $\mathbf{G}_0 \subset \mathrm{GL}_n(\mathbb{C})$ is a linear complex algebraic group, then $\mathbf{G} = X \times \mathbf{G}_0$ with the obvious regular maps $p = pr_X, \mu, i, e$ form an X-group scheme. We say that an X-group scheme $\mathbf{G}$ is *holomorphically isomorphic* to the X-group scheme $X \times \mathbf{G}_0$ locally for the complex topology, if for any point $x \in X$ there is a holomorphic isomorphism $\varphi : \mathbf{G}|_U = p^{-1}(U) \to U \times \mathbf{G}_0$, which respects to the projection on U and to all the group data on both sides.

An X-group scheme $\mathbf{G}$ is called *a reductive (respectively, semi-simple; respectively, simple)* if it is an affine complex algebraic variety and for certain complex algebraic reductive group $\mathbf{G}_0$ it is holomorphically isomorphic to the X-group scheme $X \times \mathbf{G}_0$ locally for the complex topology on X. Recall that $\mathbf{G}_0$ is *required to be connected* .

This definition in the case of smooth affine complex algebraic variety X coincides with the one from Demazure and Grothendieck [1970b][Exp. XIX, Defn.2.7]. The class of reductive group schemes contains the class of semi-simple group schemes which in turn contains the class of simple group schemes. This notion of a simple X-group scheme coincides with the notion of a simple semi-simple X-group scheme from Demazure and Grothendieck [ibid.][Exp. XIX, Def. 2.7 and Exp. XXIV, 5.3].

Definition 3.2. Let $\mathbf{G}$ be a reductive X-group scheme. *A principal* $\mathbf{G}$*-bundle over* X consists of data $(p : E \to X, \nu : \mathbf{G} \times_X E \to E)$ such that p is a smooth surjective

regular map, ν is a $\mathbf{G}$-action on E respecting to the projections on X and
1) the regular map $\mathbf{G} \times_X E \to E \times_X E$ taking (g, e) to (ge, e) is an isomorphism of algebraic varieties;
2) for any point $x \in X$ there are a neighborhood V of x in the complex topology on X and an isomorphism of complex holomorphic varieties $\varphi : E|_V := p^{-1}(V) \to \mathbf{G}|_V$ such that φ respects to the projection on V and φ respects to the obvious left $\mathbf{G}$-actions on both sides.

A principal $\mathbf{G}$-bundle E *is called trivial* if there is an isomorphism $E \to \mathbf{G}$ over X, which respects to the obvious left $\mathbf{G}$-action on both sides. It is easy to check that E *is trivial* if and only if there is a section $s : X \to E$ of the projection $p : E \to X$.

In the Equation (1) in this section the X-group scheme is defined by the equation $T_1^2 - aT_2^2 = 1$. In the example (2) the X-group scheme is defined by the equation $N_{\mathbb{C}[X']/\mathbb{C}[X]}(\alpha) = 1$. In the example (3) the X-group scheme is defined by the equation $T_1^2 - aT_2^2 - bT_3^2 + abT_4^2 = 1$. In the example (4) the X-group scheme is defined by the equation $Nrd(\alpha) = 1$. In the example (5) the X-group scheme is $Spin_Q$. In the example (6) the X-group scheme is $Spin_{A,\sigma}$. The corresponding principal homogeneous bundles are described in examples (1)-(6). All these and many other examples illustrating the conjecture are simple consequences or partial cases of the following general result.

Theorem 3.3 (Fedorov and I. Panin [2015])**.** Let X be as above in this section. Let $\mathbf{G}$ be a reductive X-group scheme and E be a principal $\mathbf{G}$-bundle. Suppose for a non-zero function f the principal $\mathbf{G}$-bundle $E|_{X_f}$ is trivial over X_f. Then it is trivial locally for the Zarisky topology on X. That is for any point $x \in X$ there is a function $g \in \mathbb{C}[X]$ such that $g(x) \neq 0$ and the principal $\mathbf{G}$-bundle $E|_{X_g}$ is trivial over X_g.

Remark 3.4. Let us point out that *the author still does not know* any proof of the result from the example (6), different from deriving it from Theorem 3.3. All results from examples (1)–(5) do have proofs avoiding any reference to Theorem 3.3.

Corollary 3.5 (of Theorem 3.3)**.** Let X be as above in this section. Let $\mathbf{G}$ be a reductive X-group scheme and E_1, E_2 be two principal $\mathbf{G}$-bundles. Suppose for a non-zero $f \in \mathbb{C}[X]$ the principal $\mathbf{G}$-bundles $E_1|_{X_f}$ and $E_2|_{X_f}$ over X_f. Then the principal $\mathbf{G}$-bundles E_1 and E_2 are isomorphic locally for the Zarisky topology on X.

Indeed, consider an X-group scheme $\underline{\mathrm{Aut}}_{\mathbf{G}}(E_1)$ of the $\mathbf{G}$-bundle automorphisms and an X-scheme of principal $\mathbf{G}$-bundle isomorphisms $\underline{\mathrm{Iso}}_{\mathbf{G}}(E_1, E_2)$. The latter scheme is a principal $\underline{\mathrm{Aut}}_{\mathbf{G}}(E_1)$-bundle and the X-group scheme $\underline{\mathrm{Aut}}_{\mathbf{G}}(E_1)$ is a reductive X-group scheme isomorphic to the X-group scheme $\mathbf{G}$ locally for the complex topology on X. A principal $\mathbf{G}$-bundle isomorphism $\varphi : E_1|_{X_f} \to E_2|_{X_f}$ is a section of $\underline{\mathrm{Iso}}_{\mathbf{G}}(E_1, E_2)$ over X_f. Hence $\underline{\mathrm{Iso}}_{\mathbf{G}}(E_1, E_2)$ has sections locally for the Zarisky topology on X. Thus the principal $\mathbf{G}$-bundles E_1 and E_2 are isomorphic locally for the Zarisky topology on X.

Corollary 3.6 (of Theorem 3.3)**.** Let $\mathbf{G}_1, \mathbf{G}_2$ be two simple X-group schemes of the type G_2 (resp. F_4, resp. E_8). That is the fibres and $\mathbf{G}_1, \mathbf{G}_2$ over a point $x \in X$ are of the type G_2 (resp. F_4, resp. E_8). Suppose for a non-zero element $f \in \mathbb{C}[X]$ the X_f-group schemes $(\mathbf{G_1})|_{X_f}$ and $(\mathbf{G_2})|_{X_f}$ are isomorphic. Then the X-group schemes $\mathbf{G_1}$ and $\mathbf{G_2}$ are isomorphic locally for the Zarisky topology on X.

Indeed, consider an X-scheme $\underline{\mathrm{Iso}}_{X-gr-sch}(\mathbf{G_1}, \mathbf{G_2})$. There is a regular map

$$\mathbf{G}_1 \times_X \underline{\mathrm{Iso}}_{X-gr-sch}(\mathbf{G_1}, \mathbf{G_2}) \to \underline{\mathrm{Iso}}_{X-gr-sch}(\mathbf{G_1}, \mathbf{G_2})$$

given by $(g_1, \varphi) \mapsto \varphi \circ \mathrm{conj}(g_1)$. This map makes the X-scheme $\underline{\mathrm{Iso}}_{X-gr-sch}(\mathbf{G_1}, \mathbf{G_2})$ a principal $\mathbf{G_1}$-bundle over X. This principal $\mathbf{G_1}$-bundle has a section over X_f. Hence for any point $x \in X$ there is a function $g \in \mathbb{C}[X]$ such that $g(x) \neq 0$ and the X-scheme $\underline{\mathrm{Iso}}_{X-gr-sch}(\mathbf{G_1}, \mathbf{G_1})$ has a section over X_g. The latter means that the X_g-group schemes $(\mathbf{G_1})|_{X_g}$ and $(\mathbf{G_2})|_{X_g}$ are isomorphic.

4 The conjecture, main results and some corollaries

Assume that U is a regular scheme. Let $\mathbf{G}$ be a reductive U-group scheme, that is, $\mathbf{G}$ is affine and smooth as a U-scheme and, moreover, the geometric fibers of $\mathbf{G}$ are connected reductive algebraic groups (see Demazure and Grothendieck [1970b][Exp. XIX, Definition 2.7]). Recall that a U-scheme E with an action of $\mathbf{G}$ is called a principal $\mathbf{G}$-bundle over U, if $\mathbf{G}$ is faithfully flat and quasi-compact over U and the action is simply transitive, that is, the natural morphism $\mathbf{G} \times_U E \to E \times_U E$ is an isomorphism. It is well known that such a bundle is trivial locally in the étale topology but in general not in the Zariski topology. Grothendieck and Serre conjectured that if E is generically trivial, then it is locally trivial in the Zariski topology (see Serre [1958][Remarque, p. 31], Grothendieck [1958][Remarque 3, pp. 26–-27], and Grothendieck [1968a][Remarque 1.11.a]). More precisely, the following conjecture is widely attributed to them.

Conjecture 1. Let R be a regular local ring, let K be its field of fractions. Let $\mathbf{G}$ be a reductive group scheme over $U := Spec R$, let E be a principal $\mathbf{G}$-bundle. If E is trivial over $Spec K$, then it is trivial. That is $E(R) \neq \varnothing$.

Theorem 4.1 (Main)**.** If R is a regular local ring containing a field, then the above conjecture holds.

This theorem is proved by R. Fedorov and the author in Fedorov and I. Panin [2015] in the case, when R contains an infinite field. It is proved by the author in I. Panin [2017b], when R contains a finite field.

Corollary 4.2 (of Theorem 4.1)**.** Let R be a regular local ring containing a field and $\mathbf{G}$ be a reductive R-group scheme. Let E_1, E_2 be two principal $\mathbf{G}$-bundles. Suppose they are isomorphic over the fraction field of R. Then they are isomorphic.

The proof literally repeats the proof of Corollary 3.5.

Corollary 4.3 (of Theorem 4.1)**.** Let R be a regular local ring containing a field and $\mathbf{G}$ be a reductive R-group scheme. Let $\mu : \mathbf{G} \to \mathbf{T}$ be a group scheme morphism to an R-torus $\mathbf{T}$ such that μ is locally in the étale topology on $Spec R$ surjective. Assume further that the R-group scheme $\mathbf{H} := \mathrm{Ker}(\mu)$ is reductive. Let K be the fraction field of R. Then the group homomorphism

$$\mathbf{T}(R)/\mu(\mathbf{G}(R)) \to \mathbf{T}(K)/\mu(\mathbf{G}(K)).$$

is injective.

To derive this corollary from Theorem 4.1 consider a commutative diagram

$$\begin{array}{ccccc} \mathbf{G}(R) & \xrightarrow{\mu} & \mathbf{T}(R) & \xrightarrow{\nu} & H^1_{et}(R, \mathbf{H}) \\ \downarrow & & \downarrow & & \downarrow \\ \mathbf{G}(K) & \xrightarrow{\mu} & \mathbf{T}(K) & \xrightarrow{\nu} & H^1_{et}(K, \mathbf{H}) \end{array}$$

By Theorem 4.1 the right vertical arrow has trivial kernel. Now a simple diagram chase completes the proof. The latter corollary extends all the known results of this form proved in Colliot-Thélène and Ojanguren [1992], I. A. Panin and Suslin [1997], Zaĭnullin [2000], and Ojanguren, I. Panin, and Zainoulline [2004].

Corollary 4.4 (of Theorem 4.1)**.** Under the notation and the hypothesis of the previous corollary the following sequence is exact

$$\{1\} \to \mathbf{T}(R)/\mu(\mathbf{G}(R)) \to \mathbf{T}(K)/\mu(\mathbf{G}(K)) \xrightarrow{\Sigma\, res_p} \oplus_{ht(p)=1} \mathbf{T}(K)/\mathbf{T}(R_p)\cdot\mu(\mathbf{G}(K)) \to \{1\},$$

where p runs all hight 1 prime ideals in R and res_p is the obvious map.

The exactness at the term $\mathbf{T}(R)/\mu(\mathbf{G}(R))$ is due to the previous corollary. The surjectivity of the map $\Sigma\, res_p$ is due to Colliot-Thélène and Sansuc [1987]. The exactness at the middle term is proved in I. A. Panin [2016a], I. Panin [2017c].

There are two other very general results concerning the conjecture: due to Nisnevič [1977] and due to Colliot-Thélène and Sansuc [1987] (see the history of the topic).

5 History of the topic

History of the topic. — In his 1958 paper Jean-Pierre Serre asked whether a principal bundle is Zariski locally trivial, once it has a rational section (see Serre [1958][Remarque, p. 31]). In his setup the group is any algebraic group over an algebraically closed field. He gave an affirmative answer to the question when the group is PGL(n) (see Serre [ibid.][Prop. 18]) and when the group is an abelian variety (see Serre [ibid.][Lemme 4]). In the same year, Alexander Grothendieck asked a similar question (see Grothendieck [1958][Remarque 3, pp. 26–27]). A few years later, Grothendieck conjectured that the statement is true for any semi-simple group scheme over any regular local scheme (see Grothendieck [1965][Remarque 1.11.a]). Now by the Grothendieck–Serre conjecture we mean Conjecture 1 though this may be slightly inaccurate from historical perspective. Many results corroborating the conjecture are known.

Here is a list of known results in the same vein, corroborating the Grothendieck–Serre conjecture.

• The case when the group is PGL_n and the base field is algebraically closed is done by J.-P. Serre in 1958 in Serre [1958, Prop. 18].

• The case when the group scheme is PGL_n and the ring R is an arbitrary regular local ring is done by A. Grothendieck in 1968 in Grothendieck [1968a].

• The case when the local ring R contains a field of characteristic not 2 the group is SO_n over the ground field is done by M. Ojanguren in 1982 in Ojanguren [1980].

• The case of an arbitrary reductive group scheme over a discrete valuation ring or over a henselian ring is solved by Nisnevič [1977] in 1984.

• The case, where $\mathbf{G}$ is an arbitrary torus over a regular local ring, was settled by Colliot-Thélène and Sansuc [1987] in 1987.

• The case, when $\mathbf{G}$ is quasi-split reductive group scheme over arbitrary two-dimensional local rings, is solved by Nisnevich [1984] in 1989.

• The case, where the group scheme $\mathbf{G}$ comes from an infinite perfect ground field, solved by Colliot-Thélène and Ojanguren [1992] in 1992. As far as we know this work was inspired by the one Ojanguren [1980].

• The case, where the group scheme $\mathbf{G}$ comes from an arbitrary infinite ground field, solved by Raghunathan [1994, 1995] in 1994;

• O. Gabber announced in 1994 a proof for group schemes coming from arbitrary ground fields (including finite fields).

• For the group scheme $\mathrm{SL}_{1,A}$, where A is an Azumaya R-algebra and R contains a field the conjecture is solved by I. A. Panin and Suslin [1997] in 1998.

• For the unitary group scheme $\mathrm{U}^{\varepsilon}_{A,\sigma}$, where (A,σ) is an Azumaya R-algebra with involution R contains a field of characteristic not 2 the conjecture is solved by Ojanguren and I. Panin [2001] in 2001.

• For the special unitary group scheme $\mathrm{SU}_{A,\sigma}$, where (A,σ) is an Azumaya R-algebra with a unitary involution and R contains a field of characteristic not 2 the conjecture is solved by Zaĭnullin [2000] in 2001.

• For the spinor group scheme Spin_Q of a quadratic space Q over R containing a field of characteristic not 2 the conjecture is solved Ojanguren, I. Panin, and Zainoulline [2004] in 2004.

• Under an isotropy condition on $\mathbf{G}$ the conjecture is proved by A. Stavrova, N. Vavilov and the author in a series of preprints in 2009, published as papers in 2015 in I. Panin, A. Stavrova, and Vavilov [2015a] and in 2016 in I. A. Panin [2016a].

• The case of strongly inner simple adjoint group schemes of the types E_6 and E_7 is done by the second author, V. Petrov, A. Stavrova and the second author in 2009 in I. Panin, Petrov, and A. Stavrova [2009]. No isotropy condition is imposed there.

• The case, when $\mathbf{G}$ is of the type F_4 with trivial f_3-invariant and the field is infinite and perfect, is settled by Petrov and A. Stavrova [2009] in 2009.

• The case, when $\mathbf{G}$ is of the type F_4 with trivial g_3-invariant and the field is of characteristic zero, is settled by Chernousov [2010] in 2010;

• The conjecture is solved when R contains an infinite field, by R. Fedorov and the author in a preprint in 2013 and published in Fedorov and I. Panin [2015] in 2015.

• The conjecture is solved by the author in the case, when R contains a finite field in I. Panin [2015] (for a better structured proof see I. Panin [2017b]).

So, *the conjecture is solved in the case, when R contains a field*.

The case of mixed characteristic is widely open. Let us indicate two recent interesing preprints Fedorov [2015] and I. A. Panin and A. K. Stavrova [2016]. In Fedorov [2015] the conjecture is solved for a large class of regular local rings of mixed characteristic assuming that $\mathbf{G}$ splits. In I. A. Panin and A. K. Stavrova [2016] the conjecture is solved for any semi-local Dedekind domain providing that $\mathbf{G}$ is simple simply-connected and $\mathbf{G}$ contains a torus $\mathbb{G}_{m,R}$.

6 Sketch of the proof of Theorem 4.1 for an infinite field

To escape technicalities we suppose also that the field k below *is algebraically closed* (for instance, k is the complex numbers $\mathbb{C}$). And also suppose that the ring R is the semi-local ring $\mathcal{O}_{X,x_1,\dots,x_n}$ of finitely many closed points on a smooth affine k-variety X. There are two very general purity theorems I. A. Panin [2016a, Thm. 1.0.1, Thm. 1.0.2] which allows I. A. Panin [ibid., Thm. 1.0.3] to reduce Theorem 4.1 to the case, when the group scheme $\mathbf{G}$ is semi-simple simply-connected. Then using standard arguments as in I. Panin, A. Stavrova, and Vavilov [2015b] one can reduce the latter case to the case of simple and simply-connected group scheme $\mathbf{G}$ (*point out that this reduction requires to work with semi-local rings*). So, we will consider below only the case of simple and simply-connected group scheme **G**. And for simplicity of notation we will suppose below the ring R is the local ring $\mathcal{O}_{X,x}$ of a closed point x on a smooth affine k-variety X.

Theorem 6.1 (I. Panin, A. Stavrova, and Vavilov [ibid.]). Let R be the local ring of a closed point on an irreducible smooth affine variety over the field k, set $U = \operatorname{Spec} R$. Let **G** be a simple simply-connected group scheme over U (see Demazure and Grothendieck [1970a, Exp. XXIV, Sect. 5.3] for the definition). Let $\mathcal{G}$ be a principal **G**-bundle over U which is trivial over the principal open subset $U_f \subset U$ for a non-zero $f \in R$. Then there exists a principal **G**-bundle E_t over $\mathbb{A}^1_U$ and a monic polynomial $h(t) \in R[t]$ such that
(i) the **G**-bundle E_t is trivial over $(\mathbb{A}^1_U)_h$,
(ii) the evaluation of E_t at $t = 0$ coincides with the original **G**-bundle $\mathcal{G}$,
(iii) $\{1\} \times U \subset (\mathbb{A}^1_U)_h$.

Remark 6.2. If the field $k = \mathbb{C}$, then the principal **G**-bundle E_t regarded as a topological principal **G**-bundle for the complex topology is of the form $p^*(E_0)$ for a topological principal **G**-bundle E_0, where $p : \mathbb{A}^1_U \to U$ is the projection. By the item (iii) and (ii) of the latter theorem the principal **G**-bundle $\mathcal{G}$ *regarded as a topological principal* **G***-bundle is trivial.* Hence it is trivial even as the complex holomorphic principal **G**-bundle.

However *these kind of arguments do not work in general for algebraic principal* **G***-bundles* since there are principal **G**-bundles on $\mathbb{A}^1_U$ which do not come from U (see Fedorov [2016]). If $k = \mathbb{R}$ then there are many examples of principal **G**-bundles on $\mathbb{A}^1_U$ which do not come from U. Those examples can be deduced from Knus, R. Parimala, and Sridharan [1981/82], Ojanguren, R. Parimala, and Sridharan [1983], S. Parimala [1978].

That is why we need in the following proposition and theorem.

Proposition 6.3 (Fedorov and I. Panin [2015]). Let k,R, U, **G**, be the same as in Theorem 6.1. Let $Z \subset \mathbb{A}^1_U$ be a closed subscheme finite over U. Then there exists a closed subscheme Y in $\mathbb{A}^1_U$ such that Y is étale and finite over U, the Y-group scheme $\mathbf{G}_Y := \mathbf{G}\times_U Y$ is quasi-split and $Y \cap Z = \varnothing$.

Theorem 6.4 (Fedorov and I. Panin [ibid.]). Let k, R, U, **G**, be the same as in Theorem 6.1. Let $Z \subset \mathbb{A}^1_U$ be a closed subscheme finite over U. Let $Y \subset \mathbb{A}^1_U$ be a closed subscheme étale and finite over U. Assume that $Y \cap Z = \varnothing$, and $\mathbf{G}_Y := \mathbf{G} \times_U Y$ is quasi-split.

Let E be a principal **G**-bundle over $\mathbb{P}^1_U$ such that its restriction to $\mathbb{P}^1_U - Z$ is trivial. Then the restriction of E to $\mathbb{P}^1_U - Y$ is also trivial.

Derive now the simple simply-connected case (geometric) of Theorem 4.1 from these three statements. Let $\mathcal{G}$ be a principal **G**-bundle over U which is trivial over the principal open subset $U_f \subset U$ for a non-zero $f \in R$. By Theorem 6.1 there are a monic polinomial $h(t) \in R[t]$ and a principal **G**-bundle E_t over $\mathbb{A}^1_U$ such that (i) and (ii) hold. Since E_t is trivial over $(\mathbb{A}^1_U)_{h(t)}$ there is a principal **G**-bundle E over $\mathbb{P}^1_U$ such that $E|_{\mathbb{P}^1_U - Z}$ is trivial and $E_{\mathbb{A}^1_U} = E_t$ (here $Z \subset \mathbb{A}^1_U \subset \mathbb{P}^1_U$ is the vanishing locus of $h(t) = 0$). By Proposition 6.3 there is a closed subscheme Y in $\mathbb{A}^1_U$ such that Y is étale and finite over U, the Y-group scheme $\mathbf{G}_Y := \mathbf{G} \times_U Y$ is quasi-split and $Y \cap Z = \varnothing$. By Theorem 6.4 the restriction of E to $\mathbb{P}^1_U - Y$ is trivial. Since U is local for each section $s : U \to \mathbb{A}^1_U$ of the projection $\mathbb{A}^1_U \to U$ either $s(U) \cap Y = \varnothing$ or $s(U) \cap Z = \varnothing$. In any case, the principal $\mathbf{G}$-bundle $s^*(E_t) = s^*(E)$ is trivial. By the item (ii) of Theorem 6.1 the original $\mathbf{G}$-bundle $\mathcal{G}$ is trivial.

First, we give a sketch of the proof of Theorem 6.1. Let k be the field. Let X be an affine k-smooth irreducible k-variety, and let x be a closed point in X. Let $U = Spec(\mathcal{O}_{X,x})$ and f $\in k[X]$ be a non-zero function vanishing the point x. Let $\mathbf{G}_X$ be a simple simply-connected group scheme over X, $\mathbf{G}$ be its restriction to U.

Beginning with these data it is constructed in I. Panin, A. Stavrova, and Vavilov [2015b] a monic polinomial $h \in \mathcal{O}_{X,x}[t]$, a commutative diagram of schemes with the irreducible affine U-smooth variety Y

$$\begin{array}{ccccc} (\mathbb{A}^1 \times U)_h & \xleftarrow{\ \tau_h\ } & Y_h := Y_{\tau^*(h)} & \xrightarrow{(p_X)|_{Y_h}} & X_f \\ \big\downarrow{\scriptstyle inc} & & \big\downarrow{\scriptstyle inc} & & \big\downarrow{\scriptstyle inc} \\ (\mathbb{A}^1 \times U) & \xleftarrow{\ \tau\ } & Y & \xrightarrow{\ p_X\ } & X \end{array} \tag{6}$$

and a morphism $\delta : U \to Y$ subjecting to the following conditions:

(a) the left hand side square is *an elementary distinguished square* in the category of affine U-smooth schemes in the sense of Morel and Voevodsky [1999, Defn.3.1.3];

(b) $p_X \circ \delta = can : U \to X$, where can is the canonical morphism;

(c) $\tau \circ \delta = i_0 : U \to \mathbb{A}^1 \times U$ is the zero section of the projection $pr_U : \mathbb{A}^1 \times U \to U$;

(d) $h(1) \in \mathcal{O}_{X,x}[t]$ is a unit;

(e) for $p_U := pr_U \circ \tau$ there is a Y-group scheme isomorphism $\Phi : p_U^*(\mathbf{G}) \to p_X^*(\mathbf{G}_X)$ with $\delta^*(\Phi) = id_{\mathbf{G}}$.

Given this geometric result a proof of Theorem 6.1 run as follows. In general, $\mathbf{G}$ does not come from X. However we may assume, that $\mathbf{G}$ is a restriction to U of a simple and simply-connected X-group scheme $\mathbf{G}_X$, $\mathcal{G}$ is defined over X. Say, let $\mathcal{G}'$ be a principal $\mathbf{G}_X$-bundle on X with $\mathcal{G}'|_U = \mathcal{G}$ and such that $\mathcal{G}'$ is trivial over X_f for an $0 \neq f \in k[X]$ with $f(x) = 0$. In this case there are two reductive group schemes on Y. Namelly, $p_U^*(\mathbf{G})$ and $p_X^*(\mathbf{G}_X)$. By the property (b) they coincides when restricted to $\delta(U)$. By the property (e) the scheme Y is chosen such that two reductive group schemes $p_U^*(\mathbf{G})$ and $p_X^*(\mathbf{G}_X)$

on Y are isomorphic via an Y-group scheme isomorphism Φ and the restriction of Φ to $\delta(U)$ is the identity. Take $p_X^*(\mathcal{G}')$ and regard it as a principal $p_U^*(\mathbf{G})$-bundle using the isomorphism Φ. Denote that principal $p_U^*(\mathbf{G})$-bundle ${}_U p_X^*(\mathcal{G})$. It is trivial on Y_h, since $p_X^*(\mathcal{G}')$ is trivial on Y_h. Take the trivial $pr_U^*(\mathbf{G})$-bundle on $\mathbb{A}^1 \times U$ and glue it with ${}_U p_X^*(\mathcal{G})$ via an isomorphism over Y_h. That is possible by the condition (a). This way we get a principal $\mathbf{G}$-bundle $\mathcal{G}_t$ over $\mathbb{A}^1 \times U$ which is trivial over the open subscheme $(\mathbb{A}^1 \times U)_h$ and such that ${}_U p_X^*(\mathcal{G}) = \tau^*(\mathcal{G}_t)$. Clearly, it is the desired one. The polinomial h is the polinomial above. Whence the Theorem 6.1.

Secondly, we give a sketch of the proof of Proposition 6.3. Let $\mathfrak{B}$ be the U-scheme of Borel subgroup schemes of $\mathbf{G}$. It is a smooth projective U-scheme (see Demazure and Grothendieck [1970a, Cor. 3.5, Exp. XXVI]). Take an embedding of $\mathfrak{B}$ into a projective space $\mathbb{P}_U^N$ and intersect $\mathfrak{B}$ with appropriately chosen family of hyperplanes. Arguing as in the proof of Ojanguren and I. Panin [2001, Lemma 7.2], we get a scheme Y finite and étale over U and such that the Y-group scheme $\mathbf{G}_Y := \mathbf{G} \times_U Y$ is quasi-split. Since the field k is infinite and Y is finite étale over U, we can choose a closed U-embedding of Y in $\mathbb{A}_U^1$. We will identify Y with the image of this closed embedding. Since Y is finite over U, it is closed in $\mathbb{P}_U^1$. Applying to Y an appropriative affine U-transformation of $\mathbb{A}_U^1$ we get Y such that $Y \cap Z = \varnothing$. Whence the Proposition 6.3

The next result is a partial case of Theorem 9.6 of I. Panin, A. Stavrova, and Vavilov [2015b].

Proposition 6.5. Let U be as above and let $u \in U$ be its closed point. Let $\mathcal{E}$ be a $\mathbf{G}$-bundle over $\mathbb{P}_U^1$ such that $\mathcal{E}|_{\mathbb{P}_u^1}$ is a trivial $\mathbf{G}_u$-bundle. Assume that there exists a closed subscheme T of $\mathbb{P}_U^1$ finite over U such that the restriction of $\mathcal{E}$ to $\mathbb{P}_U^1 - T$ is trivial. Then E is of the form: $\mathcal{E} = \mathrm{pr}^*(\mathcal{E}_0)$, where $\mathcal{E}_0$ is a principal $\mathbf{G}$-bundle over U and $\mathrm{pr} : \mathbb{P}_U^1 \to U$ is the canonical projection.

If furthermore $T \cap \{\infty\} \times U = \varnothing$, then $\mathcal{E}$ is trivial.

Finally, we give a sketch of the proof of Theorem 6.4. Let $(Y^h, \pi : Y^h \to \mathbb{A}_U^1, s : Y \to Y^h)$ be the henselization of the pair $(\mathbb{A}_U^1, Y)$. Here $s : Y \to Y^h$ is the canonical closed embedding, see Fedorov and I. Panin [2015, Sect. 5.3] for more details. Let $in : \mathbb{A}_U^1 \to \mathbb{P}_U^1$ be the embedding. Set $\dot{Y}^h := Y^h - s(Y)$. Note that as Y^h, so $\dot{Y}^h$ *are affine schemes*, see Fedorov and I. Panin [ibid., Sect. 5.3, Prop. 5.13]. Consider the following cartesian square of schemes

$$\begin{array}{ccc} \dot{Y}^h & \xrightarrow{j} & Y^h \\ \downarrow & & \downarrow{\scriptstyle in\circ\pi} \\ \mathbb{P}_U^1 - Y & \xrightarrow{i} & \mathbb{P}_U^1 \end{array} \tag{7}$$

As explained in Fedorov and I. Panin [2015, Prop. 5.15, Constr. 5.16] that square can be used to get $\mathbf{G}$-bundles on $\mathbb{P}^1_U$ beginning with a $\mathbf{G}$-bundle on $\mathbb{P}^1_U - Y$ and its trivialization over $\dot{Y}^h$. Let E' be a $\mathbf{G}$-bundle over $\mathbb{P}^1_U - Y$. Denote by $\mathrm{Gl}(E', \varphi)$ the $\mathbf{G}$-bundle over $\mathbb{P}^1_U$ obtained by gluing E' with the trivial $\mathbf{G}$-bundle $\mathbf{G} \times_U Y^h$ via a $\mathbf{G}$-bundle isomorphism $\varphi : \mathbf{G} \times_U \dot{Y}^h \to E'|_{\dot{Y}^h}$.

Similarly, set $Y_u := Y \times_U u$ and denote by Y^h_u the henselization of the pair $(\mathbb{A}^1_u, Y_u)$, let $s_u : Y_u \to Y^h_u$ be the closed embedding. Set $\dot{Y}^h_u := Y^h_u - s_u(Y_u)$. Let E'_u be a $\mathbf{G}_u$-bundle over $\mathbb{P}^1_u - Y_u$, where $\mathbf{G}_u := \mathbf{G} \times_U u$. Denote by $\mathrm{Gl}_u(E'_u, \varphi_u)$ the $\mathbf{G}_u$-bundle over $\mathbb{P}^1_u$ obtained by gluing E'_u with the trivial bundle $\mathbf{G}_u \times_u Y^h_u$ via a $\mathbf{G}_u$-bundle isomorphism $\varphi_u : \mathbf{G}_u \times_u \dot{Y}^h_u \to E'_u|_{\dot{Y}^h_u}$.

Note that the $\mathbf{G}$-bundle E can be presented in the form $\mathrm{Gl}(E', \varphi)$, where $E' = E|_{\mathbb{P}^1_U - Y}$. The idea is to show that

(∗) *There is $\alpha \in \mathbf{G}(\dot{Y}^h)$ such that the $\mathbf{G}_u$-bundle $Gl(E', \varphi \circ \alpha)|_{\mathbb{P}^1_u}$ is trivial (here α is regarded as an automorphism of the $\mathbf{G}$-bundle $\mathbf{G} \times_U \dot{Y}^h$ given by the right translation by the element α).*

If we find α satisfying condition (∗), then Proposition 6.5, applied to $T = Y \cup Z$, shows that the $\mathbf{G}$-bundle $\mathrm{Gl}(E', \varphi \circ \alpha)$ is trivial over $\mathbb{P}^1_U$. On the other hand, its restriction to $\mathbb{P}^1_U - Y$ coincides with the $\mathbf{G}$-bundle $E' = E|_{\mathbb{P}^1_U - Y}$. *Thus $E|_{\mathbb{P}^1_U - Y}$ is a trivial $\mathbf{G}$-bundle*
.

To prove (∗), one should show that

(i) the bundle $E|_{\mathbb{P}^1_u - Y_u}$ is trivial;

(ii) each element $\gamma_u \in \mathbf{G}_u(\dot{Y}^h_u)$ can be written in the form $\gamma_u = \alpha|_{\dot{Y}^h_u}$ for a certain element $\alpha \in \mathbf{G}(\dot{Y}^h)$.

If we succeed to show (i) and (ii), then we proceed as follows. Present the $\mathbf{G}$-bundle E in the form $\mathrm{Gl}(E', \varphi)$ as above. Observe that

$$\mathrm{Gl}(E', \varphi)|_{\mathbb{P}^1_u} \cong \mathrm{Gl}_u(E'_u, \varphi_u),$$

where $E'_u := E'|_{\mathbb{P}^1_u - Y_u}$, $\varphi_u := \varphi|_{\mathbf{G}_u \times_u \dot{Y}^h_u}$.

Using property (i), find an element $\gamma_u \in \mathbf{G}_u(\dot{Y}^h_u)$ such that the $\mathbf{G}_u$-bundle $\mathrm{Gl}_u(E'_u, \varphi_u \circ \gamma_u)$ is trivial. For this γ_u find an element α as in (ii). Finally take the $\mathbf{G}$-bundle $\mathrm{Gl}(E', \varphi \circ \alpha)$. Then its restriction to $\mathbb{P}^1_u$ is trivial. Indeed, one has a chain of $\mathbf{G}_u$-bundle isomorphisms

$$\mathrm{Gl}(E', \varphi \circ \alpha)|_{\mathbb{P}^1_u} \cong \mathrm{Gl}_u(E'_u, \varphi_u \circ \alpha|_{\dot{Y}^h_u}) = \mathrm{Gl}_u(E'_u, \varphi_u \circ \gamma_u),$$

which is trivial by the very choice of γ_u. Thus, (∗) will be achieved.

Let us prove (i) and (ii). The $\mathbf{G}_u$-bundle E_u is trivial over $\mathbb{P}^1_u - Z_u$. The field $k(u) = k$ is algebraically closed. By a theorem Grothendieck–Harder Harder [1968, Satz 3.1, 3.4] there is an algebraic group morphism $\lambda : \mathbb{G}_{m,k(u)} \to \mathbf{G}_u$ such that the $\mathbf{G}_u$-bundle E_u on $\mathbb{P}^1_u$ is isomorphic to the one $\mathbf{G}_u \times_{\mathbb{G}_{m,k(u)}} \mathcal{O}(-1)$, where $\mathcal{O}(-1)$ is the $\mathbb{G}_{m,k(u)}$-bundle

$\mathbb{A}^2_{k(u)} - 0 \to \mathbb{P}^1_{k(u)}$. Since the field k is algebraically closed, hence $\mathbb{P}^1_u - Y_u$ is contained in an affine line $\mathbb{A}^1_u$. Thus the restrictions of $\mathcal{O}(-1)$ and E_u to $\mathbb{P}^1_u - Y_u$ are trivial. So, (i) is achieved.

To complete the proof it remains to achieve (ii). By our assumption on Y, the group scheme $\mathbf{G}_Y = \mathbf{G} \times_U Y$ is quasi-split. Thus we can and will choose a Borel subgroup scheme $\mathbf{B}^+$ in $\mathbf{G}_Y$.

Since Y is an affine scheme, by Demazure and Grothendieck [1970a, Exp. XXVI, Cor. 2.3, Th 4.3.2(a)] there is an opposite to $\mathbf{B}^+$ Borel subgroup scheme $\mathbf{B}^-$ in $\mathbf{G}_Y$. Let $\mathbf{U}^+$ be the unipotent radical of $\mathbf{B}^+$, and let $\mathbf{U}^-$ be the unipotent radical of $\mathbf{B}^-$.

We will write $\mathbf{E}$ for the functor, sending a Y-scheme T to the subgroup $\mathbf{E}(T)$ of the group $\mathbf{G}_Y(T) = \mathbf{G}(T)$ generated by the subgroups $\mathbf{U}^+(T)$ and $\mathbf{U}^-(T)$ of the group $\mathbf{G}_Y(T) = \mathbf{G}(T)$.

The functor $\mathbf{E}$ has the property that for every closed subscheme S in an affine Y-scheme T *the induced map* $\mathbf{E}(T) \to \mathbf{E}(S)$ *is surjective.* Indeed, the restriction maps $\mathbf{U}^\pm(T) \to \mathbf{U}^\pm(S)$ are surjective, since $\mathbf{U}^\pm$ are isomorphic to vector bundles as Y-schemes (see Demazure and Grothendieck [ibid., Exp. XXVI, Cor. 2.5]).

Recall that (Y^h, π, s) is the henselization of the pair $(\mathbb{A}^1_U, Y)$. Also, $in : \mathbb{A}^1_U \to \mathbb{P}^1_U$ is the embedding. Denote the projection $\mathbb{A}^1_U \to U$ by pr and the projection $\mathbb{A}^1_Y \to Y$ by pr_Y. It is proved in Fedorov and I. Panin [2015, Lemma 5.25] the following

Claim. There is a morphism $r : Y^h \to Y$ making the following diagram commutative

$$
\begin{array}{ccc}
Y^h & \xrightarrow{r} & Y \\
{\scriptstyle in\circ\pi}\downarrow & & \downarrow{\scriptstyle pr|_Y} \\
\mathbb{P}^1_U & \xrightarrow{pr} & U
\end{array}
\tag{8}
$$

and such that $r \circ s = \mathrm{Id}_Y$.

We view Y^h as a Y-scheme via r. Thus various subschemes of Y^h also become Y-schemes. In particular, $\dot{Y}^h$ and $\dot{Y}^h_u$ are Y-schemes, and we can consider

$$\mathbf{E}(\dot{Y}^h) \subset \mathbf{G}(\dot{Y}^h) \text{ and } \mathbf{E}(\dot{Y}^h_u) \subset \mathbf{G}(\dot{Y}^h_u) = \mathbf{G}_u(\dot{Y}^h_u).$$

Since $\dot{Y}^h_u$ is an affine scheme corresponding to the direct product of few fields, $\mathbf{G}_u$ is *simply-connected and quasi-split*, hence one has an equality $\mathbf{G}_u(\dot{Y}^h_u) = \mathbf{E}(\dot{Y}^h_u)$. As indicated right above the diagram (7) the scheme $\dot{Y}^h$ is affine. Since $\dot{Y}^h_u$ is its closed subscheme the group homomorphism $\mathbf{E}(\dot{Y}^h) \to \mathbf{E}(\dot{Y}^h_u)$ is surjective. Thus the the group homomorphism $\mathbf{G}(\dot{Y}^h) \to \mathbf{G}(\dot{Y}^h_u) = \mathbf{G}_u(\dot{Y}^h_u)$ is surjective as well. We achieved the property (ii). Whence the Theorem 6.4. The sketch of the proof of the Theorem 4.1 is completed.

7 Sketch of the proof of Theorem 4.1 for a finite field

Let k be a finite field. Give a sketch of the proof of Theorem 4.1 in this case. The outline of the proof is the same. So, we will focus on crucial differences. There is a reduction to the case of simple and simply-connected group scheme $\mathbf{G}$ over the semi-local ring of finitely many closed points on a smooth affine variety X So, we will consider below only the case of simple and simply-connected group scheme $\mathbf{G}$. And for simplicity of notation we will suppose below the ring R is the local ring $\mathcal{O}_{X,x}$ of a closed point x on a smooth affine k-variety X.

The statement of Theorem 6.1 remains the same in the case of finite base field.

Theorem 7.1 (I. Panin [2017a])**.** Let R be the local ring of a closed point on an irreducible smooth affine variety over the finite field k, set $U = \text{Spec } R$. Let $\mathbf{G}$ be a simple simply-connected group scheme over U. Let $\mathcal{G}$ be a principal $\mathbf{G}$-bundle over U which is trivial over the principal open subset $U_f \subset U$ for a non-zero $f \in R$. Then there exists a principal $\mathbf{G}$-bundle E_t over $\mathbb{A}^1_U$ and a monic polynomial $h(t) \in R[t]$ such that

(i) the $\mathbf{G}$-bundle E_t is trivial over $(\mathbb{A}^1_U)_h$,

(ii) the evaluation of E_t at $t = 0$ coincides with the original $\mathbf{G}$-bundle $\mathcal{G}$,

(iii) $h(1) \in R$ is invertible in R.

Proposition 6.3 one needs to replace with the following one

Proposition 7.2 (I. Panin [2017b])**.** Let k,R, U, $\mathbf{G}$, be the same as in Theorem 6.1 and k be the finite field. Let $Z \subset \mathbb{A}^1_U$ be a closed subscheme finite over U. Then there exists a closed subscheme Y in $\mathbb{A}^1_U$ such that Y is étale and finite over U,

(a) the Y-group scheme $\mathbf{G}_Y := \mathbf{G} \times_U Y$ is quasi-split,

(b) $\text{Pic}(\mathbb{P}^1_u - Y_u) = 0$,

(c) $Y \cap Z = \varnothing$.

Theorem 6.4 one needs to replace with the following one

Theorem 7.3 (I. Panin [ibid.])**.** Let k, R, U, $\mathbf{G}$, be the same as in Theorem 6.1. Let $Z \subset \mathbb{A}^1_U$ be a closed subscheme finite over U. Let $Y \subset \mathbb{A}^1_U$ be a closed subscheme étale and finite over U. Assume that $Y \cap Z = \varnothing$, $\mathbf{G}_Y := \mathbf{G} \times_U Y$ is quasi-split and $\text{Pic}(\mathbb{P}^1_u - Y_u) = 0$.

Let E be a principal $\mathbf{G}$-bundle over $\mathbb{P}^1_U$ such that its restriction to $\mathbb{P}^1_U - Z$ is trivial. Then the restriction of E to $\mathbb{P}^1_U - Y$ is also trivial.

The derivation of the simple simply-connected case (geometric) of Theorem 4.1 from these three statements remains the same as in the infinite field case above.

The proof of Theorem 7.1 is essentially more involved than the proof of Theorem 6.1 and is based on some new ideas (see I. Panin [2017a]).

Give a sketch of the proof of Proposition 7.2. For the closed point $u \in U$ choose a Borel subgroup $\mathbf{B}_u$ in $\mathbf{G}_u$. The latter is possible since the field $k(u)$ is finite. Let $\mathcal{B}$ be the U-scheme of Borel subgroup schemes of $\mathbf{G}$. It is a smooth projective U-scheme (see Demazure and Grothendieck [1970a, Cor. 3.5, Exp. XXVI]). The subgroup $\mathbf{B}_u$ in $\mathbf{G}_u$ is a $k(u)$-rational point b in the fibre of $\mathcal{B}$ over the point u.

Applying several many times Poonen's Bertini type theorem Poonen [2004, Thm. 1.2] find a closed subscheme Y' of $\mathcal{B}$ such that Y' is étale over U and the point b is in Y'. Clearly, the Y-group scheme $\mathbf{G}_Y := \mathbf{G} \times_U Y$ is quasi-split. To finish the proof of Proposition 7.2 it remains to find a closed embedding of Y' into $\mathbb{A}^1_U$ which satisfies properties (b) and (c).

However it might happen that there is no closed embedding of Y' into $\mathbb{A}^1_U$ at all. Indeed, if the number of $k(u)$-rational point on Y'_u *is strictly more* than the cardinality of the field $k(u)$, than there is no closed embedding of Y' into $\mathbb{A}^1_U$ at all. *To avoid this trouble we need in the following*

Lemma 7.4 (I. Panin [2017b]). Let U be as in the Proposition 7.2. Let $Z \subset \mathbb{A}^1_U$ be a closed subscheme finite over U. Let $Y' \to U$ be a finite étale morphism such that for the closed point u in U the fibre Y'_u of Y' over u contains a $k(u)$-rational point. Then there are finite field extensions k_1 and k_2 of the finite field k such that
(i) the degrees $[k_1 : k]$ and $[k_2 : k]$ are coprime,
(ii) $k(u) \otimes_k k_r$ is a field for $r = 1$ and $r = 2$,
(iii) the degrees $[k_1 : k]$ and $[k_2 : k]$ are strictly greater than any of the degrees $[k(z) : k(u)]$, where z runs over all closed points of Z,
(iv) there is a closed embedding of U-schemes $Y'' = ((Y' \otimes_k k_1) \sqcup (Y' \otimes_k k_2)) \xrightarrow{i} \mathbb{A}^1_U$,
(v) for $Y = i(Y'')$ one has $Y \cap Z = \varnothing$,
(vi) for the closed point u in U one has $\mathrm{Pic}(\mathbb{P}^1_u - Y_u) = 0$.

Finish now the proof of the proposition. The U-scheme Y' satisfies the hypotheses of Lemma 7.4. Take the closed subscheme Y of $\mathbb{A}^1_U$ as in the item (v) of the Lemma. For that specific Y the conditions (b) and (c) of the Proposition are obviously satisfied. The condition (a) is satisfied too, since it is satisfied already for the U-scheme Y'. The proposition follows.

Finally, we give a sketch of the proof of Theorem 7.3. It almost literally repeats the sketch of the proof of Theorem 6.4. The only difference is in checking the triviality of the bundle $E|_{\mathbb{P}^1_u - Y_u}$.

The $\mathbf{G}_u$-bundle E_u is trivial over $\mathbb{P}^1_u - Z_u$. The field $k(u)$ is finite and the $k(u)$-group $\mathbf{G}_u$ is quasi-split. By a theorem due to Harder Harder [1968, Satz 3.1, 3.4] there is an algebraic group morphism $\lambda : \mathbb{G}_{m,k(u)} \to \mathbf{G}_u$ such that the $\mathbf{G}_u$-bundle E_u on $\mathbb{P}^1$ is isomorphic to the one $\mathbf{G}_u \times_{\mathbb{G}_{m,k(u)}} \mathcal{O}(-1)$, where $\mathcal{O}(-1)$ is the $\mathbb{G}_{m,k(u)}$-bundle $\mathbb{A}^2_{k(u)} - 0 \to \mathbb{P}^1_{k(u)}$. Since $\mathrm{Pic}(\mathbb{P}^1_u - Y_u) = 0$, hence the restriction of $\mathcal{O}(-1)$ to $\mathbb{P}^1_u - Y_u$

is trivial. Thus, so is the restriction of E_u to $\mathbb{P}^1_u - Y_u$. Theorem 4.1 for the finite field case is proved.

Acknowledgments. The author is very much grateful to A. Suslin, M. Ojanguren, J.-L. Colliot-Thélène, J.-P. Serre, Ph. Gille, N. Vavilov, A. Stavrova, V. Chernousov, A. Merkurjev, R. Fedorov, K. Zainoulline, D. Orlov and many, many others for their deep and very stimulating interest in the topic of the present paper.

REPRESENTATIONS OF FINITE GROUPS AND APPLICATIONS

PHAM HUU TIEP

Abstract

We discuss some basic problems in representation theory of finite groups, and current approaches and recent progress on some of these problems. We will also outline some applications of these and other results in representation theory of finite groups to various problems in group theory, number theory, and algebraic geometry.

1 Introduction

Let G be a finite group and $\mathbb{F}$ be a field. A (finite-dimensional) *representation of G over* $\mathbb{F}$ is a group homomorphism $\Phi : G \to \mathrm{GL}(V)$ for some finite-dimensional vector space V over $\mathbb{F}$. Such a representation Φ is called *irreducible* if $\{0\}$ and V are the only $\Phi(G)$-invariant subspaces of V.

Representation theory of finite groups started with the letter correspondence between Richard Dedekind and Ferdinand Georg Frobenius in April (12th, 17th, 26th) 1896. In the same year, Frobenius constructed the character table of $\mathrm{PSL}_2(p)$, p any prime. Later on, the foundations of the *complex* representation theory (i.e. when $\mathbb{F} = \mathbb{C}$), were developed by Frobenius, Dedekind, Burnside, Schur, Noether, and others. Foundations of the *modular* representation theory (that is, when $p = \mathrm{char}(\mathbb{F}) > 0$ and p divides $|G|$) were (almost singlehandedly) laid out by Richard Brauer, started in 1935 and continued over the next few decades.

A natural question arises: in a more-than-century-old theory such as the representation theory of finite groups, what could still remain to be studied? By the Jordan–Hölder theorem, irreducible representations are the building blocks of any finite-dimensional representation of any finite group G. The main problem of representation theory of finite groups, which still remains wide open in full generality as well as for many important families of finite groups, can be formulated as follows:

The author gratefully acknowledges the support of the NSF (grants DMS-1201374 and DMS-1665014), the Simons Foundation, and the Clay Mathematics Institute.

MSC2010: primary 20C15; secondary 20C20, 20C33.

Problem 1.1. *Given a finite group G and a field $\mathbb{F}$, describe all irreducible representations of G over $\mathbb{F}$.*

Likewise, finite *simple* groups are building blocks of any finite group, and they are known thanks to the *Classification of Finite Simple Groups* (CFSG) Gorenstein, Lyons, and Solomon [1994], arguably one of the most monumental achievements of modern mathematics. So it is natural to focus our attention on studying Problem 1.1 for groups G that are simple, or more generally, *almost quasisimple*, that is, when $S \lhd G/\mathbf{Z}(G) \leq \mathrm{Aut}(S)$ for some finite non-abelian simple group S. Aside from the symmetric group S_n and alternating group A_n of degree n, almost quasisimple groups include the finite classical groups with natural module $V = \mathbb{F}_q^n$ (such as the special linear group $\mathrm{SL}(V) \cong \mathrm{SL}_n(q)$, the special unitary group $\mathrm{SU}(V) \cong \mathrm{SU}_n(q^{1/2})$ when q is a square, the symplectic group $\mathrm{Sp}(V) \cong \mathrm{Sp}_n(q)$ when $2|n$, and the special orthogonal groups $\mathrm{SO}(V)$), as well as their exceptional and twisted analogues. When q is a power of a fixed prime p, the latter are usually referred to as *finite groups of Lie type in characteristic p*. A more precise definition and a technically convenient framework, particularly for the Deligne-Lusztig theory Lusztig [1988, 1984], are provided by viewing the latter groups as the fixed point subgroups

$$\mathcal{G}^F := \{g \in \mathcal{G} \mid F(g) = g\}$$

for a Steinberg endomorphism $F : \mathcal{G} \to \mathcal{G}$ on a connected reductive algebraic group $\mathcal{G}$ defined over a field of characteristic p.

Throughout the paper, for a finite group G, $\mathrm{Irr}(G)$ denotes the set of complex irreducible characters of G, and $\mathrm{IBr}_p(G)$ denotes the set of irreducible p-Brauer characters of G (that is, the Brauer characters of irreducible representations of G over $\overline{\mathbb{F}}_p$) for a given prime p.

Example 1.2. Just to see how difficult Problem 1.1 can be, let us consider the example of the symmetric group $G = \mathsf{S}_n$.

(i) When $\mathbb{F} = \mathbb{C}$, according to the classical theory of Frobenius and Young, the complex irreducible characters $\chi = \chi^\lambda$ of G are labeled by the partitions λ of n, and the *hook length formula* gives us the degree $\chi^\lambda(1)$ for any $\lambda \vdash n$, and the *Frobenius character formula* determines the character values $\chi^\lambda(g)$ for all $g \in G$. Nevertheless, for a random partition λ of a large n and a random permutation $g \in \mathsf{S}_n$, it remains a difficult problem to compute $\chi^\lambda(g)$ efficiently. Even by now one still does not know a precise formula for the largest degree $b(\mathsf{S}_n) = \max_{\lambda \vdash n} \chi^\lambda(1)$ (which has importance in probabilistic group theory and various applications). The best until now, still asymptotic, answer to this question is given by work of Vershik and Kerov [1985] and independently of Logan and Shepp [1977] in 1977:

$$e^{-1.2826\sqrt{n}}\sqrt{n!} \leq b(\mathsf{S}_n) \leq e^{-0.1156\sqrt{n}}\sqrt{n!}.$$

(This result implies that, in a sense, a randomly chosen partition λ of n already yields an irreducible character of degree close to be largest possible, and thus explains the difficulty of the question.)

(ii) For various applications, one also needs to know good *exponential* bounds on character values for symmetric groups. For instance, for each $1 \neq g \in \mathsf{S}_n$ one would like to find an (explicit) constant $0 < \alpha = \alpha(g) < 1$ such that $|\chi(g)| \leq \chi(1)^{\alpha}$ for all $\chi \in \mathrm{Irr}(\mathsf{S}_n)$. Such an $\alpha(g)$ was found by Fomin and Lulov [1995] in the case all cycles of g have same size. The general case was settled by Larsen and Shalev [2008] only in 2008, and it led to important results in a number of applications.

(iii) Now let us keep the same group $G = \mathsf{S}_n$ but change $\mathbb{F}$ to $\mathbb{F}_2$. Then the irreducible representations of G over $\mathbb{F}$ are labeled by partitions of λ into distinct parts. But now, for a given degree, say $n = 1000$, and given such a partition λ, one still does not know what is the dimension of the corresponding representation. The same story goes with the similar question for $G = \mathrm{GL}_{1000}(2)$ and $\mathbb{F} = \mathbb{F}_2$ or $\mathbb{F} = \mathbb{F}_3$.

Various questions mentioned in Example 1.2 also remain open, say, for most of the finite groups of Lie type.

Problem 1.3. *Let G be a finite group of Lie type. For any $g \in G \smallsetminus \mathbf{Z}(G)$, find a constant $0 < \alpha = \alpha(g) < 1$, as small and explicit as possible, such that $|\chi(g)| \leq \chi(1)^{\alpha}$ for all $\chi \in \mathrm{Irr}(G)$.*

Given a finite group G, let $\mathfrak{d}_p(G)$ denote the smallest degree of *faithful* representations of G over $\overline{\mathbb{F}}_p$. We would like to study the following special instance of Problem 1.1, which turns out to be of importance for many applications:

Problem 1.4. *Given an almost quasisimple group G and a prime p,*

(i) *determine $\mathfrak{d}_p(G)$, and*

(ii) *classify irreducible $\overline{\mathbb{F}}_p G$-representations of degree up to $\mathfrak{d}_p(G)^{2-\epsilon}$, for a fixed $0 < \epsilon < 1$.*

To formulate further conjectures, let us introduce some more notation. For a fixed group G and p, let $P \in \mathrm{Syl}_p(G)$, and let

$$\mathrm{Irr}_{p'}(G) = \{\chi \in \mathrm{Irr}(G) \mid p \nmid \chi(1)\}.$$

We say that $\chi \in \mathrm{Irr}(G)$ has *p-defect* 0 if $\chi(1)_p = |G|_p$. If χ belongs to a p-block B of G with defect group D, then χ is said to have *height* 0 if $\chi(1)_p = [G : D]_p$.

Several fundamental conjectures in representation theory of finite groups follow the *global-local principle*, which in this case states that *certain global invariants of a finite group G can be determined locally, in terms of its p-subgroups, their normalizers, etc.*

The following is probably the easiest one to formulate among all the global-local conjectures:

Conjecture 1.5 (McKay [1972]). *There exists a bijection* $\mathrm{Irr}_{p'}(G) \stackrel{\pi}{\longleftrightarrow} \mathrm{Irr}_{p'}(\mathbf{N}_G(P))$.

The *Alperin-McKay conjecture* Alperin [1976] is a blockwise version of the McKay conjecture and asserts: *If a p-block B of a finite group G has a defect group D and Brauer correspondent b, a p-block of $\mathbf{N}_G(D)$, then B and b have the same number of characters of height* 0. There are several recent refinements (due to Isaacs, Navarro, Turull, and others) of the McKay conjecture, which roughly say that in Conjecture 1.5 there should exist a bijection π that is compatible with the action of certain Galois automorphisms of $\overline{\mathbb{Q}}$ and preserving congruences modulo p, local Schur indices, etc.

Even if the Problem 1.1 remains unsolved, can one hope for a "natural" labeling of the irreducible representations of G? If G is a connected reductive algebraic group defined over $\mathbb{F}$, then one can label the finite-dimensional rational irreducible representations of G by their highest weights. Alperin [1987] conjectured in 1986 that one should be able to do the same for any finite group G. More precisely, a *p-weight* of G is a pair (Q, δ), where Q is a p-subgroup of G and $\delta \in \mathrm{Irr}(\mathbf{N}_G(Q)/Q)$ has p-defect 0.

Conjecture 1.6 (**Alperin**). *The number of irreducible p-Brauer characters of a finite group G equals the number of G-conjugate classes of p-weights of G.*

Given a p-block B of G, a *p-weight of B* is a p-weight (Q, δ) with δ belonging to an $\mathbf{N}_G(Q)$-block b with $b^G = B$. Then the blockwise version of the Alperin weight Conjecture 1.6 asserts that *the number of irreducible p-Brauer characters of G that belong to B equals the number of G-conjugate classes of p-weights of B.*

Finally, we recall the *Brauer height zero conjecture* Brauer [1956], perhaps one of the oldest and deepest conjectures in the modular representation theory:

Conjecture 1.7 (**Brauer**, 1955). *All complex irreducible characters in a p-block B of a finite group G have height zero if and only if the defect groups D of B are abelian.*

2 Current Approaches and Recent Results

The aforementioned, and several other, fundamental conjectures in representation theory of finite groups have been proved to hold for many classes of finite groups, including solvable groups, p-solvable groups, as well as various families of simple groups. As important evidence in favor of these conjectures as these results are, none of the above conjectures has been proved to hold for *all* arbitrary finite groups.

A possible approach to tackle these conjectures, which was already one of the main ideas in Dade's works in the '90s, is to try to use the CFSG to reduce to *simple* groups. As we will see, such reductions are possible, on the one hand, and they have led to important progress on some of these conjectures. On the other hand, oftentimes such reductions require one to prove much stronger statements about the simple groups, not merely the original conjecture in question. We will now discuss recent progress on various problems mentioned in §1.

2.1 The McKay conjecture.

In 2007, Isaacs, Malle, and Navarro succeeded in proving the following reduction theorem for the McKay Conjecture 1.5:

Theorem 2.1.1. Isaacs, Malle, and Navarro [2007] *Suppose that every finite non-abelian simple group S is* **McKay-good** *for the prime p. Then the McKay conjecture holds for arbitrary finite groups (for the prime p).*

Here, the *McKay-goodness* (also known as *the inductive McKay condition*) for the prime p is much more than just satisfying the McKay conjecture. It is in fact a long and complicated list of conditions concerning representations and cohomology of certain subgroups of the universal cover of S, occupying a couple of pages of Isaacs, Malle, and Navarro [ibid.]. Later, a reduction theorem in the same spirit for the Alperin-McKay conjecture was obtained by Späth in Späth [2013a]. Combined efforts of Malle, Cabanes, and Späth have also led to the proof of the inductive McKay condition for all simple groups, except for simple orthogonal groups in odd characteristics and exceptional groups of type E_6, ${}^2E_6$, and E_7. Moreover, a breakthough has recently been achieved by Malle and Späth, showcasing the strengths of the current approach:

Theorem 2.1.2. Malle and Späth [2016] *The McKay conjecture for $p = 2$ holds for all finite groups G.*

Less is currently known about various refinements of the McKay conjecture, which, if true, would imply many interesting consequences. For instance, the Galois-McKay conjecture, as proposed by Navarro in Navarro [2004], implies that *the character table of any finite group G detects whether a Sylow p-subgroup of G is self-normalizing*. This would give a partial answer to Problem 12 in Brauer's celebrated list Brauer [1963]: *Given the character table of a group G and a prime p dividing $|G|$, how much information about the Sylow p-groups P of G can be obtained?* In fact, a unconditional answer has been obtained, supporting the Galois-McKay conjecture:

Theorem 2.1.3. *Let G be a finite group, p a prime, and let $P \in \mathrm{Syl}_p(G)$.*

(i) *Navarro, Tiep, and Turull [2007] Suppose $p > 2$. Then $P = \mathbf{N}_G(P)$ if and only if $\mathrm{Irr}_{p'}(G)$ contains a unique character χ with $\mathbb{Q}(\chi) \subseteq \mathbb{Q}(\exp(2\pi i/|G|_{p'}))$.*

(ii) *Schaeffer Fry [2016] and Schaeffer Fry and J. Taylor [2018] Suppose $p = 2$ and let σ be the automorphism of $\mathbb{Q}(\exp(2\pi i/|G|))$ that fixes every root of unity of 2-power order and squares every root of unity of odd order. Then $P = \mathbf{N}_G(P)$ if and only if every $\chi \in \mathrm{Irr}_{2'}(G)$ is fixed by σ.*

Finite groups with self-normalizing Sylow p-subgroups (with $p > 2$) also stand out as one of the few cases where a *canonical* bijection $\boldsymbol{\pi}$ satisfying the McKay Conjecture 1.5 can be found (and therefore it is compatible with the action of Galois automorphisms). As shown in Navarro, Tiep, and Vallejo [2014], in this case $\boldsymbol{\pi}(\chi)$ can be taken to be the (unique) linear constituent of $\chi|_P$ for any $\chi \in \mathrm{Irr}_{p'}(G)$. (Also see Isaacs [1973], Navarro [2003], Giannelli, Kleshchev, Navarro, and Tiep [2017], Isaacs, Navarro, Olsson, and Tiep [2017], Giannelli, Tent, and Tiep [2018] for some other occurrences of canonical McKay correspondences.) We also note the following recent result:

Theorem 2.1.4. Guralnick, Navarro, and Tiep [2016] *Let G be a finite group, p be a prime, and $P \in \mathrm{Syl}_p(G)$. Suppose that $\mathbf{N}_G(P)$ has odd order. Then the McKay conjecture, the Alperin weight conjecture, and their blockwise versions hold for G and the prime p.*

2.2 The Alperin weight conjecture (AWC).

The following reduction theorem for the Alperin weight Conjecture 1.6 was proved in 2011:

Theorem 2.2.1. *Navarro and Tiep [2011] Suppose that every finite non-abelian simple group S is* **AWC-good** *for the prime p. Then the Alperin weight conjecture holds for arbitrary finite groups (for the prime p).*

Another reduction theorem for the AWC was obtained by Puig [2011], and the blockwise version of the AWC was reduced to simple groups by Späth in Späth [2013b].

As it was the case with the inductive McKay condition, the *AWC-goodness* in Theorem 2.2.1 is much stronger than just satisfying the AWC. Nevertheless, the list of AWC-good simple groups for the prime p has been shown to include the simple groups of Lie type in the same characteristic p, the alternating groups, and all the sporadic simple groups.

2.3 The Brauer height zero conjecture (BHZ).

The "if" direction of the Brauer height zero Conjecture 1.7 was reduced by Berger and Knörr [1988] in 1988 to quasisimple groups. This was a "pure" reduction; namely they showed that *if the "if" direction of the BHZ holds for all blocks (with abelian defect groups) of all finite quasisimple groups, then it also holds for all blocks (with abelian defect groups) of all finite groups.* The verification of (both directions of) the BHZ for quasisimple groups was completed recently by Kessar and Malle [2013, 2017]. Thus *the "if" direction of the BHZ holds for arbitrary finite groups.*

The “only if” direction of the BHZ is even more difficult. The Gluck–Wolf proof of this direction for p-solvable groups was already extraordinarily complicated. For arbitrary finite groups, the following reduction theorem was obtained in 2014:

Theorem 2.3.1. *Navarro and Späth [2014] Suppose all of the following statements hold:*

(i) *The inductive Alperin-McKay condition Späth [2013a] holds for all finite simple groups S for the prime p;*

(ii) *A generalized Gluck-Wolf theorem (gGW) holds; and*

(iii) *The “only if” direction of the BHZ holds for all finite quasisimple groups.*

Then the “only if” direction of the BHZ holds for all finite groups for the prime p.

Another reduction theorem, with condition 2.3.1(i) replaced by the projective Dade conjecture Dade [1994], was obtained earlier by Murai in Murai [2012]. As mentioned above, condition (iii) in Theorem 2.3.1 holds, thanks to Kessar and Malle [2017]. The statement (gGW) alluded to in Theorem 2.3.1(ii) is a relative version of the BHZ, and is now also a theorem:

Theorem 2.3.2. *Navarro and Tiep [2013] Let G be a finite group with a normal subgroup Z, p be a prime, and let $\lambda \in \mathrm{Irr}(Z)$. Suppose that $\chi(1)/\lambda(1)$ is coprime to p for all $\chi \in \mathrm{Irr}(G)$ lying above λ. Then the Sylow p-subgroups of G/Z are abelian.*

Let us also mention

Theorem 2.3.3. *Navarro and Tiep [2012] The Brauer height zero conjecture holds for all 2-blocks of G with defect groups $P \in \mathrm{Syl}_2(G)$.*

2.4 Dimensions of irreducible representations and Problem 1.4. For an almost quasisimple group G, let S denote the unique non-abelian composition factor of G. In the case S is a sporadic simple group, Problem 1.4 depends largely on latest developments in computational group theory. In particular, $\mathfrak{d}_p(G)$ has been completely determined Jansen [2005]. However, Problem 1.4 remains open for a number of large sporadic groups, for instance in the case where $G = M$ is *the Monster* and $p = 2$.

Next, let us consider the case $S = \mathsf{A}_n$ with $n \geq 5$. Here, certainly the case of complex representations is very well understood, thanks to classical work of Frobenius and Schur. The case of modular representations of S_n was settled by James in James [1983]. In particular, he showed that

$$\mathfrak{d}_p(\mathsf{S}_n) = \begin{cases} n-1, & p \nmid n \\ n-2, & p \mid n \end{cases} .$$

In fact, James proved that, for a fixed p-regular partition $\mu = (\lambda_2, \dots, \lambda_k)$ of m,

$$\dim D^{(n-m,\lambda_2,\dots,\lambda_k)} \approx \frac{n^m}{m!} \dim D^{\mu}$$

when $n \to \infty$ (if D^λ is the p-modular irreducible representation of S_n labeled by the p-regular partition $\lambda \vdash n$). This beautiful result gives however only an asymptotic bound on the dimension of D^λ. For a number of applications, one needs an effective bound on $\dim D^\lambda$, and the first such bound was obtained in Guralnick, Larsen, and Tiep [2012]. Define for $p \neq 2$

$$m_p(\lambda) := \max(\lambda_1, (\lambda^{\mathbf{M}})_1),$$

(the longest row of partitions λ and $\lambda^{\mathbf{M}}$), where $\lambda \mapsto \lambda^{\mathbf{M}}$ is the Mullineux bijection on the set of p-regular partitions of n; also set $m_2(\lambda) := \lambda_1$.

Theorem 2.4.1. *Guralnick, Larsen, and Tiep [ibid.] For any $p \geq 0$, and any p-regular partition λ of n,*

$$\dim D^\lambda \geq 2^{\frac{n-m_p(\lambda)}{2}}.$$

This effective bound was used to establish polynomial representation growth for the modular representations of S_n and A_n, see Guralnick, Larsen, and Tiep [ibid., Theorem 1.1]. It also allowed to deduce quantitative results on branching rules for irreducible S_n-representations over A_n, and, as a consequence, resolve Problem 1.4 for $G = \mathsf{A}_n$. However, the bound in Theorem 2.4.1 is not of the right magnitude. This issue has been rectified very recently:

Theorem 2.4.2. *Kleshchev and Tiep [n.d.] Let p be a prime, $m \geq 2$, and let $\lambda = (n - m, \lambda_2, \dots, \lambda_k)$ be a p-regular partition of $n \geq (m-1)p + 2$. Then*

$$\dim D^\lambda \geq \begin{cases} \left(\prod_{j=0}^{m-1}(n - jp)\right)/m!, & p \geq 5 \\ \left(\prod_{j=0}^{m-1}(n-2-jp)\right)/m!, & p = 2, 3 \end{cases}.$$

For *spin* representations, i.e. faithful representations of double covers of S_n and A_n, Problem 1.4 has been studied in Kleshchev and Tiep [2004, 2012]. In particular, it was shown in Kleshchev and Tiep [2004] that

$$\mathfrak{d}_p(2\mathsf{S}_n) = \begin{cases} 2^{\lfloor (n-1)/2 \rfloor}, & p \nmid n \\ 2^{\lfloor (n-2)/2 \rfloor}, & p \mid n. \end{cases}$$

Furthermore, irreducible spin modular representations of degree up to $(n/2) \cdot \mathfrak{d}_p(G)$ for $G = 2\mathsf{S}_n$ and $2\mathsf{A}_n$ were determined in Kleshchev and Tiep [2012].

Now we discuss the main case of Problem 1.4 when S is a simple group of Lie type in characteristic ℓ. In the defining characteristic case, that is when $p = \mathrm{char}(\mathbb{F}) = \ell$, Problem 1.4 can be solved using the representation theory of reductive algebraic groups (namely the theory of highest weight modules), and Premet's theorem Premet [1987]. In fact, this was done by Liebeck for classical groups, and by Lübeck for exceptional groups.

Next we consider the cross characteristic case, that is when $p = \mathrm{char}(\mathbb{F}) \neq \ell$. If, moreover, $p = 0$ or $0 < p \nmid |G|$, then Problem 1.4 can be solved using the *Deligne-Lusztig theory* Lusztig [1988, 1984]. This was done in Tiep and Zalesskii [1996] for classical groups, and by Lübeck for exceptional groups.

The remaining case ($\ell \neq p > 0$ and $p||G|$) turns out to be much harder and is still ongoing. Complete results have been obtained for groups of type A, that is when $G = \mathrm{SL}_n(q)$, see Guralnick and Tiep [1999] and Brundan and Kleshchev [2000], and when $G = \mathrm{SU}_n(q)$, see Hiss and Malle [2001] and Guralnick, Magaard, Saxl, and Tiep [2002].

Theorem 2.4.3. *Guralnick and Tiep [1999] Assume $n \geq 4$ and $(n,q) \neq (4,2), (4,3)$. Then*

$$\mathfrak{d}_p(\mathrm{SL}_n(q)) = \frac{q^n-1}{q-1} - \begin{cases} 1, & p \nmid \frac{q^n-1}{q-1} \\ 2, & p | \frac{q^n-1}{q-1}. \end{cases}$$

Moreover, $\mathrm{SL}_n(q)$ *has one irreducible representation over* $\mathbb{F}$ *of degree* $\mathfrak{d}_p$ *and* $(q-1)_{p'}-1$ *of degree* $(q^n-1)/(q-1)$*. All other nontrivial irreducible representations have degree at least* $(q^{n-1}-1)\left(\dfrac{q^{n-2}-q}{q-1}-1\right)$.

Theorem 2.4.4. *Guralnick, Magaard, Saxl, and Tiep [2002] Assume $n \geq 5$ and $(n,q) \neq (6,2)$. Then*

$$\mathfrak{d}_p(\mathrm{SU}_n(q)) = \left\lfloor \frac{q^n-1}{q+1} \right\rfloor.$$

Moreover, $\mathrm{SU}_n(q)$ *has* $(q+1)_{p'}$ *irreducible representations over* $\mathbb{F}$ *of degree* $\mathfrak{d}_p$ *or* $\mathfrak{d}_p+1$*. All other nontrivial irreducible representations have degree at least* $\dfrac{(q^n-1)(q^{n-1}-q^2)}{(q+1)(q^2-1)}$.

The case of symplectic groups was also settled in Guralnick, Magaard, Saxl, and Tiep [ibid.] and Guralnick and Tiep [2004]; in particular,

$$\mathfrak{d}_p(Sp_{2n}(q)) = \begin{cases} (q^n-1)/2, & q \text{ odd} \\ (q^n-1)(q^n-q)/2(q+1), & q \text{ even.} \end{cases}$$

Less complete results have also been obtained for other families of finite groups of Lie type, see Tiep [2003], Tiep [2006] for relevant references. All these results rely crucially on the Deligne-Lusztig theory and further important results of Broué and Michel [1989] and Bonnafé and Rouquier [2003].

As mentioned in Example 1.2, of interest is also the *largest degree*

$$b(G) = \max_{\chi \in \mathrm{Irr}(G)} \chi(1)$$

of complex irreducible characters of an almost quasisimple group G. In the case G is of Lie type in characteristic p, the Steinberg character St has quite a large degree, equal to $|G|_p$. It turns out that $b(G)/\mathsf{St}(1)$ can grow unbounded when we fix the size q of the defining field $\mathbb{F}_q$ and let the rank r of G grow. An upper bound for $b(G)$ was given in Seitz [1990, Theorem 2.1], which yields the exact value of $b(G)$ when q is large enough compared to r.

Theorem 2.4.5. *Larsen, Malle, and Tiep [2013] For any $1 > \varepsilon > 0$, there are (explicit) constants $A, B > 0$ depending on ε such that, for any simple algebraic group $\mathcal{G}$ in characteristic p of rank r and any Steinberg endomorphism $F : \mathcal{G} \to \mathcal{G}$, the largest degree $b(G)$ of the corresponding finite group $G := \mathcal{G}^F$ over $\mathbb{F}_q$ satisfies the following inequalities:*

$$A(\log_q r)^{(1-\varepsilon)/\gamma} < \frac{b(G)}{|G|_p} < B(1 + \log_q r)^{2.54/\gamma}$$

if G is classical, and $1 \leq b(G)/|G|_p < B$ if G is an exceptional group of Lie type. Here, $\gamma = 1$ if G is untwisted of type A, and $\gamma = 2$ otherwise.

A lower bound for the largest degree of modular irreducible representations of $G = \mathcal{G}^F$ was also given in Larsen, Malle, and Tiep [ibid., Theorem 1.4]. Theorem 2.4.5 implies the following, somewhat surprising, consequence which answers a question raised by D. Vogan and J. Berstein:

Corollary 2.4.6. *Let q be any prime power and let $n > 2q^{6815}$. Consider a non-degenerate quadratic space $V = \mathbb{F}_q^n$, a non-degenerate subspace U of codimension 1 in V, and embed the full orthogonal group $H = \mathrm{GO}(U) \cong \mathrm{GO}^{\pm}_{n-1}(q)$ via $g \mapsto \mathrm{diag}(g, \det(g))$ in the special orthogonal group $G = \mathrm{SO}(V) \cong \mathrm{SO}^{\pm}_n(q)$. Then there exists a character $\chi \in \mathrm{Irr}(G)$ such that its restriction to H is not multiplicity-free (and χ is trivial at $\mathbf{Z}(G)$).*

Proof. We give a proof for the case $n = 2m + 1 \geq 9$; the case $n = 2m$ is completely similar. By Larsen, Malle, and Tiep [ibid., Theorem 5.2] (and its proof), there is $\chi \in \mathrm{Irr}(G)$ such that χ is trivial at $\mathbf{Z}(G)$ and

$$\chi(1) > q^{m^2} \cdot \frac{1}{5}\left(\log_q(m + 10)\right)^{3/8}.$$

On the other hand, $|\,\mathrm{Irr}(H)| < 15q^m$ by Theorems 3.14 and 3.21 of Fulman and Guralnick [2012]. Now if $\chi|_H$ is multiplicity-free, then by Schwarz's inequality we must have that

$$\chi(1) \leq \sum_{\alpha \in \mathrm{Irr}(H)} \alpha(1) \leq (|H| \cdot |\,\mathrm{Irr}(H)|)^{1/2} < \sqrt{30} \cdot q^{m^2},$$

contradicting the above lower bound on $\chi(1)$ when $m \geq q^{6815}$. □

In fact, Corollary 2.4.6 also holds if we take U to be any nonzero proper non-degenerate subspace of V and replace H with $\mathrm{SO}(V) \cap (\mathrm{GO}(U) \times \mathrm{GO}(U^{\perp}))$.

2.5 Bounds on character values: Problem 1.3. For a finite group G, a *character ratio* is a complex number of the form $\chi(g)/\chi(1)$, where $g \in G$ and χ is an irreducible character of G. Upper bounds for absolute values of character values and character ratios have long been of interest, for various reasons; these include applications to random generation, covering numbers, mixing times of random walks, word maps, representation varieties and other areas.

The first significant bounds on character ratios for finite groups of Lie type G, defined over a field $\mathbb{F}_q$, were obtained by Gluck [1993, 1997]. In particular, he showed that $|\chi(g)|/\chi(1) \leq Cq^{-1/2}$ for any non-central element $g \in G$ and any non-linear character $\chi \in \mathrm{Irr}(G)$, where C is an absolute constant. Another explicit character bound for finite classical groups, with natural module $V = \mathbb{F}_q^n$, was obtained in Larsen, Shalev, and Tiep [2011, Theorem 4.3.6]:

$$\frac{|\chi(g)|}{\chi(1)} < q^{-\sqrt{\mathsf{supp}(g)}/481},$$

where $\mathsf{supp}(g)$ is the codimension of the largest eigenspace of $g \in G$ on $V \otimes_{\mathbb{F}_q} \overline{\mathbb{F}}_q$.

These bounds have played a crucial role in a number of applications (some described in §3). However, in many situations of these and other applications, one needs stronger, exponential character bounds as described in Problem 1.3. Such a bound was established for S_n in Larsen and Shalev [2008]. For finite groups of Lie type, it has been obtained for the first time in Bezrukavnikov, Liebeck, Shalev, and Tiep [n.d.]. For a subgroup X of an algebraic group $\mathcal{G}$, write X_{unip} for the set of non-identity unipotent elements of X. For a fixed Steinberg endomorphism $F : \mathcal{G} \to \mathcal{G}$, a Levi subgroup $\mathcal{L}$ of $\mathcal{G}$ is called *split*, if it is an F-stable Levi subgroup of an F-stable proper parabolic subgroup of $\mathcal{G}$. For an F-stable Levi subgroup $\mathcal{L}$ of $\mathcal{G}$ and $L := \mathcal{L}^F$, we define

$$\alpha(L) := \max{}_{u \in L_{\mathrm{unip}}} \frac{\dim u^{\mathcal{L}}}{\dim u^{\mathcal{G}}}, \quad \alpha(\mathcal{L}) := \max{}_{u \in \mathcal{L}_{\mathrm{unip}}} \frac{\dim u^{\mathcal{L}}}{\dim u^{\mathcal{G}}}$$

if $\mathcal{L}$ is not a torus, and $\alpha(L) = \alpha(\mathcal{L}) := 0$ otherwise.

Theorem 2.5.1. *Bezrukavnikov, Liebeck, Shalev, and Tiep [ibid.] There exists a function $f : \mathbb{N} \to \mathbb{N}$ such that the following statement holds. Let $\mathcal{G}$ be a connected reductive algebraic group such that $[\mathcal{G}, \mathcal{G}]$ is simple of rank r over a field of good characteristic $p > 0$. Let $G := \mathcal{G}^F$ for a Steinberg endomorphism $F : \mathcal{G} \to \mathcal{G}$. Let $g \in G$ be any* *element such that* $\mathbf{C}_G(g) \leq L := \mathcal{L}^F$, *where* $\mathcal{L}$ *is a split Levi subgroup of* $\mathcal{G}$. *Then, for any character* $\chi \in \mathrm{Irr}(G)$ *and* $\alpha := \alpha(L)$, *we have*

$$|\chi(g)| \leq f(r)\chi(1)^{\alpha}.$$

The α-bound in Theorem 2.5.1 is sharp in many cases; for instance, it is always optimal in the case $G = \mathrm{SL}_n(q)$, see Bezrukavnikov, Liebeck, Shalev, and Tiep [n.d., Theorem 1.3]. Furthermore, the function $f(r)$ is given explicitly in Bezrukavnikov, Liebeck, Shalev, and Tiep [ibid., Proposition 2.7]. Explicit bounds for $\alpha(L)$ can be found in Bezrukavnikov, Liebeck, Shalev, and Tiep [ibid.]; in particular, it is shown in Bezrukavnikov, Liebeck, Shalev, and Tiep [ibid., Theorem 1.6] that

$$\alpha(L) \leq \alpha(\mathcal{L}) \leq \frac{1}{2}\left(1 + \frac{\dim \mathcal{L}}{\dim \mathcal{G}}\right)$$

if $\mathcal{G}$ is a classical group. As a consequence, the following Lie-theoretic analogue of the celebrated Fomin–Lulov bound Fomin and Lulov [1995] was obtained in Bezrukavnikov, Liebeck, Shalev, and Tiep [n.d.]:

Corollary 2.5.2. *Let* $m < n$ *be a divisor of* n *and let* $L \leq G = \mathrm{GL}_n(q)$ *be a Levi subgroup of the form* $L = \mathrm{GL}_{n/m}(q)^m$. *Let* $g \in G$ *with* $\mathbf{C}_G(g) \leq L$. *Then we have*

$$|\chi(g)| \leq f(n-1)\chi(1)^{\frac{1}{m}}$$

for all $\chi \in \mathrm{Irr}(G)$, *where* $f : \mathbb{N} \to \mathbb{N}$ *is the function specified in Theorem 2.5.1.*

Again, the exponent $1/m$ in Corollary 2.5.2 is sharp. Moreover, an exponential character bound for ℓ-Brauer characters of $G = \mathrm{GL}_n(q)$, $\mathrm{SL}_n(q)$ (in the case $\ell \nmid q$ and for the elements $g \in G$ with $\mathbf{C}_G(g)$ contained in a split Levi subgroup of G), has also been established in Bezrukavnikov, Liebeck, Shalev, and Tiep [ibid.].

The above results do not cover, for instance, the case where $g \in \mathcal{G}^F$ is a unipotent element. However, a complete result covering all elements in $\mathrm{GL}_n(q)$ and $\mathrm{SL}_n(q)$ has been obtained in Bezrukavnikov, Liebeck, Shalev, and Tiep [ibid.]:

Theorem 2.5.3. *There is a function* $h : \mathbb{N} \to \mathbb{N}$ *such that the following statement holds. For any* $n \geq 5$, *any prime power* q, *any irreducible complex character* χ *of* $G := \mathrm{GL}_n(q)$ *or* $\mathrm{SL}_n(q)$, *and any non-central element* $g \in G$,

$$|\chi(g)| \leq h(n) \cdot \chi(1)^{1-\frac{1}{2n}}.$$

There is also a different approach to Problem 1.3, which so far has been worked out completely for groups of type A in Guralnick, Larsen, and Tiep [n.d.]. It has long been observed that irreducible characters of symmetric groups and of finite groups of Lie type seem to appear in "clusters", where the characters in a given cluster have roughly the same degree (as a polynomial function of n in the case of S_n, and of q^r in the case of a Lie-type group of rank r over $\mathbb{F}_q$), and display roughly the same behavior in several contexts. The main goal of this approach is to develop the concept of *character level* – the characters $\chi \in \mathrm{Irr}(G)$ will then be grouped in clusters according to their level, and then prove exponential character bounds for characters (at least of not-too-large level).

Let us use the notation GL^ϵ to denote GL when $\epsilon = +$ and GU when $\epsilon = -$, and similarly for SL^ϵ. Let $V = \mathbb{F}_Q^n$ be the natural module of $G \in \{\mathrm{GL}_n^\epsilon(q), \mathrm{SL}_n^\epsilon(q)\}$, where $Q = q$ when $\epsilon = +$, and $Q = q^2$ when $\epsilon = -$. It is known that the class function

$$\tau : g \mapsto \epsilon^n (\epsilon q)^{\dim_{\mathbb{F}_Q} \mathrm{Ker}(g - 1_V)}$$

is a (reducible) character of G. The *true level* $\mathfrak{l}^*(\chi)$ of a character $\chi \in \mathrm{Irr}(G)$ is then defined to be the smallest non-negative integer j such that χ is an irreducible constituent of τ^j; and the *level* $\mathfrak{l}(\chi)$ is the smallest non-negative integer j such that $\lambda\chi$ is an irreducible constituent of τ^j for some character λ of degree 1 of G, see Guralnick, Larsen, and Tiep [ibid.].

Theorem 2.5.4. *Guralnick, Larsen, and Tiep [ibid.] Let $G \in \{\mathrm{GL}_n^\epsilon(q), \mathrm{SL}_n^\epsilon(q)\}$ with $n \geq 2$, $\epsilon = \pm$, and let $\chi \in \mathrm{Irr}(G)$ have level $j = \mathfrak{l}(\chi)$. Then the following statements hold.*

(i) $q^{j(n-j)}/2(q+1) \leq \chi(1) \leq q^{nj}$. *If furthermore $j \geq n/2$, then*

$$\chi(1) > q^{n^2/4-2}/(q-\epsilon).$$

(ii) *If $n \geq 7$ and $\lceil (1/n) \log_q \chi(1) \rceil < \sqrt{n-1} - 1$, then*

$$\mathfrak{l}(\chi) = \left\lceil \frac{\log_q \chi(1)}{n} \right\rceil.$$

(iii) *If $\mathfrak{l}(\chi) \leq \sqrt{(8n-17)/12} - 1/2$ for $\chi \in \mathrm{Irr}(G)$, then $|\chi(g)| < 2.43\chi(1)^{1-1/n}$ for all $g \in G \smallsetminus \mathbf{Z}(G)$. Moreover, if $\mathfrak{l}(\chi) \leq (\sqrt{12n-59} - 1)/6$ for $\chi \in \mathrm{Irr}(G)$, then*

$$|\chi(g)| < 2.43\chi(1)^{\max(1-1/2\mathfrak{l}(\chi), 1-\mathsf{supp}(g)/n)}$$

for all $g \in G$.

(iv) *Suppose that $g \in G$ satisfies $|\mathbf{C}_{\mathrm{GL}_n^\epsilon(q)}(g)| \leq q^{n^2/12}$. Then $|\chi(g)| \leq \chi(1)^{8/9}$.*

Note that the exponent $1 - 1/n$ in the character bound in Theorem 2.5.4(iii) is optimal. Another feature of character level is provided by the following result, which shows that the characters of level $j < n/2$ of $\mathrm{SL}_n^\epsilon(q)$ are controlled by $\mathrm{GL}_j^\epsilon(q)$:

Theorem 2.5.5. *Guralnick, Larsen, and Tiep [n.d.] For any $0 \leq j \leq n$, there is a canonical bijection $\alpha \mapsto \Theta(\alpha)$ between $\{\alpha \in \mathrm{Irr}(\mathrm{GL}_j^\epsilon(q)) \mid \mathfrak{l}^*(\alpha) \geq 2j - n\}$ and $\{\chi \in \mathrm{Irr}(\mathrm{GL}_n^\epsilon(q)) \mid \mathfrak{l}^*(\chi) = j\}$. If furthermore $j < n/2$, then the map $\alpha \mapsto \Theta(\alpha)|_S$ yields a canonical bijection between $\mathrm{Irr}(\mathrm{GL}_j^\epsilon(q))$ and $\{\theta \in \mathrm{Irr}(S) \mid \mathfrak{l}(\theta) = j\}$ for $S = \mathrm{SL}_n^\epsilon(q)$.*

3 Some Recent Applications

Results on Problems 1.3, 1.4 and other have been used in the *revision of the Classification of Finite Simple Groups* (for instance, in the classification of *quadratic modules*), in computational group theory (e.g. in the recognition of permutation/matrix groups of moderate degree). They also played a key role in the proofs Guralnick and Tiep [2005], Guralnick and Tiep [2008] of Larsen's conjecture on moments Katz [2004, 2005] and the Kollár-Larsen conjecture Balaji and Kollár [2008] on symmetric powers, and the solution Guralnick and Tiep [2012] of the Kollár-Larsen problem Kollár and Larsen [2009] on linear groups generated by elements of bounded deviation and crepant resolutions.

We will now discuss some recent applications in group theory, number theory, and algebraic geometry.

3.1 Automorphy lifting and adequate groups.

For a number field $\mathbb{K}$, let $G_{\mathbb{K}}$ denote the absolute Galois group of $\mathbb{K}$. A key ingredient of Wiles' celebrated proof of Fermat's Last Theorem is the following modularity lifting theorem:

Theorem 3.1.1 (Taylor-Wiles, R. Taylor and Wiles [1995]). *Let $p > 2$, $\mathcal{O}$ be the ring of integers in some finite extension of $\mathbb{Q}_p$, and let $\Phi : G_{\mathbb{Q}} \to \mathrm{GL}_2(\mathcal{O})$ be a Galois representation such that*

(i) *Φ "looks like" coming from a modular form;*

(ii) *The associated p-modular representation $\overline{\Phi} : G_{\mathbb{Q}} \to \mathrm{GL}_2(\overline{\mathbb{F}}_p)$ is modular;*

(iii) *$\overline{\Phi}(G_{\mathbb{Q}(\sqrt{(-1)^{(p-1)/2}p})})$ is* **big**.

Then Φ is modular.

Here, *bigness* means just *irreducibility*.

In 2010, Harris, Shepherd-Barron, and R. Taylor [2010] proved the Sato-Tate conjecture for any non-CM elliptic curve over $\mathbb{Q}$ with non-integral j-invariant. A key role in this important result is played by an automorphy lifting theorem, due to Clozel, Harris, and

R. Taylor [2008], that generalizes the Taylor-Wiles Theorem 3.1.1 to GL_n. Now, *bigness* means irreducibility plus some more conditions, including a condition on the existence of a special element with a special *multiplicity-one* eigenvalue. The Clozel–Harris–Taylor theorem was generalized further by Thorne [2012], removing the multiplicity-one condition, and thus replacing *bigness* by *adequacy*:

Definition 3.1.2 (Thorne Thorne [2012] and Guralnick, Herzig, and Tiep [2015]**).** Let $\mathbb{F}$ be a field of characteristic p. A finite irreducible subgroup $G \leq \mathrm{GL}(V) = \mathrm{GL}_n(\mathbb{F})$ is called *adequate*, if

(A1) $H^1(G, \mathbb{F}) = 0$;
(A2) $H^1(G, \mathrm{End}(V)/\mathbb{F}) = 0$;
(A3) $\mathrm{End}(V)$ is linearly spanned by the p'-elements $g \in G$.

Which irreducible subgroups of $\mathrm{GL}(V)$ are adequate? Extending Guralnick, Herzig, R. Taylor, and Thorne [2012], and using results on Problem 1.4 as well as Blau and Zhang [1993], the following adequacy theorem has recently been proved:

Theorem 3.1.3. *Guralnick, Herzig, and Tiep [2015] Let $G < \mathrm{GL}(V)$ be a finite irreducible subgroup and let $\mathbf{O}^{p'}(G)$ denote the subgroup of G generated by all p-elements $x \in G$. Suppose that the $\mathbf{O}^{p'}(G)$-module V contains an irreducible submodule of dimension $< p$. Then, aside from a few explicitly described examples, G is adequate.*

This result has been extended in Guralnick, Herzig, and Tiep [2017] to include finite linear groups in dimension p. As a by-product, answers to a question of Serre concerning complete reducibility of subgroups in classical groups of low dimension, and a question of Mazur concerning $\dim \mathrm{Ext}^1(V, V)$ and $\dim \mathrm{Ext}^1(V, V^*)$ (which is of interest in deformation theory), have been obtained.

3.2 The α-invariant and Thompson's conjecture. Let $V = \mathbb{C}^n$ and let $G < GL(V)$ be a finite group. Then G acts on the dual space V^*, and a nonzero element $f \in \mathrm{Sym}^k(V^*)$ is said to be an *invariant*, respectively a *semi-invariant*, of degree k for G if G fixes f, respectively if G fixes the 1-dimensional space $\langle f \rangle_{\mathbb{C}}$. Let

$$d(G) := \min\{k \in \mathbb{N} | G \text{ has a semi-invariant of degree } k\}.$$

In 1981, Thompson proved the following theorem:

Theorem 3.2.1. *Thompson [1981] Let $n \in \mathbb{N}$ be any integer and $G < GL_n(\mathbb{C})$ be any finite subgroup. Then $d(G) \leq 4n^2$.*

It turns out that this result also has interesting implications in algebraic geometry, in particular, in regard to the α-invariant $\alpha_G(\mathbb{P}^{n-1})$ when $G < GL(V)$ acts on the projective space $\mathbb{P}V = \mathbb{P}^{n-1}$.

The *α-invariant* $\alpha_G(X)$ for a compact group G of automorphisms of a Kähler manifold X was introduced by Tian in 1987 Tian [1987], Tian and Yau [1987]. This invariant is of importance in differential geometry and algebraic geometry. As shown by Demailly and Kollár Demailly and Kollár [2001], in the case X is a Fano variety the α-invariant coincides with the *log-canonical threshold*

$$\mathrm{lct}(X,G) = \sup\left\{\lambda \in \mathbb{Q} \;\middle|\; \begin{array}{c}\text{the log pair } (X,\lambda D) \text{ has log-canonical singularities}\\ \text{for every } G\text{-invariant effective } \mathbb{Q}\text{-divisor } D \sim_{\mathbb{Q}} -K_X\end{array}\right\}.$$

An important example of Fano varieties is the projective space $\mathbb{P}V = \mathbb{P}^{n-1}$, where $V = \mathbb{C}^n$. Consider the natural action of any finite subgroup $G < GL(V)$ on $\mathbb{P}^{n-1}$. Then

$$\alpha_G(\mathbb{P}V) \leq \frac{d(G)}{\dim(V)},$$

see Cheltsov and Shramov [2011, §1], and so Theorem 3.2.1 implies

Theorem 3.2.2. *Thompson [1981] Let $n \in \mathbb{N}$ be any integer and $G < GL_n(\mathbb{C})$ be any finite subgroup. Then $\alpha_G(\mathbb{P}^{n-1}) \leq 4n$.*

In the same paper Thompson [ibid.], Thompson raised (the first part of) the following conjecture:

Conjecture 3.1 (Thompson). *There is a positive constant C such that for any $n \in \mathbb{N}$ and for any finite subgroup $G < GL_n(\mathbb{C})$, the following statements hold:*

(i) *$d(G) \leq Cn$; and*

(ii) *$\alpha_G(\mathbb{P}^{n-1}) \leq C$.*

This conjecture has recently been proved in Tiep [2016], relying on Aschbacher's theorem Aschbacher [1984] and results on Problem 1.4:

Theorem 3.2.3. *Tiep [2016] Thompson's Conjecture 3.1 is true, with $C = 1184036$.*

This implies

Corollary 3.2.4. *Let $G \leq GL(V)$ be a finite group. Then G has a nonzero polynomial invariant, of degree at most* $\min(1184036 \cdot \dim(V) \cdot \exp(G/G'), |G|)$.

3.3 Word maps on simple groups. The classical Waring problem, solved in 1909 by Hilbert, asks if given any $k \geq 1$, there is a (smallest) $g(k)$ such that every positive integer is a sum of at most $g(k)$ k^{th} powers. Recently, there has been considerable interest in non-commutative versions of the Waring problem, particularly for finite simple groups. Here, one asks if given any $k \geq 1$, there exists a (smallest) $f(k)$ such that every element in any finite non-abelian simple group G is a product of $f(k)$ k^{th} powers, provided that $\exp(G) \nmid k$. It was shown by Martinez and Zelmanov [1996] and independently by Saxl and Wilson [1997] that $f(k)$ exists (but implicitly).

More generally, given a *word*, i.e. an element $w(x_1, \ldots, x_d)$ of the free group $F(x_1, \ldots, x_d)$, and a group G, one considers the *word map* $w : G^d \to G$ and defines

$$w(G) := \{w(g_1, \ldots, g_d) \mid g_i \in G\}$$

to be the image of the word map w on G^d. Then the *non-commutative Waring problem* (for simple groups) can be formulated as follows

Problem 3.2. *Is there any integer c (possibly depending on w) such that*

$$w(G)^c := \{y_1 y_2 \ldots y_c \mid y_i \in w(G)\}$$

equals G, for any finite non-abelian simple group G with $w(G) \neq 1$?

Such smallest $c = c(w)$ is called the *width* of w. Of particular interest is the case where $w = w(x, y) = xyx^{-1}y^{-1}$, where the assertion $c(w) = 1$ is known as the *Ore conjecture* (1951), which is now a theorem:

Theorem 3.3.1. *Liebeck, O'Brien, Shalev, and Tiep [2010] Every element in any finite non-abelian simple group is a commutator.*

A particular motivation for Problem 3.2 comes from the celebrated Nikolov–Segal proof of the Serre conjecture on finitely generated profinite groups. The existence of $c(w)$ was first established in Liebeck and Shalev [2001] (again implicitly). Note that, in general, the width of w on simple groups can grow unbounded: as shown in Kassabov and Nikolov [2013] and Guralnick and Tiep [2015], for any $k \in \mathbb{N}$, there is a word w and a simple group S such that $w(S) \neq 1$ but $w(S)^N \neq S$. So in Problem 3.2 it is natural to bound the width of w on *sufficiently large* simple groups. In this asymptotic setting, a breakthrough was achieved by Shalev [2009], where he proved that *for any $w \neq 1$, $w(S)^3 = S$ for all sufficiently large simple groups S*. Building on Shalev [ibid.] and Larsen and Shalev [2008, 2009], the best solution for Problem 3.2 was achieved in Larsen, Shalev, and Tiep [2011]:

Theorem 3.3.2. *Larsen, Shalev, and Tiep [ibid.] The following statements hold.*

(i) *For any word $w \neq 1$, there exists a constant N_w depending on w, such that for all finite non-abelian simple groups S of order greater than N_w we have $w(S)^2 = S$.*

(ii) *For any two words $w_1, w_2 \neq 1$, there exists a constant N_{w_1,w_2} depending on w_1 and w_2 such that for all finite non-abelian simple groups S of order greater than N_{w_1,w_2} we have $w_1(S)w_2(S) = S$.*

As regards the Waring problem for quasisimple groups, the best solution has also been achieved:

Theorem 3.3.3. *Larsen, Shalev, and Tiep [2013] and Guralnick and Tiep [2015] The following statements hold.*

(i) *For any $w_1, w_2, w_3 \neq 1$, there exists a constant N_{w_1,w_2,w_3} depending on w_1, w_2, and w_3 such that for all finite quasisimple groups G of order greater than N_{w_1,w_2,w_3} we have $w_1(G)w_2(G)w_3(G) = G$.*

(ii) *For any $w_1, w_2 \neq 1$, there exists a constant N_{w_1,w_2} depending on w_1 and w_2 such that for all finite quasisimple groups G of order greater than N_{w_1,w_2} we have $w_1(G)w_2(G) \supseteq G \smallsetminus \mathbf{Z}(G)$.*

The aforementioned results on the Waring problem are mostly asymptotic and non-effective. Recently, effective versions of the main results of Martinez and Zelmanov [1996] and Saxl and Wilson [1997], as well as of Theorem 3.3.2 for power word maps, have been obtained:

Theorem 3.3.4. *Guralnick and Tiep [2015]*

(i) *Let $k \geq l \geq 1$. If S is any finite simple group of order $\geq k^{8k^2}$, then every $g \in S$ can be written as $x^k \cdot y^l$ for some $x, y \in S$.*

(ii) *Let $k \geq 1$ and let S be any finite simple group such that $\exp(S) \nmid k$. Then any element of S is a product of at most $80k\sqrt{2\log_2 k} + 56$ k^{th} powers in S.*

Also for power word maps, the following result has been proved, which generalizes classical theorems of Burnside and Feit–Thompson:

Theorem 3.3.5. *Guralnick, Liebeck, O'Brien, Shalev, and Tiep [n.d.]*

(i) *Let p, q be primes, let a, b be non-negative integers, and let $N = p^a q^b$. The word map $(x, y) \mapsto x^N y^N$ is surjective on all finite non-abelian simple groups.*

(ii) *Let N be an odd positive integer. The word map $(x, y, z) \mapsto x^N y^N z^N$ is surjective on all finite quasisimple groups.*

See also Guralnick, Liebeck, O'Brien, Shalev, and Tiep [ibid., Theorems 3–5] for results concerning power word maps $x \mapsto x^N$ for a general composite integer N.

3.4 Random walks, probabilistic generation, and representation varieties of Fuchsian groups. Let G be a finite group with a generating set S. Then the corresponding Cayley graph $\Gamma = \Gamma(G, S)$ has G as its vertex set and $\{(g, gs) \mid g \in G, s \in S\}$ as edge set. A *random walk* on Γ starts from 1, and at each step moves from a vertex g to gs chosen according to some probability distribution P on S. For any $t \in \mathbb{N}$, let $P^t(x)$ denote the probability of reaching $x \in G$ after t steps. A basic question is how fast P^t is converging to the uniform distribution U on G (i.e. $U(x) = 1/|G|$ for all $x \in G$), in the l^1-norm:

$$||P^t - U|| = \sum_{x \in G} |P^t(x) - U(x)|.$$

One then defines the *mixing time* $T = T(G, S)$ as

$$T = \min\{t \in \mathbb{N} \mid ||P^t - U|| < 1/e\}.$$

The study of random walks is pioneered by the influential work of Diaconis. A classical random walk was studied in Diaconis and Shahshahani [1981], where we want to shuffle a deck of n cards and at each shuffle we swap cards i and j with i, j chosen uniformly at random from $\{1, 2, \ldots, n\}$, that is, with $G = \mathsf{S}_n$ and $S = \{1, (ij) \mid 1 \leq i \neq n\}$. It was shown in Diaconis and Shahshahani [ibid.] that $T \approx (n \log n)/2$ for this card shuffle.

We will consider the case where $S = g^G = \{zgz^{-1} \mid z \in G\}$ and the distribution P is uniform: $P(s) = 1/|S|$ for all $s \in S$. In this case, the "Upper Bound Lemma" of Diaconis and Shahshahani [ibid.] states:

Lemma 3.4.1. *Suppose G is generated by $S = g^G$ and P is uniform on S. Then for any $t \in \mathbb{N}$,*

$$||P^t - U||^2 \leq \sum_{1_G \neq \chi \in \mathrm{Irr}(G)} \left(\frac{|\chi(g)|}{\chi(1)}\right)^{2t} \chi(1)^2.$$

Another tool allowing us to apply character-theoretic methods to these questions is provided by the following analogue of the Riemann zeta function

$$\zeta^G(s) = \sum_{\chi \in \mathrm{Irr}(G)} \chi(1)^{-s},$$

first considered by Witten [1991]. Now, sharp bounds on $\zeta^G(s)$ and exponential character bounds on $|\chi(g)|$ lead to strong results on mixing time $T(G, g^G)$, see e.g. Larsen and Shalev [2008] for the case of S_n.

Theorem 3.4.2. *Guralnick, Larsen, and Tiep [n.d.] Let $G = \mathrm{SL}_n^\epsilon(q)$ with $\epsilon = \pm$ and $n \geq 10$. Suppose that $g \in G$ is such that $|\mathbf{C}_{\mathrm{GL}_n^\epsilon(q)}(g)| \leq q^{n^2/12}$. Then $T(G, g^G) \leq 10$ for q sufficiently large.*

Proof. According to Theorem 2.5.4(iv), $|\chi(g)| \leq \chi(1)^{8/9}$. It then follows by Lemma 3.4.1 that

$$||P^t - U||^2 \leq \sum_{1_G \neq \chi \in \mathrm{Irr}(G)} \left(\frac{|\chi(g)|}{\chi(1)}\right)^{2t} \chi(1)^2 \leq \zeta^G(2t/9 - 2) - 1.$$

Taking $t \geq 10$, we have $2t/9 - 2 \geq 2/9 > 2/n$, whence $\lim_{q\to\infty} \zeta^G(2t/9 - 2) = 1$ by Liebeck and Shalev [2005a, Theorem 1.1], and the result follows. □

Similarly, the character bounds in Theorem 2.5.1 imply the following results on mixing time of random walks on quasisimple groups:

Theorem 3.4.3. *Bezrukavnikov, Liebeck, Shalev, and Tiep [n.d.] Suppose $\mathcal{G}$ is a simple algebraic group in good characteristic, and $G = G(q) = \mathcal{G}^F$ is a finite quasisimple group over $\mathbb{F}_q$. Let $g \in G$ be such that $\mathbf{C}_G(g) \leq L$, where $L = \mathcal{L}^F$ for a split Levi subgroup $\mathcal{L}$ of $\mathcal{G}$. Let $r = \mathrm{rank}(\mathcal{G})$ and let $h = (\dim \mathcal{G})/r - 1$ be the Coxeter number of $\mathcal{G}$.*

(i) *Suppose $\mathcal{G}$ is of classical type. Then the mixing time*

$$T(G, g^G) \leq \min\left\{r + 2, \left\lceil (2 + \frac{2}{h}) \cdot \frac{\dim \mathcal{G}}{\dim \mathcal{G} - \dim \mathcal{L}} \right\rceil\right\}$$

for large q.

(ii) *If $\mathcal{G}$ is of exceptional type, then $T(G, g^G) \leq 3$ for large q.*

Using Theorem 2.5.3, we obtain the following result covering all elements of $\mathrm{SL}_n(q)$:

Corollary 3.4.4. *Bezrukavnikov, Liebeck, Shalev, and Tiep [ibid.] Let $G = \mathrm{SL}_n(q)$ with $n \geq 5$ and let g be an arbitrary non-central element of G. Then the mixing time $T(G, g^G) \leq 2n + 3$ for large q.*

Next we discuss some applications to the study of representation varieties of Fuchsian groups, and also to probabilistic generation of finite simple groups. Recall that *Fuchsian groups* are finitely generated non-elementary discrete groups of isometries of the hyperbolic plane. Fuchsian groups, which include free groups, the modular group $\mathrm{PSL}_2(\mathbb{Z})$, surface groups, the Hurwitz group and hyperbolic triangle groups, play an important role in geometry, analysis, and algebra. Representation varieties of Fuchsian groups provide a convenient framework to generalize various results on random generation of finite simple groups (e.g. by two random elements, or by elements of orders 2 and 3). An old conjecture of G. Higman (now a theorem thanks to work of Conder, Everitt, and Liebeck and Shalev [2005b]) states that every Fuchsian group surjects onto all large enough alternating groups. Extending this, the following conjecture was raised by Liebeck and Shalev in Liebeck and Shalev [ibid.]:

Conjecture 3.3. *For any Fuchsian group Γ there is an integer $f(\Gamma)$, such that if G is a finite simple classical group of rank at least $f(\Gamma)$, then the probability $P_G(\Gamma)$ that a randomly chosen homomorphism from Γ to G is onto tends to 1 as $|G| \to \infty$.*

This conjecture was proved in Liebeck and Shalev [ibid.] for oriented Fuchsian groups of genus at least 2 and non-oriented Fuchsian groups of genus at least 3. Our new results on character bounds have allowed us to establish Conjecture 3.3 in various cases that had resisted all attacks so far.

Let Γ be a co-compact Fuchsian group of genus g having d elliptic generators of orders $m_1, \dots, m_d$ (all at least 2). Thus if Γ is oriented, it has a presentation of the following form:

$$\langle a_1, b_1, \dots, a_g, b_g,\ x_1, \dots, x_d \mid x_1^{m_1} = \dots = x_d^{m_d} = 1,\ x_1 \cdots x_d \prod_{i=1}^{g} [a_i, b_i] = 1 \rangle,$$

and if Γ is non-oriented it has a presentation

$$\langle a_1, \dots, a_g,\ x_1, \dots, x_d \mid x_1^{m_1} = \dots = x_d^{m_d} = 1,\ x_1 \cdots x_d\, a_1^2 \cdots a_g^2 = 1 \rangle.$$

The *measure* of Γ is defined to be

$$\mu = \mu(\Gamma) := vg - 2 + \sum_{i=1}^{d} \left(1 - \frac{1}{m_i}\right) > 0,$$

where $v = 2$ if Γ is oriented and $v = 1$ otherwise. Let

$$N(\Gamma) := \max\left(\frac{2 + \sum \frac{1}{m_i}}{\mu},\ \frac{d+16}{4(\mu - 2)},\ m_1, \dots, m_d\right) + 1.$$

Theorem 3.4.5. *Liebeck, Shalev, and Tiep [n.d.] Let $\mathbb{K} = \overline{\mathbb{K}}$ be a field of characteristic not dividing $m_1 \cdots m_d$.*

(i) *If $\mu > 2$ and $n \geq N(\Gamma)$, then*

$$\dim \operatorname{Hom}(\Gamma, \mathrm{GL}_n(\mathbb{K})) = n^2(1 + \mu) - c,$$

where $-1 \leq c \leq \mu + 1 + \sum_{i=1}^{d} m_i$.

(ii) *Assume $\mu > \nu := \max\left(2,\ 1 + \sum \frac{1}{m_i}\right)$, and define*

$$\mathfrak{Q} := \bigcup_{primes\ p} \{q : q = p^a \equiv 1 (\operatorname{mod} m_i)\ \forall i\}.$$

Then for $n \geq \nu N(\Gamma) + 2\sum m_i$, *we have*

$$\lim_{q\to\infty,\, q\in\mathbb{Q}} P_\Gamma(\mathrm{SL}_n(q)) = 1.$$

(iii) *Let* $G(q)$ *denote a simple group of exceptional Lie type over* $\mathbb{F}_q$, *and suppose that* $\gcd(m_1\cdots m_d, 30) = 1$. *Then*

$$\lim_{q\to\infty,\, q\in\mathbb{Q},\, \gcd(q,30)=1} P_\Gamma(G(q)) = 1.$$

Theorem 3.4.5(iii) implies, for instance, that exceptional groups of Lie type $G(q)$, with $q \in \mathbb{Q}$ sufficiently large and $\gcd(m_1m_2m_3q, 30) = 1$, are images of the triangle group

$$T_{m_1,m_2,m_3} = \langle x_1, x_2, x_3 \mid x_1^{m_1} = x_2^{m_2} = x_3^{m_3} = x_1x_2x_3 = 1\rangle.$$

Results of this flavor on triangle generation were obtained by completely different methods in Larsen, Lubotzky, and Marion [2014a,b]. Further results concerning other finite groups of Lie type are also obtained in Liebeck, Shalev, and Tiep [n.d.].

p-ADIC VARIATION OF AUTOMORPHIC SHEAVES

Fabrizio Andreatta, Adrian Iovita and Vincent Pilloni

Abstract

We review the construction of analytic families of Siegel modular cuspforms based on the notion of overconvergent modular forms of p-adic weight. We then present recent developments on the following subjects: the halo conjecture, the construction of p-adic L-functions, and the modularity of irregular motives.

1 Introduction

We start by fixing a number field F, a prime integer $p > 0$ and an integer $n \geq 1$ and by denoting G_F and respectively $\mathbb{A}_F$ the absolute Galois group and the ring of adeles of F. We fix an isomorphism $\mathbb{C} \simeq \overline{\mathbb{Q}}_p$. One of the most mysterious conjectures in number theory, known as the *Langlands, Clozel, Fontaine-Mazur Conjecture* is the statement of the existence of a bijection respecting L-functions between the following families of isomorphic classes of representations:

$\mathrm{Rep}^{\mathrm{geom}}_{p,F} :=$ {Irreducible representations $\rho\colon G_F \to \mathrm{GL}_n(\bar{\mathbb{Q}}_p)$ which are continuous, ramified only at a finite number of places and de Rham at the places dividing p}

and

$\mathrm{Aut}^{\mathrm{alg}}_F :=$ {Cuspidal algebraic automorphic representations π of the group $\mathrm{GL}_n(\mathbb{A}_F)$}.

The algebraicity condition of an automorphic form π is the condition that the infinitesimal character (also called the weight) of the π_v is algebraic for all infinite places v of F (Clozel [1990], Buzzard and Gee [2011]). It is known that there are only countably many isomorphism classes of algebraic automorphic representations (Harish-Chandra [1968], Thm. 1). On the other hand the objects in $\mathrm{Rep}^{\mathrm{geom}}_{p,F}$ should arise from the cohomology of proper smooth varieties over F (Fontaine and Mazur [1995], Conj. 1). The bijection we are seeking should therefore be a bijection of (conjecturally) countable sets.

Having written this let us remark that in fact each of these countable sets can be embedded in certain analytic varieties over $\mathbb{Q}_p$. To be more precise, for $\mathrm{Rep}^{\mathrm{geom}}_{p,F}$, one can

MSC2010: primary 11G18; secondary 11G40.

relax the condition of the representations being de Rham at places dividing p and obtain a moduli space of more general, non-geometric p-adic Galois representations enjoying reasonable finiteness properties (Mazur [1989]).

Concerning $\mathrm{Aut}_F^{\mathrm{alg}}$, one would also like to see them as a subset of a larger set of p-adic automorphic forms. For the moment there are several good definitions of a p-adic automorphic form depending on the way one endows the space $\mathrm{Aut}_F^{\mathrm{alg}}$ with a p-adic topology.

The general method to study elements of $\mathrm{Aut}_F^{\mathrm{alg}}$ is to realize them (when this is possible!) in the Betti cohomology of a locally symmetric space or in the coherent cohomology of a Shimura variety (Harris [1990]). These cohomology groups naturally carry structures of finite dimensional $\mathbb{Q}$-vector spaces and these structures can be used to equip the automorphic forms with a p-adic topology. Once a cohomological realization has been chosen, one can start to vary the levels and the weights of the algebraic automorphic representations. Miraculously, we find in many cases that the countable set of systems of eigenvalues associated to the cuspidal algebraic automorphic forms is not isolated in the space of p-adic automorphic forms and that its closure acquires the structure of an analytic space.

The point of view of p-adically deforming the elements of $\mathrm{Rep}_{p,F}^{\mathrm{geom}}$ and $\mathrm{Aut}_F^{\mathrm{alg}}$ proves to be very fruitful as it is sometimes easier to study and work with these analytic varieties than to work with the geometric Galois representations and algebraic automorphic forms individually.

In this note we begin by explaining one possible approach for the construction of the p-adic analytic spaces (also called eigenvarieties) attached to p-adic automorphic forms based on the coherent cohomology realization in a Shimura variety of PEL type[1]. We shall actually limit ourselves to the Siegel moduli spaces of polarized abelian varieties with level structure. We explain how to vary p-adically the weight of the automorphic forms. One has as a guiding principle that in order to be able to deform automorphic forms one needs to allow them, seen as global sections of certain automorphic sheaves, to have essential singularities at non-ordinary points. Restricting the automorphic vector bundles to the complement of these non-ordinary points has the advantage that they (the automorphic vector bundles) acquire extra structures arising from the universal p-divisible group via the Hodge-Tate period map. Our main task is to define overconvergent modular forms of any p-adic weight. This is a refinement of the definition of p-adic modular forms of Serre, Katz [1973] and Hida [1986] and an interpolation of the notion of overconvergent modular forms of integral weight considered by Dwork, Coleman and Mazur [1998]... This material has already appeared in print (for example in Andreatta, Iovita, and Pilloni [2015]).

[1]This choice is made to the expense of ignoring interesting automorphic forms because the condition of admitting a cohomological realization in the coherent cohomology of a Shimura variety is restrictive. There are other approaches based on the Betti realization but for the sake of brevity we will not discuss them here.

Next we present three recent developments in this area: the halo conjecture, the construction of triple product p-adic L functions in the finite slope case, and the modularity of certain irregular motives.

2 Vector bundles with marked sections

In this section we review some constructions which applied to various contexts provide examples of interpolation of automorphic sheaves in the subsequent sections. We have tried to isolate the key representation theoretic ideas outlining a general method to get interpolations that might be useful in other situations.

2.1 Some classical representation theory. We start by recalling the construction of the irreducible representations of the group GL_g. Let $\mathrm{B} \subset \mathrm{GL}_g$ be the upper triangular Borel and let T be the usual diagonal torus. Let $X(\mathrm{T})$ be the character group of T. This group is isomorphic to $\mathbb{Z}^g$ via the map sending $(k_1, \cdots, k_g)$ to the character $\mathrm{diag}(t_1, \cdots, t_g) \mapsto \prod_{i=1}^{g} t_i^{k_i}$. We let $X(\mathrm{T})^+$ be the cone of dominant weights given by the condition $k_1 \geq k_2 \cdots \geq k_g$.

If $k \in X(\mathrm{T})^+$, we define the algebraic induction $V^k = \{f : \mathrm{GL}_g \to \mathbb{A}^1,\ f(gb) = k(b)f(g),\ \forall (g, b) \in \mathrm{GL}_g \times \mathrm{B}\}$ where k has been extended to a character of B via the projection $\mathrm{B} \to \mathrm{T}$. The group GL_g acts on this space via $f \mapsto f(g \cdot -)$.

2.2 p-Adic representation theoretic variations. Next we explain how to interpolate the weights k and the spaces V^k, for $k \in X(\mathrm{T})^+$. We let $\Lambda = \mathbb{Z}_p[\![T(\mathbb{Z}_p)]\!]$ be the Iwasawa algebra of the torus. The universal continuous character of $\mathrm{T}(\mathbb{Z}_p)$ is the tautological character:

$$k^{\mathrm{un}} \colon \mathrm{T}(\mathbb{Z}_p) \longrightarrow \Lambda^\times.$$

We can consider the formal spectrum $\mathfrak{W} = \mathrm{Spf}\,\Lambda$ and denote by $\mathcal{W}$ its rigid analytic fiber over $\mathrm{Spa}(\mathbb{Q}_p, \mathbb{Z}_p)$. This is a finite union of open unit polydiscs of dimension g. Given a complete Huber pair (B, B^+) over $(\mathbb{Q}_p, \mathbb{Z}_p)$, the morphisms $\mathrm{Spa}(B, B^+) \to \mathcal{W}$ correspond to $\mathrm{Hom}_{\mathrm{cont}}(\mathrm{T}(\mathbb{Z}_p), B^\times)$. In particular $\mathcal{W}(\mathbb{Q}_p)$ contains the algebraic weights $X(\mathrm{T})$. Observe that $X(\mathrm{T})$ is totally disconnected in $\mathcal{W}$ but Zariski dense and that $\mathcal{W}$ has only a finite number of connected components.

The character k^{un} interpolates the algebraic characters $X(\mathrm{T})$. We now explain how to interpolate the representations $\{V^k\}_{k \in X(\mathrm{T})^+}$ over $\mathcal{W}$ (Stevens [2000]). We switch to the analytic setting and let now GL_g, T, B denote the analytifications over $\mathrm{Spa}(\mathbb{Q}_p, \mathbb{Z}_p)$ of the respective group schemes. Let $\mathrm{Iw} \subset \mathrm{GL}_g(\mathbb{Z}_p)$ be the Iwahori subgroup of matrices which are upper triangular modulo p. For any number $w \in \mathbb{Q}_{>0} \cup \{\infty\}$, we denote by $\mathrm{Iw}_w \subset \mathrm{GL}_g$ the adic analytic subgroup of GL_g of integral matrices which are congruent modulo p^w to an element of Iw and we let $\mathrm{B}_w = \mathrm{B} \cap \mathrm{Iw}_w$ and $\mathrm{T}_w = \mathrm{T} \cap \mathrm{Iw}_w$. Let $\mathcal{U} \hookrightarrow \mathcal{W}$ be an open subspace. Let w be such that the universal character extends to a pairing $k^{\mathrm{un}}_{\mathcal{U}} \colon \mathrm{T}_w \times \mathcal{U} \to \mathbb{G}_m$. In this case we say that k^{un} is w-analytic over $\mathcal{U}$. Remark that if $\mathcal{U}$ is quasi-compact, then $k^{\mathrm{un}}_{\mathcal{U}}$ is always w-analytic for some $w \in \mathbb{Q}_{>0}$. We may define a representation of the group Iw_w as the analytic induction

$$V_w^{k^{\mathrm{un}}_{\mathcal{U}}} = \{ f : \mathrm{Iw}_w \times \mathcal{U} \to \mathbb{A}^1 \times \mathcal{U},\ \forall (i,b) \in \mathrm{Iw}_w \times \mathrm{B}_w \ \ f(ib) = k^{\mathrm{un}}_{\mathcal{U}}(b) f(i) \}.$$

If $\mathcal{U} = \mathrm{Spa}(\mathbb{Q}_p, \mathbb{Z}_p)$ and $k^{\mathrm{un}}_{\mathcal{U}} = k \in X(\mathrm{T})^+$ (k is algebraic and therefore w-analytic for all w) we have an inclusion $V^k \hookrightarrow V_w^{k^{\mathrm{un}}_{\mathcal{U}}}$. Observe that unless $g = 1$, the space $V_w^{k^{\mathrm{un}}_{\mathcal{U}}}$ is an infinite dimensional Banach space and the inclusion is not an isomorphism. This should not be a surprise as for $g \geq 2$ the dimensions of the spaces $\{V^k\}_{k \in X(\mathrm{T})^+}$ vary and the only possibility to interpolate them is to embed them in larger spaces (infinite dimensional) which can then be interpolated. It is moreover possible to characterize V^k inside $V_w^{k^{\mathrm{un}}_{\mathcal{U}}}$ by using some differential operators (analytic BGG resolution, Jones [2011]).

2.3 Relative constructions. The classical case. We use the notation of Section 2.1. Let X be a scheme, let $\mathcal{E}$ be a locally free sheaf of rank g over X and denote by $\mathcal{E}^\vee = \underline{\mathrm{Hom}}(\mathcal{E}, \mathcal{O}_X)$ the dual sheaf. We associate to any dominant weight $k \in X(\mathrm{T})^+$ a locally free sheaf $\mathcal{E}^k$ over X as follows. Consider the GL_g-torsor $f : \mathcal{T}(\mathcal{E}) \to X$ associated to $\mathcal{E}$, namely $\mathcal{T}(\mathcal{E}) := \mathrm{Isom}(\mathcal{O}_X^g, \mathcal{E}^\vee)$. Define $\mathcal{E}^k = f_* \mathcal{O}_{\mathcal{T}(\mathcal{E})}[k]$, the functions on $\mathcal{T}(\mathcal{E})$ transforming via k under the action of B. One gets a finite, locally free $\mathcal{O}_X$-module which locally on X is isomorphic to the space V^k introduced in Section 2.1.

2.4 Relative constructions. *p*-Adic variations. We now assume that $\mathcal{X}$ is an analytic adic space over $\mathrm{Spa}(\mathbb{Q}_p, \mathbb{Z}_p)$. Let $\mathcal{E}$ be a locally free sheaf of rank g over $\mathcal{X}$ and let $\mathcal{E}^+$ be an integral structure, namely a subsheaf of finite and locally free $\mathcal{O}^+_{\mathcal{X}}$-modules of rank g such that $\mathcal{E} = \mathcal{E}^+ \otimes_{\mathcal{O}^+_{\mathcal{X}}} \mathcal{O}_{\mathcal{X}}$. Let $w \in \mathbb{Q}_{>0} \cup \{\infty\}$. We now provide a formalism which leads to the construction of families of sheaves interpolating the sheaves $\{\mathcal{E}^k\}_{k \in X(\mathrm{T})^+}$ on $\mathcal{X}$ and which, locally on $\mathcal{X}$, are isomorphic to the spaces V_w^k of Section 2.2. The new essential ingrediants are the "marked sections" $s_1, \dots, s_g \in \mathrm{H}^0(\mathcal{X}, \mathcal{E}^+/p^w\mathcal{E}^+)$ with the property that the induced map $(\mathcal{O}^+_{\mathcal{X}}/p^w\mathcal{O}^+_{\mathcal{X}})^g \to \mathcal{E}^+/p^w\mathcal{E}^+$ is bijective.

Define $\mathcal{T}_w(\mathcal{E}^+, \{s_1, \dots, s_g\})$ as the functor that associates to any adic space $t : \mathcal{Z} \to \mathcal{X}$ the set of sections $(\rho_1, \cdots, \rho_g) \in \mathrm{H}^0\big(\mathcal{Z}, t^*(\mathcal{E}^+)^\vee\big)$ such that $(\langle t^*(s_i), \rho_j \rangle)_{1 \leq i,j \leq g} \in \mathrm{Iw}$ mod p^w. Here $t^\star(\mathcal{E}^+)$ is the sheaf $t^{-1}(\mathcal{E}^+) \otimes_{t^{-1}\mathcal{O}^+_{\mathcal{X}}} \mathcal{O}^+_{\mathcal{Z}}$ and $t^\star(\mathcal{E}^+)^\vee$ is its $\mathcal{O}^+_{\mathcal{Z}}$-dual. One proves easily that $\mathcal{T}_w(\mathcal{E}^+, \{s_1, \dots, s_g\})$ is representable by an adic space and is a Iw_w-torsor. We now assume that there is a map $\mathcal{X} \to \mathcal{W}$ and that the character $k_{\mathcal{X}}$ pulled back from the universal character on $\mathcal{W}$ is w-analytic. Under this assumption we define the sheaf

$$\mathcal{E}_w^k := f_* \mathcal{O}_{\mathcal{T}_w(\mathcal{E}^+, \{s_1, \ldots, s_g\})}[k_{\mathfrak{X}}].$$

This sheaf is a relative version of the construction of $V_w^{k_{\mathfrak{X}}}$ given in Section 2.2.

We now describe a slight variant of this construction where we only assume that we have a partial set of sections. In this situation it is still possible to realize a partial interpolation. Let $1 \leq r \leq g$. We define the subgroup $\mathrm{Iw}_{w,r}$ of GL_g of integral matrices of the form

$$\begin{pmatrix} A & D \\ B & C \end{pmatrix},$$

where $A \in \mathrm{GL}_r$ and $A \mod p^w$ is upper triangular with entries in $\mathbb{Z}_p/p^w$, $D \in \mathrm{M}_{r,g-r}$, $C \in \mathrm{GL}_{g-r}$, $B \in \mathrm{M}_{g-r,r}$ and $B = 0 \mod p^w$. We denote by $\mathrm{T}_{w,r} = \mathrm{T} \cap \mathrm{Iw}_{w,r}$, $\mathrm{B}_{w,r} = \mathrm{B} \cap \mathrm{Iw}_{w,r}$ and $\mathrm{T}_{w,r} = \mathrm{T} \cap \mathrm{Iw}_{w,r}$. We assume that we have sections $s_1, \cdots, s_r \in \mathrm{H}^0(\mathfrak{X}, \mathcal{E}^+/p^w \mathcal{E}^+)$ such that the induced map $(\mathcal{O}_{\mathfrak{X}}^+/p^w \mathcal{O}_{\mathfrak{X}}^+)^r \to \mathcal{E}^+/p^w \mathcal{E}^+$ is injective with locally free cokernel of rank $g - r$. We define $\mathcal{T}_w(\mathcal{E}^+, \{s_1, \ldots, s_r\})$ as the functor that associates to any adic space $t : \mathcal{Z} \to \mathfrak{X}$ the set of basis $(\rho_1, \cdots, \rho_g) \in \mathrm{H}^0(\mathcal{Z}, t^\star(\mathcal{E}^+)^\vee)$ such that:

- $(\langle t^\star(s_i), \rho_j \rangle)_{1 \leq i,j \leq r} \in \mathrm{GL}_r(\mathbb{Z}_p) \mod p^w$ and is upper triangular modulo p^w,
- $\langle t^\star(s_i), \rho_j \rangle = 0 \mod p^w$ for all $1 \leq i \leq r$ and $g - r + 1 \leq j \leq g$.

It is clear that $\mathcal{T}_w(\mathcal{E}^+, \{s_1, \ldots, s_r\})$ is an $\mathrm{Iw}_{w,r}$-torsor. We now assume that the character $k_{\mathfrak{X}}$ extends to a character of $\mathrm{T}_{w,r}$ and we denote by $\mathcal{E}_w^k := f_* \mathcal{O}_{\mathcal{T}_w(\mathcal{E}^+, \{s_1, \ldots, s_r\})}[k_{\mathfrak{X}}]$.

We remark that the relative constructions in Sections 2.2 and 2.4 could have been made exactly in the same way by working with an invertible ideal $I \subset \mathcal{O}_{\mathfrak{X}}^+$ such that $I \cap \mathbb{Z}_p = p^w \mathbb{Z}_p$, instead of with $p^w \mathcal{O}_{\mathfrak{X}}^+$.

3 Variations in the Siegel case

Let GSp_{2g} be the group of similitudes of $(\mathbb{Z}^{2g}, \langle , \rangle)$ where $\langle , \rangle$ is the alternating form given by $\langle e_i, e_{2g-i+1} \rangle = 1$ if $1 \leq i \leq g$ and $\langle e_i, e_j \rangle = 0$ if $i + j \neq 2g + 1$. Let $K \subset \mathrm{GSp}_{2g}(\mathbb{A}_f)$ be a neat compact open subgroup, where $\mathbb{A}_f$ denotes the ring of finite adels of the rationals. Let $Y_K \to \mathrm{Spec}\ \mathbb{Q}$ be the Siegel moduli space of polarized abelian varieties A of dimension g and level structure K. Its complex analytification $(Y_K \times \mathrm{Spec}\ \mathbb{C})^{an}$ is the locally symmetric space $\mathrm{GSp}_{2g}(\mathbb{Q}) \backslash \big(\mathcal{H}_g \times \mathrm{GSp}_{2g}(\mathbb{A}_f)/K\big)$ where $\mathcal{H}_g = \{M \in \mathrm{M}_g(\mathbb{C}), M^t = M,\ \mathrm{Im}(M)$ is definite positive or negative$\}$ is the Siegel space i.e. the union of the Siegel upper and lower half-spaces.

3.1 The classical construction. To any g-uple $k = (k_1, \dots, k_g) \in \mathbb{Z}^g$ satisfying $k_1 \geq k_2 \geq \dots \geq k_g$, one attaches an automorphic locally free sheaf ω^k on Y_K using the construction of Section 2.3 for the sheaf ω_A of invariant differentials of the universal abelian scheme over Y_K. Let X_K be a toroidal compactification of Y_K (Faltings and Chai [1990]). The sheaf ω^k extends canonically to X_K. The global sections form the space of classical holomorphic Siegel modular forms of weight k and level K. This is a finite dimensional $\mathbb{Q}$-vector space. It carries an action of the Hecke algebra $\mathcal{C}_c^\infty(\mathrm{GSp}_{2g}(\mathbb{A}_f)//K, \mathbb{Z})$ of locally constant and compactly supported functions which are left and right K invariant on $\mathrm{GSp}_{2g}(\mathbb{A}_f)$.

After tensoring with $\mathbb{C}$, these Siegel modular forms can be described as holomorphic vector valued functions on $\mathcal{H}_g$ satisfying a transformation property with respect to a congruence subgroup of $\mathrm{GSp}_{2g}(\mathbb{Q})$. The cuspidal forms (those vanishing on $D = X_K \setminus Y_K$) define (via a usual lifting process) special vectors in the space of algebraic automorphic forms for the group $\mathrm{GSp}_{2g}(\mathbb{A})$. Here and elsewhere $\mathbb{A}$ denotes the ring of adels of $\mathbb{Q}$.

3.2 Interpolation. Let $p > 0$ be a prime integer. We now assume that $K = K^p K_p$ where $K^p \subset \mathrm{GSp}_{2g}(\mathbb{A}_f^{(p)})$ and $K_p = \mathrm{GSp}_{2g}(\mathbb{Z}_p)$. In this setting, Y_K and X_K admit canonical models over Spec $\mathbb{Z}_{(p)}$ and we denote by $\mathcal{Y}$ and respectively $\mathcal{X}$ the associated analytic spaces over $\mathrm{Spa}(\mathbb{Q}_p, \mathbb{Z}_p)$. Over $\mathcal{Y}$ there is a universal p-divisible group $A[p^\infty]$, which comes with a quasi-polarisation: $A[p^\infty] \simeq (A[p^\infty])^D$.

We review the method of Andreatta, Iovita, and Pilloni [2015] to construct a sheaf interpolating the classical automorphic sheaves ω^k. We shall work over $\mathcal{Y}$ for simplicity, but everything extends to $\mathcal{X}$. This construction relies on the Hodge-Tate period map

$$\mathrm{HT} : T_p(A) \to \omega_A$$

where $T_p(A)$ is the Tate-module of the p-divisible group $A[p^\infty]$, a pro-étale sheaf locally isomorphic to $\mathbb{Z}_p^{2g}$. Over the ordinary locus $\mathcal{Y}^{\mathrm{ord}}$ we have an étale-multiplicative extension $0 \to T_p(A)^m \to T_p(A) \to T_p(A)^{et} \to 0$ and the Hodge-Tate map factors through a map $T_p(A)^{et} \to \omega_A$ which induces an isomorphism of pro-étale sheaves $T_p(A)^{et} \otimes \mathcal{O}_{\mathcal{Y}^{\mathrm{ord}}} \to \omega_A|_{\mathcal{Y}^{\mathrm{ord}}}$. Thus the GL_g-torsor ω_A arises from a $\mathrm{GL}_g(\mathbb{Z}_p)$-torsor over the ordinary locus and this allows the interpolation of the sheaves ω^k over $\mathcal{Y}^{\mathrm{ord}}$. It is nevertheless important in order to have compact operators and for the construction of eigenvarieties to go beyond the ordinary locus.

Given an integer $r \geq 0$ we let $\mathcal{Y}_r \subset \mathcal{Y}$ be the open defined by the valuations x satisfying the inequality $|\widetilde{\mathrm{Ha}}^{p^{r+1}}|_x \geq |p|_x$ where $\widetilde{\mathrm{Ha}}$ is locally defined as a (any) lift of the Hasse invariant on the special fiber of Y_K. Each $\mathcal{Y}_r$ should be thought of as a tubular neighborhood of the ordinary locus $\mathcal{Y}^{\mathrm{ord}}$ in $\mathcal{Y}$, where $\mathcal{Y}^{\mathrm{ord}}$ is defined by the condition that $|\widetilde{\mathrm{Ha}}|_x \geq 1$. It follows from the theory of the canonical subgroup that the p^r-torsion of A

over $\mathcal{Y}_r$ contains a canonical subgroup $H_r \subset A[p^r]$ (see Fargues [2011]). Over $\mathcal{Y}^{\mathrm{ord}}$ it coincides with the multiplicative part of $A[p^r]$.

In order to apply the general machinery of Section 2.4 we need to exhibit a vector bundle with marked sections. Consider the finite étale cover of adic spaces $\mathcal{IG}_r \to \mathcal{Y}_r$ classifying trivializations $\psi : (\mathbb{Z}/p^r\mathbb{Z})^g \cong H_r^D$. Then $\mathcal{IG}_r$ carries several sheaves:

1) we have the sheaf H_r and its Cartier dual H_r^D;

2) we have a sheaf ω_A^+, resp. ω_A of $\mathcal{O}^+_{\mathcal{IG}_r}$-modules, resp. of $\mathcal{O}_{\mathcal{IG}_r}$-modules, which are locally free and finite of rank g. Over affinoids $\mathrm{Spa}(B, B^+) \subset \mathcal{IG}_r$ such that the pull-back of A extends to an abelian scheme $\widetilde{A}$ over B^+, the value of ω_A^+ and of ω_A are the module of invariant differentials of $\widetilde{A}$, resp. of A;

3) we have a sheaf $\omega^+_{H_r}$ of $\mathcal{O}^+_{\mathcal{IG}_r}$-modules and a morphism $\mathrm{HT}\colon H_r^D \to \omega^+_{H_r}$. Over affinoids $\mathrm{Spa}(B, B^+) \subset \mathcal{IG}_r$ such that the pull-back of H_r extends to a finite and flat group scheme $\widetilde{H}_r \hookrightarrow \widetilde{A}$ over B^+, the value of $\omega^+_{H_r}$ is the module of invariant differentials $\omega_{\widetilde{H}_r}$ and the map HT is the Hodge-Tate map.

Notice that we have a natural morphism $\omega_A^+ \to \omega^+_{H_r}$. With this we define a *modification* $\omega_A^\sharp \subset \omega_A^+$ as the inverse image in ω_A^+ of $\mathrm{HT}\big(H_r^D \otimes \mathcal{O}^+_{\mathcal{IG}_r}\big)$. One proves that this is a finite and locally free sheaf of $\mathcal{O}^+_{\mathcal{IG}_r}$-modules over $\mathcal{IG}_r$ of rank g and that for every rational number $0 < w \le r - \frac{1}{p(p-1)}$ the morphism HT defines an isomorphism of $\mathcal{O}^+_{\mathcal{IG}_r}/p^w$-modules

$$\mathrm{HT}_w\colon H_r^D \otimes \mathcal{O}^+_{\mathcal{IG}_r}/p^w \cong \omega_A^\sharp/p^w\omega_A^\sharp.$$

which is a good substitute of the comparison map we had over the ordinary locus.

Consider $\mathcal{E} := \omega_A$, $\mathcal{E}^+ := \omega_A^\sharp$ and the sections $s_1, \ldots, s_g$ of $\omega_A^\sharp/p^w\omega_A^\sharp$ provided by the images of the canonical basis of $(\mathbb{Z}/p^r\mathbb{Z})^g$ via $\mathrm{HT}_w \circ \psi$. Let $\mathcal{U} \subset \mathcal{W}$ be an open subset where the character $k^{un}_{\mathcal{U}}$ is w-analytic. Applying the construction explained in Section 2.4 we get the sheaves we are looking for

$$\omega^{k^{\mathrm{un}}}_{r,\mathcal{U}} := \pi_\star\big(\mathcal{O}_{\mathcal{T}_w(\omega_A^\sharp,\{s_1,\ldots,s_g\})\times\mathcal{U}}\big)[k^{\mathrm{un}}],$$

where $\pi : \mathcal{T}_w(\omega_A^\sharp, \{s_1, \ldots, s_g\}) \to \mathcal{IG}_r$ is the torsor of trivializations of $\omega_A^\sharp$ with marked sections $s_1, \ldots, s_g$.

Actually, denote by $\mathcal{Y}_{\mathrm{Iw},r} \to \mathcal{Y}_r$ be the covering parametrizing full flags of H_1^D. Then the sheaf $\omega^{k^{\mathrm{un}}}_{r,\mathcal{U}}$ descends canonically along the natural map $\mathcal{IG}_r \to \mathcal{Y}_{\mathrm{Iw},r}$. Moreover it extends without much difficulties to the toroidal compactification $\mathcal{X}_{\mathrm{Iw},r}$ of $\mathcal{Y}_{\mathrm{Iw},r}$.

3.2.1 A perfectoid digression. We'd like to explain the construction of the previous section when $g = 1$ in more elementary terms. Let N be an integer, $N \ge 3$ and $(N, p) = 1$.

Recall (see Katz [1973]) that a modular form f of weight $k \in \mathbb{Z}$ with level $\Gamma_1(N)$ over $\mathbb{Z}[1/N]$ can be viewed as a functorial rule mapping a triple $(E/R, P, \omega)$ (consisting of an elliptic curve $E \to \operatorname{Spec} R$ for a $\mathbb{Z}[1/N]$-algebra R, a point $P \in E[N]$ of order exactly N, and a nowhere vanishing differential form ω) to $f(E/R, P, \omega) \in R$ satisfying the additional transformation property: $f(E, P, \lambda.\omega) = \lambda^{-k} f(E, P, \omega)$ for any $\lambda \in R^\times$ and some growth condition at infinity.

Over $\mathbb{C}$, we can pull back f to a function on the Poincaré upper half plane by setting $F(\tau) = f(\mathbb{C}/(\mathbb{Z} + \tau\mathbb{Z}), \frac{1}{N}, \mathrm{d}z)$ for the coordinate z on $\mathbb{C}$. For $\gamma = \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in \Gamma_1(N)$, multiplication by $(c\tau+d)^{-1}$ on $\mathbb{C}$ identifies the triples $(\mathbb{C}/(\mathbb{Z}+\tau\mathbb{Z}), \frac{1}{N}, \mathrm{d}z)$ and $(\mathbb{C}/(\mathbb{Z}+\gamma.\tau\mathbb{Z}), \frac{1}{N}, (c\tau + d)\mathrm{d}z)$ and therefore F satisfies a descent condition with respect to the action of $\Gamma_1(N)$, namely $F(\gamma.\tau) = (c\tau + d)^k F(\tau)$.

We now express our definition of overconvergent modular forms of some $\mathbb{C}_p$-valued character $k : \mathbb{Z}_p^\times \to \mathbb{C}_p^\times$ in similar terms. Assume that k is w-analytic and choose a positive integer r such that $r-1 < w \le r - \frac{1}{(p-1)p}$ (this can be achieved at the expense of increasing w). Then an r-overconvergent modular form f of weight k is a rule associating to every quadruple (E, P, ψ, ω) an element $f(E, P, \psi, \omega) \in \mathbb{C}_p$, where E is an elliptic curve over $\mathbb{C}_p$ such that $|\widetilde{\mathrm{Ha}}^{p^{r+1}}(E)| \ge |p|$, P is a point of order N, ψ is point of order p^r of the dual canonical subgroup H_r^D, ω is an integral differential form on E such that $\omega \mod p^w = \mathrm{HT}_w(\Psi)$. Moreover we demand that f is "analytic", extends to the cusps, and satisfies the functional equation $f(E, P, \lambda\psi, \lambda\omega) = k^{-1}(\lambda) f(E, P, \psi, \omega)$ for all $\lambda \in \mathbb{Z}_p^\times(1 + p^w\mathbb{C}_p)$.[2]

Following Chojecki, Hansen, and Johansson [2017], one can describe an analogue of the passage from f to F in the p-adic world. Let $\mathfrak{X}(\infty) \to \mathfrak{X}$ be the prefectoid modular curve of level $\Gamma(p^\infty) \cap \Gamma_1(N)$ constructed by Scholze [2015] and $\mathcal{Y}(\infty)$ the complement of the boundary. Over $\mathcal{Y}(\infty)$ we have a universal trivialization $\psi_\infty \colon \mathbb{Z}_p^2 \cong T_p(E)$ and the Hodge-Tate map $\mathrm{HT}\colon T_p(E) \to \omega_E$ induces a period map:

$$\pi_{\mathrm{HT}} \colon \mathfrak{X}(\infty) \longrightarrow \mathbb{P}^1$$

which, over $\mathcal{Y}(\infty)$, is characterized by the fact that $\pi_{\mathrm{HT}}^\star\big(\mathcal{O}_{\mathbb{P}^1}(1)\big) = \omega_E$ and the pull-back of the two canonical sections s_0 and s_1 of $\mathcal{O}_{\mathbb{P}^1}(1)$ are the images via $\mathrm{HT} \circ \psi_\infty$ of the canonical basis e_0, e_1 of $\mathbb{Z}_p \oplus \mathbb{Z}_p$. For any $v \in \mathbb{Q}_{>0}$, let $\mathbb{P}^1_v$ be the open of $\mathbb{P}^1$ defined by the condition $|s_1| \le |p^v s_0|$.

Let $\mathfrak{X}(\infty)_v = \pi_{\mathrm{HT}}^{-1}(\mathbb{P}^1_v)$ and $\mathcal{Y}(\infty)_v = \mathcal{Y}(\infty) \cap \mathfrak{X}(\infty)_v$. For v large enough, $(E, P, \psi_\infty) \in \mathcal{Y}(\infty)_v$ has a canonical subgroup of level r which is generated by the image of $\psi_\infty(e_1)$ in

[2] In order to make sense of the functional equation it is necessary to restrict to differential forms which "arise" from the dual canonical subgroup

$E[p^r]$, and $\psi_\infty(e_0)$ maps to a generator $\overline{\psi_\infty(e_0)}$ of H_r^D. We can therefore pullback f to a function on $\mathcal{Y}(\infty)_v$ by setting $F(E, P, \psi_\infty) = f(E, P, \overline{\psi_\infty(e_0)}, s_0 = \mathrm{HT}(\psi_\infty(e_0)))$.

This identifies the space of overconvergent modular forms of weight k with a space of functions on the open $\mathfrak{X}(\infty)_v$ of $\mathfrak{X}(\infty)$. These functions satisfy a descent condition which reminds us of the descent condition on the upper half plane. Namely, let n be the smallest integer greater than v. We consider the subgroup $K_0(p^n) \subset \mathrm{GL}_2(\mathbb{Z}_p)$ of elements $\begin{pmatrix} a & b \\ c & d \end{pmatrix}$ such that $c \in p^n\mathbb{Z}_p$. For any $\gamma \in K_0(p^n)$ as above, we find that $F(E, P, \psi_\infty \circ \gamma) = k^{-1}(a + b\frac{s_1}{s_0})F(E, P, \psi_\infty)$. [3]

3.3 Eigenvarieties. The sheaves $\omega_{r,\mathfrak{U}}^{k^{\mathrm{un}}}$ produce variations of Hecke eigensystems as follows. The global sections of $\omega_{r,\mathfrak{U}}^{k^{\mathrm{un}}}$ over $\mathfrak{X}_{\mathrm{Iw},r}$, vanishing at the boundary, form the Banach module of r-overconvergent, w-analytic cuspidal Siegel modular forms of weight parametrized by $\mathfrak{U}$. Passing to the limit over r and w we obtain the space of overconvergent, locally analytic cuspidal Siegel modular forms of weight parametrized by $\mathfrak{U}$. Let N be the product of primes different from p for which $K_\ell \neq \mathrm{GSp}_{2g}(\mathbb{Z}_\ell)$. This space carries an action of the commutative spherical Hecke algebra $\mathbb{T}^{Np} := \mathcal{C}_c^\infty(\mathrm{GSp}_{2g}(\mathbb{A}_f^{(Np)})//K^{Np}, \mathbb{Z})$. Let $\mathrm{Iw}_p \subset \mathrm{GSp}_{2g}(\mathbb{Z}_p)$ be the Iwahori parahoric of upper triangular matrices modulo p. At p, there is an action of the dilating Hecke algebra $\mathbb{U}_p := \mathbb{Z}[U_{p,1}, \cdots, U_{p,g}]$[4] $\subset \mathcal{C}_c^\infty(\mathrm{GSp}_{2g}(\mathbb{Q}_p)//\mathrm{Iw}_p, \mathbb{Z})$, and the operator $U = \prod_i U_{p,i}$ is compact.

Let f be a classical cuspidal eigenform of weight k and level $K^p\mathrm{Iw}_p$. We denote by $\Theta_f : \mathbb{T}^{Np} \otimes \mathbb{U}_p \to \bar{\mathbb{Q}}$ the associated character.[5] We have the following:

Theorem 3.1. *There is a rigid analytic space $\mathcal{E}$, called the eigenvariety of tame level K^p, equipped with a weight map $w : \mathcal{E} \to \mathcal{W}$ which is locally on the source and the target finite and torsion free and there is a universal Hecke character $\Theta : \mathbb{T}^{Np} \otimes \mathbb{U}_p \to \mathcal{O}_\mathcal{E}$ with dense image such that:*

- *Any classical cuspidal eigenform f of weight k and level $K^p\mathrm{Iw}_p$ provides a unique point x_f on $\mathcal{E}$ such that $\Theta|_{x_f} = \Theta_f$ and $w(x_f) = k$,*
- *Conversely, any point $x \in \mathcal{E}$ satisfying $w(x) = (k_1, \ldots, k_g) \in X(\mathrm{T})^+$ satisfying $v(\Theta|_x(U_{p,i})) < k_{g-i} - k_{g-i+1} + 1$ for $1 \leq i \leq g-1$ and $v(\Theta|_x(U_{p,g})) < k_g - \frac{g(g+1)}{2}$ arises from a cuspidal eigenform f of weight k and level $K^p\mathrm{Iw}_p$.*

[3] $F(E, P, \psi_\infty \circ \gamma) = f(E, P, \overline{\psi_\infty(ae_0)}, \mathrm{HT} \circ \psi_\infty(ae_0 + be_1)) = f(E, P, \overline{\psi_\infty(ae_0)}, (a + b\frac{s_1}{s_0})\mathrm{HT} \circ \psi_\infty(e_0)) = k^{-1}(a + b\frac{s_1}{s_0})F(E, P, \psi_\infty)$.

[4] If $i \in \{1, \cdots, g-1\}$, $U_{p,i}$ is the characteristic function of the double class $\mathrm{Iw}_p\mathrm{diag}(p^2 Id_i, pId_{2g-2i}, Id_i)\mathrm{Iw}_p$, $U_{p,g}$ is the characteristic function of the double class $\mathrm{Iw}_p\mathrm{diag}(pId_g, Id_g)\mathrm{Iw}_p$

[5] Since f has Iwahori level at p, then $\Theta_f(U_{p,i}) \neq 0$ and f is of finite slope.

Remark 3.3.1. 1) The case $g = 1$ of Theorem 3.1 was first proved by Coleman and Mazur in Coleman and Mazur [1998]. They used a different construction of the p-adic families of modular forms in which the Eisenstein family plays a crucial role and which could not be generalized for $g > 1$.

2) The cuspidality condition is crucial for the theorem for $g \geq 2$. We prove an acyclicity result for the cuspidal sheaves $\omega^{k^{\mathrm{un}}}_{r,\mathcal{U}}(-D)$ using that $\mathcal{X}_{\mathrm{Iw,r}}$ has affine image in the minimal compactification and showing that the relative cohomology of cuspidal sheaves between the toroidal and the minimal compactifications vanishes in degrees greater than 1. In particular the acyclicity allows us to prove that the degree zero cohomology of $\omega^{k^{\mathrm{un}}}_{r,\mathcal{U}}(-D)$ commutes with specializations in the weight space $\mathcal{U} \subset \mathcal{W}$.

3) We outlined the construction for Siegel modular varieties but the same method applies more generally for PEL type Shimura varieties having dense ordinary locus, see Andreatta, Iovita, and Pilloni [2016a] for the Hilbert case and Brasca [2016] for the general case.

4) Even for Shimura varieties with empty ordinary locus, one can proceed in a similar way. The ordinary locus is replaced by the so called μ-ordinary locus, introduced by T. Wedhorn, and the Hasse invariant is replaced by the μ-Hasse invariant, defined at various levels of generality by G. Boxer, W. Goldring-M.H. Nicole, V. Hernandez, J.S. Koskivirta-T. Wedhorn. The last ingredient one needs is a replacement for the canonical subgroup and the Hodge-Tate map. We refer to Kassaei [2013] and Brasca [2013] for the case of Shimura curves and to Hernandez [2016] for the more general case of PEL type Shimura varieties and for a thorough account of the problem.

5) The last point of the Theorem 3.1 is proven in Bijakowski, Pilloni, and Stroh [2016] (and already by Coleman and Kassaei for $g = 1$). It is a *classicity criterion* which roughly asserts that small slope overconvergent modular forms are classical. It is a crucial result in order to study eigenvarieties as it provides a dense set of points, the classical ones. In a certain sense, these classical points characterize uniquely the eigenvariety. In particular, it often happens that a given property known at the classical points can be inferred by continuity for the whole eigenvariety.

4 Variations at infinity

We now restrict to the case $g = 1$. In this case we have an eigencurve $\mathcal{E} \to \mathcal{Z} \to \mathcal{W}$ where $\mathcal{Z} \hookrightarrow \mathcal{W} \times \mathbb{G}_m$, the so called *spectral curve*, is the zero locus of the characteristic series $\mathcal{P}(X)$ of the U-operator acting on the space of overconvergent modular forms. The map $\mathcal{E} \to \mathcal{Z}$ is finite and both $\mathcal{E}$ and $\mathcal{Z}$ are equidimensional of dimension 1. Therefore the geometry of $\mathcal{E}$ can be understood, to some extent, by studying the apparently simpler space $\mathcal{Z}$.

4.1 The spectral halo. Recall that the weight space $\mathcal{W}$ is the rigid analytic fiber of $\operatorname{Spf} \mathbb{Z}_p[\![\mathbb{Z}_p^\times]\!]$. One can consider a slightly bigger space $\mathcal{W}^{\mathrm{an}}$ defined by the analytic points of the adic space $\operatorname{Spa}(\mathbb{Z}_p[\![\mathbb{Z}_p^\times]\!], \mathbb{Z}_p[\![\mathbb{Z}_p^\times]\!])$. Recall that

$$\mathbb{Z}_p[\![\mathbb{Z}_p^\times]\!] \cong \mathbb{Z}_p\big[(\mathbb{Z}/p\mathbb{Z})^\times\big][\![T]\!]$$

where T is defined by imposing that the grouplike element $\exp(p)$ is equal to $T+1$. The complement of $\mathcal{W}$ in $\mathcal{W}^{\mathrm{an}}$ consists of finitely many points in characteristic p, corresponding to the T-adic valuations on $\mathbb{F}_p\big[(\mathbb{Z}/p\mathbb{Z})^\times\big](\!(T)\!)$ and $\mathcal{W}^{\mathrm{an}}$ is a compactification of $\mathcal{W}$, obtained by adding a point at the boundary of each rigid analytic open unit disc.

Coleman observed that the characteristic series $\mathcal{P}(X)$ of the U-operator on the eigencurve has coefficients in Λ and, hence one can consider the extended spectral curve $\mathcal{Z}^{an} \hookrightarrow \mathcal{W}^{an} \times \mathbb{G}_m = V(\mathcal{P})$. The fiber of $\mathcal{Z}^{an}$ over a boundary point

$$k\colon \operatorname{Spa}\big(\mathbb{F}_p(\!(T)\!), \mathbb{F}_p[\![T]\!]\big) \to \mathcal{W}^{an}$$

is the zero set of the specialization $\mathcal{P}_k(X)$ at k, over the non-archimedean field $\mathbb{F}_p(\!(T)\!)$.

In Andreatta, Iovita, and Pilloni [2018] we prove a conjecture of Coleman in which he stated the existence of a Banach space over $\mathbb{F}_p(\!(T)\!)$ and of a compact operator whose characteristic series is $\mathcal{P}_k(X)$. More precisely, we prove the following result. Let $\mathcal{X}_{\mathcal{W}^{\mathrm{an}}}$ be the analytic adic space defined by the pull back of the modular curve to $\mathcal{W}^{\mathrm{an}}$. Given $v \in \mathbb{Q}_{\geq 0}^\times$ we define $\mathcal{X}_{\mathcal{W}^{\mathrm{an}}}(v)$ to be the open consisting of the points x satisfying the condition $|\widetilde{\mathrm{Ha}}|_x \geq \sup\{|T^v|_x, |p^v|_x\}$.

Theorem 4.1. *For $v > 0$ small enough we have an invertible sheaf $\omega^{k^{\mathrm{un}}}$ over $\mathcal{X}_{\mathcal{W}^{\mathrm{an}}}(v)$, endowed with an action of the Hecke operators, that coincides with the construction in Section 3.2 over* $\operatorname{Spa}(\mathbb{Q}_p, \mathbb{Z}_p)$.

Moreover, given a boundary point k of $\mathcal{W}^{\mathrm{an}}$, the sections of the fiber of $\omega^{k^{\mathrm{un}}}$ at k form a Banach module over $\mathbb{F}_p(\!(T)\!)$ such that the characteristic series of the U-operator is Coleman's series $\mathcal{P}_k(X)$.

The sections of the characteristic p fiber of $\omega^{k^{\mathrm{un}}}$ are called *T-adic overconvergent modular forms* (of radius of convergence v). They are actually functions on certain overconvergent Igusa tower in characteristic p. Using the sheaf $\omega^{k^{\mathrm{un}}}$ over $\mathcal{X}_{\mathcal{W}^{\mathrm{an}}}(v)$ one manages to extend the Coleman-Mazur eigencurve to an eigencurve $\mathcal{E}^{\mathrm{an}}$ over the whole $\mathcal{Z}^{\mathrm{an}}$.

Each finite slope eigenform f in characteristic p defines a point on $\mathcal{E}^{\mathrm{an}}$ and we can associate to it a semi-simple two dimensional Galois representation

$$\rho_f\colon \operatorname{Gal}(\overline{\mathbb{Q}}/\mathbb{Q}) \to \mathrm{GL}_2\big(\overline{\mathbb{F}_p[\![T]\!]}\big)$$

unramified at the primes different form p and not dividing the tame level. Here $\overline{\mathbb{F}_p[\![T]\!]}$ denotes an algebraic closure of $\mathbb{F}_p[\![T]\!]$. If f is ordinary, ρ_f has already been constructed by Hida. For finite slopes we get new, mysterious objects in the realm of Galois representations that deserve further study and understanding. Here are some questions that we find interesting.

Given ρ_f as above, one can construct an equicharacteristic p, étale (φ, Γ)-module $\mathfrak{D}(\rho)$ over the Robba ring for the discretely valued field $\bar{\mathbb{F}}_p((t))$ (as in Berger and Colmez [2008]). Is $\mathfrak{D}(\rho)$ trianguline (i.e., extension of one dimensional (φ, Γ)-modules)?

Does this characterize the two dimensional representations of $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$ with values in finite extensions of $\bar{\mathbb{F}}_p((T))$ which arise from T-adic overconvergent modular eigenforms of finite slope?

4.2 The halo conjecture. We would now like to discuss the halo conjecture and some questions related to the global geometry of $\mathcal{E}^{an}$. Let $x\colon \mathrm{Spa}(K, \mathcal{O}_K) \to \mathcal{W}^{an}$ be a rank one point. The choice of a pseudo uniformizer ϖ allows to normalize the associated valuation $v\colon K \to \mathbb{R} \cup \{\infty\}$ by $v(\varpi) = 1$. In that case we write v_ϖ for v. There are in general two natural choices of pseudo-uniformizer in $\mathcal{O}_K$, namely p and T, except at the boundary when $p = 0$ and at the very center $T = 0$. One can attach to the characteristic series $\mathcal{P}_k(X) = \sum_{n \geq 0} a_n X^n$ and a choice of pseudo uniformizer ϖ a Newton polygon $NP_\varpi(\mathcal{P}_k)$ which is the convex enveloppe of the points $(n, v_\varpi(a_n)) \subset \mathbb{R}^2$. This is the graph of a piecewise linear function and the sequence of slopes of $NP_\varpi(\mathcal{P}_k)$ is giving the sequence of ϖ-adic valuations of finite slope eigenvalues of U.

Conjecture 1 (Coleman-Mazur-Buzzard-Kilford)**.** *Let $k \in \mathcal{W}^{an}$ be a boundary point. Then there exists a positive rational number r such that for all rank one points*

$$k'\colon \mathrm{Spa}\big(K, \mathcal{O}_K\big) \to \mathcal{W}^{an}$$

in a neighbourhood $\mathcal{U} = \{x,\ |p^r|_x \leq |T|_x\}$ of k we have $NP_T(\mathcal{P}_{k'}) = NP_T(\mathcal{P}_k)$. Moreover, the slopes in $NP_T(\mathcal{P}_k)$ form a finite union of arithmetic progressions.

Before discussing what is known about this conjecture, let us describe some of the consequences. The first implication is that $\mathcal{Z}^{an}|_{\mathcal{U}} = \coprod_s \mathcal{Z}^{an}(s)$ splits as a disjoint union of components according to the slopes s occurring in $NP_T(\mathcal{P}_k)$. Each component $\mathcal{Z}^{an}(s)$ is finite flat over $\mathcal{U}$. In certain numerical examples it actually maps isomorphically onto $\mathcal{U}$. In this case the complement of the points at infinity can be visualized as halos, explaining the name of the conjecture.

A second implication is that the p-adic slopes tend to zero as one approaches the boundary. In particular, T-adic overconvergent modular eigenforms of finite slope (for the U-operator) are limits of classical modular forms of arbitrary fixed weight $k \geq 2$ (of course of increasing level at p) by Coleman's classicity theorem. It is known that each irreducible component of $\mathcal{Z}^{an}$ has image in the weight space equal to the complement of a finite number of points. Therefore, any irreducible component of $\mathcal{Z}^{an}$ contains at least one irreducible component of some $\mathcal{Z}^{an}(s)$. Thus each irreducible component of $\mathcal{Z}^{an}$ contains infinitely many classical points of a given weight $k \geq 2$.

Another consequence of the fact that the p-adic slopes tend to zero approaching infinity is that an irreducible component of $\mathcal{Z}^{an}$ is finite over the weight space if and only if it is ordinary (i.e., the slope is 0) (Liu, Wan, and Xiao [2017], prop. 3.24).

The conjecture has not yet been proved for the whole eigencurve $\mathcal{E}^{an}$ but it is known for all the irreducible components that arise from the p-adic Jaquet-Langlands correspondence thanks to Liu, Wan, and Xiao [ibid.]. Independently, in Bergdall and Pollack [2016] it is proved that the constancy of the Newton Polygon implies the second part of the halo conjecture, namely that the slopes form a finite union of arithmetic progressions.

Motivated by the boundary behavior provided by the conjecture and by a conjecture of Buzzard's for classical weights, Bergdall and Pollack have elaborated a unifying conjecture in Bergdall and Pollack [2017], called *ghost conjecture*, predicting (under some extra assumptions) the slopes of overconvergent cuspforms over the whole weight space.

Finally let us remark that, even though we discussed only the elliptic case, eigenvarieties might be defined over the whole analytic adic weight space for more general Shimura varieties. We refer to Andreatta, Iovita, and Pilloni [2016b] for the Hilbert case and to Johansson and Newton [2016] for a Betti cohomology approach. In contrast with the elliptic case, where at infinity the weight space consists of a finite set of points, in the Hilbert case, for a totally real field of degree g, at infinity the weight space has components of dimension $g-1$.

5 p-Adic variation of de Rham automorphic sheaves

In this section we use the notations and results of Section 2 and Section 3 for $G = \mathrm{GL}_2/\mathbb{Q}$, i.e., for $g = 1$. Here we briefly present the constructions and results of Andreatta and Iovita [2017], using adic analytic spaces instead of formal schemes. The interested reader should consult Andreatta and Iovita [ibid.] for more details.

Before getting into technicalities let us briefly explain the problem we are faced with and explain how we chose to solve it. Let $p > 2$ be a prime integer, $N \geq 3$ an integer relatively prime to p, $\mathcal{X}$ the adic analytic projective modular curve of level $\Gamma_1(N)$ over $\mathrm{Spa}(\mathbb{Q}_p, \mathbb{Z}_p)$ and $\alpha\colon E \longrightarrow \mathcal{X}$ the generalized, universal elliptic curve. We denote by $\left(\mathrm{H}_E, \mathrm{Fil}_\bullet, \nabla\right)$ the data consisting of:

i) the relative de Rham cohomology sheaf of E over $\mathcal{X}$, i.e.

$$\mathrm{H}_E := \mathbb{R}^1\alpha_*\left(\Omega^\bullet_{E/\mathcal{X}}(\log(\alpha^{-1}(\mathrm{cusps})))\right),$$

ii) the Hodge filtration $\mathrm{Fil}_\bullet$ of H_E, i.e., $\mathrm{Fil}_0 := \omega_E = \alpha_*\big(\Omega^1_{E/\mathfrak{X}}(\log(\alpha^{-1}(\mathrm{cusps})))\big)$, $\mathrm{Fil}_i = 0$ for $i < 0$ and $\mathrm{Fil}_i = \mathrm{H}_E$ for $i \geq 1$.

iii) $\nabla\colon \mathrm{H}_E \longrightarrow \mathrm{H}_E \otimes_{\mathcal{O}_{\mathfrak{X}}} \Omega^1_{\mathfrak{X}/\mathbb{Q}_p}\big(\log(\mathrm{cusps})\big)$, the Gauss-Manin connection, an integrable connection satisfying Griffith's transversality property.

We now consider the following family of data indexed by the integers:

$$(*) \qquad \Big(\big(\mathrm{Sym}^n(\mathrm{H}_E), \mathrm{Fil}_{n,\bullet}, \nabla_n\big)\Big)_{n\in\mathbb{Z}},$$

where $\mathrm{Fil}_{n,\bullet}$ and ∇_n are the natural increasing filtrations and connections on the n-th symmetric powers of H_E.

Over the complex numbers one can use the Hodge decomposition of H_E in order to describe the global sections of $\omega_E^{k-r} \otimes \mathrm{Sym}^r(\mathrm{H}_E)$ as suitable C^∞-functions on the upper half plane, called *nearly holomorphic modular forms* of weight k and order $\leq r-1$. Using this interpretation, the Gauss-Manin connection takes the form of the so called *Maass-Shimura differential operator* $\delta_k(f) = \frac{1}{2\pi i}\left(\frac{\partial f}{\partial \tau} + \frac{k}{2iy} f\right)$ where τ is the standard coordinate on the upper half plane and $y = \mathrm{Im}(\tau)$. For $k > 2r$ one also has a *holomorphic projection* $\mathrm{H}^{\mathrm{hol}}$ to weight k modular forms and, hence, a q-expansion of nearly holomorphic forms. See Urban [2014, §2] for details. This is used, for example, to study special values of triple product L-functions as follows.

Let f, g, h be a triple of normalized primitive cuspidal classical eigenforms of weights k, ℓ, m, characters χ_f, χ_g, χ_h and tame levels N_f, N_g, N_h respectively. We write $f \in S_k(N_f, \chi_f)$, $g \in S_\ell(N_g, \chi_g)$, $h \in S_m(N_h, \chi_h)$. We assume that (k, ℓ, m) is unbalanced, i.e., there is an integer $t \geq 0$ such that $k - \ell - m = 2t$. We set $N := \ell.\mathrm{c.m.}(N_f, N_g, N_h)$ and $\mathbb{Q}_{f,g,h} := \mathbb{Q}_f \cdot \mathbb{Q}_g \cdot \mathbb{Q}_h$ the number field generated over $\mathbb{Q}$ by the Hecke eigenvalues of f, g, h. We assume that $\chi_f \cdot \chi_g \cdot \chi_h = 1$.

A result of Harris and Kudla [1991], previously conjectured by H. Jacquet and recently refined by Ichino [2008] and Watson [2002] implies that there are choices of Hecke-equivariant embeddings of $S_k(N_f, \chi_f)$, $S_\ell(N_g, \chi_g)$, $(S_m(N_h, \chi_h)$ into $S_k(N)$, $S_\ell(N)$, $S_m(N)$ respectively such that the images f^o, g^o, h^o of f, g, h respectively satisfy Ichino's formula, i.e.,

$$L\left(f, g, h, \frac{k+\ell+m-2}{2}\right) = (\text{non-zero algebraic constant}) \times |I(f^o, g^o, h^o)|^2,$$

where

$$I(f^o, g^o, h^o) := \frac{\langle (f^o)^*, \mathrm{H}^{\mathrm{hol}}\big(\delta^t (g^o)^{[p]} \times h^o\big)\rangle}{\langle (f^o)^*, (f^o)^*\rangle}.$$

Here $L(f,g,h,s)$ is the complex Garrett-Rankin triple product L-function attached to f,g,h. We have denoted by $\langle\ ,\ \rangle$ the Peterson inner product on the space of weight k-modular forms, $(f^o)^* = f^o \otimes \chi_f^{-1}$, $(g^o)^{[p]}$ is defined on q-expansions by: $(g^o)^{[p]}(q) := \sum_{n=1,(n,p)=1}^{\infty} a_n q^n$ if $g^o(q) = \sum_{n=1}^{\infty} a_n q^n$ and finally δ, $\mathrm{H}^{\mathrm{hol}}$ are the operators on nearly holomorphic forms introduced above.

5.1 p-Adic variations of $(\mathrm{H}_E, \mathrm{Fil}_\bullet)$. The task before us is to p-adically interpolate the constructions over the complex numbers previously described. We fix $I := [0,b]$ a closed interval, with $b \in \mathbb{Z}_{>0}$ and let $\mathcal{W}_I$ be the open adic subspace of $\mathcal{W}$ defined by

$$\mathcal{W}_I := \{x \in \mathcal{W} \quad | \quad |T^b|_x \leq |p|_x \neq 0\}.$$

Let $r \geq 0$ be an integer and denote by $\mathcal{X}_{r,I}$ the open adic subspace of $\mathcal{X} \times \mathcal{W}_I$ defined as in Section 3 by the valuations x such that $|\widetilde{\mathrm{Ha}}^{p^{r+1}}|_x \geq |p|_x$. If $E_{r,I}$ is the inverse image of the universal generalized elliptic curve over $\mathcal{X}$. We remark that the universal character k^{un} of $\mathcal{W}_I$ is r-analytic and there is a canonical subgroup $H_r \subset E_{r,I}[p^r]$ of order p^r over $\mathcal{X}_{r,I}$. Let H_r^D denote the Cartier dual of H_r.

We denote by $\mathcal{IG}_{r,I} := \underline{\mathrm{Isom}}_{\mathcal{X}_{r,I}}(\mathbb{Z}/p^r\mathbb{Z}, H_r^D)$ the adic space over $\mathcal{X}_{r,I}$ of trivializations of H_r^D. Then $\mathcal{IG}_{r,I} \longrightarrow \mathcal{X}_{r,I}$ is a finite, étale and Galois cover with Galois group $(\mathbb{Z}/p^r\mathbb{Z})^\times$. We introduce the ideals:

i) Hdg, the ideal of $\mathcal{O}^+_{\mathcal{X}_{r,I}}$ locally generated by any lift of the Hasse invariant Ha modulo p.

ii) $\underline{\beta}_r$, the ideal of $\mathcal{O}^+_{\mathcal{X}_{r,I}}$ locally generated by $\dfrac{p}{\mathrm{Hdg}^{\frac{p^r-1}{p-1}}}$.

iii) $\underline{\delta}$, the ideal of $\mathcal{O}^+_{\mathcal{IG}_{r,I}}$ locally generated by a precisely defined $(p-1)$-st root of Hdg. For $p \geq 5$ one considers the overconvergent modular form D of weight 1 which is a certain precisely defined $(p-1)$-st root of the Eisenstein series E_{p-1}. Then D locally generates $\underline{\delta}$.

In Section 3 we have exhibited the pair of sheaves (ω_E, ω_E^+) over $\mathcal{IG}_{r,I}$ which are invertible $\mathcal{O}_{\mathcal{IG}_{r,I}}$ and respectively $\mathcal{O}^+_{\mathcal{IG}_{r,I}}$-modules and the modification $\omega_E^\#$ of ω_E^+, an $\mathcal{O}^+_{\mathcal{IG}_{r,I}}$ submodule of ω_E^+ which is itself invertible. In fact in the $g=1$ case, the situation is very simple and we happen to have $\omega_E^\# = \underline{\delta} \cdot \omega_E^+$, which implies that over $\mathcal{IG}_{r,I}$ for $p \geq 5$ we have $\omega_E^\# = D \cdot \mathcal{O}^+_{\mathcal{IG}_{r,I}}$, i.e., it is globally free.

Moreover if $\psi : \mathbb{Z}/p^r\mathbb{Z} \cong H_r^D$ denotes the universal trivialization of H_r^D over $\mathcal{IG}_{r,I}$ then $P := \psi(1)$ is a universal generator of H_r^D over $\mathcal{IG}_{r,I}$ and $s := \mathrm{HT}(P)$ is a $\mathcal{O}^+_{\mathcal{IG}_{r,I}}/\underline{\beta}_r$-basis of $\omega_E^\#/\underline{\beta}_n\omega_E^\#$. In other words the pair $(\omega_E^\#, s)$ is a locally free sheaf with a marked section as in Section 2.

Let us now denote by H_E^+ the locally free $\mathcal{O}^+_{\mathfrak{X}_{r,I}}$-module of rank 2 characterized by the following property. For $U = \mathrm{Spa}(B, B^+) \subset \mathfrak{X}_{r,I}$ an open such that the generalized elliptic curve E/B is in fact defined over B^+ we let $\pi : E \longrightarrow \mathrm{Spf}(B^+)$ be the structural morphism. Then

$$\mathrm{H}_E^+|_U = \mathbb{R}^1\pi_*\big(\Omega^\bullet_{E/B^+}(\log(\pi^{-1}(\mathrm{cusps})))\big).$$

We have $\mathrm{H}_E^+ \otimes_{\mathcal{O}^+_{\mathfrak{X}_{r,I}}} \mathcal{O}_{\mathfrak{X}_{r,I}} = \mathrm{H}_E$ and H_E^+ has a natural Hodge filtration $\mathrm{Fil}^+_\bullet$, expressed by the exact sequence:

$$0 \longrightarrow \omega_E^+ \longrightarrow \mathrm{H_E}^+ \longrightarrow (\omega_E^+)^{-1} \longrightarrow 0.$$

We also have a connection on H_E^+ but we will discuss it later.

It is natural to consider: $\mathrm{H}_E^\# := \underline{\delta}\cdot\mathrm{H}_E^+$ and $\mathrm{Fil}^\#_\bullet := \underline{\delta}\cdot\mathrm{Fil}^+_\bullet$ as $\big(\mathrm{H}_E^\#, s = \mathrm{HT}(P)\big)$ is a pair consisting of a locally free sheaf of rank 2 with a marked section and $(\omega_E^\#, s) \subset (\mathrm{H}_E^\#, s)$ is a compatible filtration. Let us then consider the sequence of adic spaces and morphisms

$$\mathcal{T}_{\underline{\beta}_n}(\mathrm{H}_E^\#, s) \xrightarrow{u} \mathfrak{IG}_{r,I} \xrightarrow{v} \mathfrak{X}_{r,I}$$

and denote by $\rho := v \circ u$. Here $\mathcal{T}_{\underline{\beta}_r}(\mathrm{H}_E^\#, s)$ denotes the VBMS of Section 2 associated to the pair $(\mathrm{H}_E^\#, s)$ and ideal sheaf $\underline{\beta}_n$. This VBMS was denoted $\mathbb{V}_0(\mathrm{H}_E^\#, s)$ in Andreatta and Iovita [2017]. Then we have a natural action of $\mathbb{Z}_p^*$ on the sheaf $\mathbb{W}^+ := \rho_*\big(\mathcal{O}^+_{\mathbb{V}_0(\mathrm{H}_E^\#, s)}\big)$.

Definition 5.1.1. *We denote by $k : \mathbb{Z}_p^\times \longrightarrow \Lambda_I^\times$ a weight in $\mathfrak{W}_I$ (it could be the universal weight or not), denote by $\mathbb{W}_k^+$ the $\mathcal{O}^+_{\mathfrak{X}_{r,I}}$-module $\mathbb{W}^+[k]$, i.e. $\mathbb{W}_k^+$ is the sub-$\mathcal{O}^+_{\mathfrak{X}_{r,I}}$ module of sections of $\mathbb{W}^+$ on which $\mathbb{Z}_p^\times$ acts by multiplication with the values of k. The formalism of vector bundles with marked sections implies that $\mathbb{W}_k^+$ has a filtration by locally free, coherent $\mathcal{O}^+_{\mathfrak{X}_{r,I}}$-submodules $\mathrm{Fil}^+_{k,\bullet}$.*

We let $\mathbb{W}_k := \mathbb{W}_k^+ \otimes_{\mathcal{O}^+_{\mathfrak{X}_{r,I}}} \mathcal{O}_{\mathfrak{X}_{r,I}}$. It is a sheaf of Banach modules on $\mathfrak{X}_{r,I}$ with a filtration $\mathrm{Fil}_{k,\bullet}$ and $\mathrm{Fil}_{k,0}$ coincides with the sheaf $\omega^k_{r,I}$ of Section 3.2.

5.2 p-Adic variations of the connection. In order to obtain a connection on $\mathbb{W}_k$ we need to first choose a formal model of the morphism $\pi : E \longrightarrow \mathfrak{X}_{r,I}$, say $\tau : \mathcal{E} \longrightarrow \mathfrak{X}$. Our favorite such formal model is obtained by taking for $\mathfrak{X}$ the partial blow-up of the base change of the formal completion of the modular curve $X_1(N)$ over $\mathbb{Z}_p$ to the formal weight space $\mathrm{Spf}(\Lambda_I)$, with respect to the ideal $(p, \mathrm{Hdg}^{p^{r+1}})$ and taking $\mathcal{E}$ to be the inverse image of the generalized elliptic curve over $X_1(N)$. We also obtain a natural formal model $\mathfrak{IG}$ of $\mathfrak{IG}_{r,I}$ given by the normalization of $\mathfrak{X}$ in $\mathfrak{IG}_{r,I}$. Having fixed these formal models we obtain: a canonical $\mathcal{O}^+_{\mathfrak{IG}_{r,I}}$-submodule $\Omega^{1,+}_{\mathfrak{IG}_{r,I}/\mathfrak{W}_I}(\log)$ of $\Omega^1_{\mathfrak{IG}_{r,I}/\mathfrak{W}_I}(\log)$ and a natural connection

$$\nabla^+ : \mathrm{H}^+_E \longrightarrow \mathrm{H}^+_E \otimes_{\mathcal{O}^+_{\mathfrak{IG}_{r,I}}} \Omega^{1,+}_{\mathfrak{IG}_{r,I}/\mathfrak{W}_I}(\log),$$

whose generic fiber is the connection ∇ described at the beginning of this section.

The connection ∇^+, the weight $k : \mathbb{Z}_p^\times \longrightarrow \Lambda_I^\times$ and the formalism of VBMS produce a connection

$$\nabla_k : \mathbb{W}_k \longrightarrow \mathbb{W}_k \otimes_{\mathcal{O}_{\mathfrak{X}_{r,I}}} \Omega^1_{\mathfrak{X}_{r,I}/\mathfrak{W}_I}(\log(\mathrm{cusps}))$$

whose properties are described in the next theorem.

Theorem 5.2.1. *a) The connection ∇_k satisfies Griffith's transversality property with respect to the filtration i.e. $\nabla_k(\mathrm{Fil}_{k,i}) \subset \mathrm{Fil}_{k,i+1} \otimes_{\mathcal{O}_{\mathfrak{X}_{r,I}}} \Omega^1_{\mathfrak{X}_{r,I}/\mathfrak{W}_I}(\log)$, for all $i \geq 0$.*

b) If $\alpha \in \mathbb{Z}_{>0} \cap \mathfrak{W}_I(\mathbb{Q}_p, \mathbb{Z}_p)$ then the specialization at α of $\left(\mathbb{W}_k, \mathrm{Fil}_{k,\bullet}, \nabla_k\right)$, which we denote by $\left(\mathbb{W}_\alpha, \mathrm{Fil}_{\alpha,\bullet}, \nabla_\alpha\right)$, has $\left(\mathrm{Sym}^\alpha(\mathrm{H}_E), \mathrm{Fil}_{\alpha,\bullet}, \nabla_\alpha\right)$ as canonical submodule with filtration and connection. Moreover their global sections with slopes $h < \alpha - 1$ are equal (classicity).

For every Λ_I-valued weight k of $\mathfrak{W}_I$ the elements $\mathrm{H}^0(\mathfrak{X}_{r,I}, \mathbb{W}_k)$ have natural *q-expansions* (for details see Andreatta and Iovita [ibid.].)

Another very interesting occurrence is the fact that given a Λ_I-valued weight k of $\mathfrak{W}_I$ satisfying certain conditions (see below) the integral powers $(\nabla_k)^n$ of the connection ∇_k, for all $n \in \mathbb{Z}_{>0}$ (when we write $(\nabla_k)^n$ we really mean $\nabla_{k+2(n-1)} \circ \nabla_{k+2(n-2)} \circ \ldots \circ \nabla_k$) can be interpolated p-adically on $\mathrm{H}^0(\mathfrak{X}_{r,I}, \mathbb{W}_k)^{U_p=0}$ to the expense of possibly increasing r. More precisely we have (see Andreatta and Iovita [ibid.] for more details).

Theorem 5.2.2. *For every pair of weights γ, k in $\mathfrak{W}_I$ satisfying the assumptions Andreatta and Iovita [ibid.] Assumption 4.1 there is $b \geq r$ such that for every $w \in \mathrm{H}^0\left(\mathfrak{X}_{r,I}, \mathbb{W}_k\right)^{U_p=0}$ we have a unique section $\nabla^\gamma_k(w) \in \mathrm{H}^0(\mathfrak{X}_{b,I}, \mathbb{W}_{k+2\gamma})$ satisfying the property: if the q-expansion of w is $w(q) := \sum_{n=0}^\infty a_n q^n$ then the q-expansion of $\nabla^\gamma_k(w)$ is $\nabla^\gamma_k(w)(q) := \sum_{n=1,(p,n)=1}^\infty \gamma(n) a_n q^n$.*

5.3 The overconvergent projection. Finally, in view of the applications to the triple product p-adic L-functions which we have in mind, we define the "overconvergent projection" which is seen as a p-adic analogue of Shimura's "holomorphic projection".

Let us fix a Λ_I-valued weight k of $\mathfrak{W}_I$ and denote by $\mathbb{W}^\bullet_k$ the complex of sheaves $\mathbb{W}_k \xrightarrow{\nabla_k} \mathbb{W}_k \otimes_{\mathcal{O}_{\mathfrak{X}_{r,I}}} \Omega^1_{\mathfrak{X}_{r,I}/\mathfrak{W}_I}$ on $\mathfrak{X}_{r,I}$. We denote by $\mathrm{H}^i_{\mathrm{dR}}(\mathfrak{X}_{r,I}, \mathbb{W}^\bullet_k)$ for $i \geq 0$, the i-th hypercohomology group with values in the complex $\mathbb{W}^\bullet_k$.

We have natural actions of all the Hecke operators on these cohomology groups and remark that if $h \geq 0$ is a finite slope, we have natural slope decompositions for the action of the operator U_p of the groups $\mathrm{H}^i_{\mathrm{dR}}(\mathfrak{X}_{r,I}, \mathbb{W}_k^\bullet)$ and we denote by $\mathrm{H}^i_{\mathrm{dR}}(\mathfrak{X}_{r,I}, \mathbb{W}_k^\bullet)^{\leq h}$ the subgroup of slope less then or equal to h classes for the action of U_p (see Andreatta and Iovita [2017] section §3.8). If we denote by $\mathfrak{K}$ the total ring of fractions of Λ_I, we can describe the base change of $\mathrm{H}^1_{\mathrm{dR}}(\mathfrak{X}_{r,I}, \mathbb{W}_k^\bullet)^{\leq h}$ to $\mathfrak{K}$ as follows:

$$\mathrm{H}^1_{\mathrm{dR}}(\mathfrak{X}_{r,I}, \mathbb{W}_k^\bullet)^{\leq h} \otimes_{\Lambda_I[1/p]} \mathfrak{K} \cong \mathrm{H}^0(\mathfrak{X}_{r,I}, \omega_{r,I}^{k+2})^{\leq h} \otimes_{\Lambda_I[1/p]} \mathfrak{K}.$$

Therefore the "overconvergent projection" denoted $H^\dagger$ is the natural map obtained as the composition:

$$\mathrm{H}^0(\mathfrak{X}_{r,I}, \mathbb{W}_k)^{\leq h} \longrightarrow \mathrm{H}^1_{\mathrm{dR}}(\mathfrak{X}_{r,I}, \mathbb{W}_k^\bullet)^{\leq h} \otimes_{\Lambda_I[1/p]} \mathfrak{K} \cong \mathrm{H}^0(\mathfrak{X}_{r,I}, \omega_{r,I}^{k+2})^{\leq h} \otimes_{\Lambda[1/p]} \mathfrak{K}.$$

5.4 Application: the triple product p-adic L-function in the finite slope case. Let f, g, h be a triple of normalized primitive cuspidal classical eigenforms of weights k, ℓ, m, characters χ_f, χ_g, χ_h and tame levels N_f, N_g, N_h respectively. Write f^o, g^o, h^o for their images in $S_k(N), S_\ell(N), S_m(N)$ respectively as explained at the beginning of this section. We assume that f has finite slope a and that (k, ℓ, m) is unbalanced, i.e., there is an integer $t \geq 0$ such that $k - \ell - m = 2t$. We denote by K a finite extension of $\mathbb{Q}_p$ which contains all the values of χ_f, χ_g, χ_h. Let $\alpha_f, \alpha_g, \alpha_h$ denote overconvergent families of modular forms interpolating f^o, g^o, h^o in weights k, ℓ, m respectively. More precisely there are: a non-negative integer r, closed intervals I_f, I_g and I_h such that the weights of these families, denoted respectively $k_f : \mathbb{Z}_p^\times \to \Lambda_{I_f,K}^\times$, $k_g : \mathbb{Z}_p^\times \to \Lambda_{I_g,K}^\times$, $k_h : \mathbb{Z}_p^\times \to \Lambda_{I_h,K}^\times$ are all adapted to a certain integer $n \geq 0$. This data gives an adic space $\mathfrak{X}_{r,I} \longrightarrow \mathfrak{X}$, where I is a closed interval containing $I_f \times I_g \times I_h$.

We denote by $\omega^{k_f}, \omega^{k_g}, \omega^{k_h}$ the respective modular sheaves (over $\mathfrak{X}_{r,I}$), then $\alpha_f \in \mathrm{H}^0(\mathfrak{X}_{r,I_f}, \omega^{k_f})$, $\alpha_g \in \mathrm{H}^0(\mathfrak{X}_{r,I_g}, \omega^{k_g})$, $\alpha_h \in \mathrm{H}^0(\mathfrak{X}_{r,I_h}, \omega^{k_h})$. We make the following assumption on the weights of $\alpha_f, \alpha_g, \alpha_h$:

1) Suppose that the weights k_f, k_g, k_h are such that $k_f - k_g - k_h$ is even, i.e., there is a weight $u : \mathbb{Z}_p^\times \longrightarrow (\Lambda_{I,K})^\times$ with $2u = k_f - k_g - k_h$.

2) the weights k_g, u are each of the form: a finite order character multiplied a strongly analytic weight (see Andreatta and Iovita [ibid.]).

We see $\alpha_f, \alpha_g, \alpha_h$ as global sections of $\mathrm{Fil}_0(\mathbb{W}_{k_f}^{\mathrm{an}})$, $\mathrm{Fil}_0(\mathbb{W}_{k_g}^{\mathrm{an}})$ and $\mathrm{Fil}_0(\mathbb{W}_{k_h}^{\mathrm{an}})$ respectively. In particular we have that $(\nabla_{k_g})^u(\alpha_g^{[p]})$ makes sense and

$$(\nabla_{k_g})^u(\alpha_g^{[p]}) \in \mathrm{H}^0(\mathfrak{X}_{r',I}, \mathbb{W}_{k_g+2u}^{\mathrm{an}}),$$

for some positive integer $r' \geq r$. Therefore we have a section

$$(\nabla_{k_g})^u\big(\alpha_g^{[p]}\big) \times \alpha_h \in \mathrm{H}^0(\mathcal{X}_{r',I_u}, \mathbb{W}^{\mathrm{an}}_{k_f}).$$

Consider its class in $\mathrm{H}^1\big(\mathcal{X}_{r',I_u}, \omega^{k_f-2}\big) \otimes \mathfrak{K}_f$ via the natural projection and its overconvergent projection

$$H^\dagger\Big(\big(\nabla_{k_g})^u\big(\alpha_g^{[p]}\big) \times \alpha_h\Big) \in \mathrm{H}^0\big(\mathcal{X}_{r',I_u}, \omega^{k_f}\big) \otimes_{\Lambda_{I_f}} \mathfrak{K}_f,$$

to which we can apply the slope smaller or equal to a projector, $e^{\leq a}$:

$$e^{\leq a}\Big(H^\dagger\Big(\big(\nabla_{k_g})^u\big(\alpha_g^{[p]}\big) \times \alpha_h\Big)\Big) \in \mathrm{H}^0\big(\mathcal{X}_{r',I_u}, \omega^{k_f}\big)^{\leq a} \otimes_{\Lambda_{I_f}} \mathfrak{K}_f.$$

We are finally able to define the Garrett-Rankin triple product p-adic L-function attached to the triple $(\alpha_f, \alpha_g, \alpha_h)$ of p-adic families of modular forms, of which α_f has finite slope $\leq a$, to be:

$$\mathcal{L}_p^f(\alpha_f, \alpha_g, \alpha_h) := \frac{\Big\langle \alpha_f^*, e^{\leq a}\Big(H^\dagger\Big(\big(\nabla_{k_g})^u\big(\alpha_g^{[p]}\big) \times \alpha_h\Big)\Big)\Big\rangle}{\langle \alpha_f^*, \alpha_f^*\rangle} \in \mathfrak{K}_f \widehat{\otimes} \Lambda_{k_g,K} \widehat{\otimes} \Lambda_{k_h,K}.$$

By the definition of the overconvergent projection the p-adic L-function $\mathcal{L}_p^f(\alpha_f, \alpha_g, \alpha_h)$ has only finitely many poles, i.e., it is meromorphic.

Remark 5.4.1. The triple product p-adic L-function attached to a triple of **ordinary** families of modular forms has been defined in Darmon and Rotger [2014], using q-expansions.

Let now $x \in \mathcal{W}_{I_f}$, $y \in \mathcal{W}_{I_g}$, $z \in \mathcal{W}_{I_g}$ be a triple of unbalanced classical weights, i.e., such that $x, y, z \in \mathbb{Z}_{\geq 2}$ and such that there is $t \in \mathbb{Z}_{\geq 0}$ with $x - y - z = 2t$. Let us denote by f_x, g_y, h_z the specializations of $\alpha_f, \alpha_g, \alpha_h$ at x, y, z respectively, seen as sections over $\mathcal{X}_{r',I_u}$ of $\omega^x \subset \mathrm{Fil}_{x-2}(\mathbb{W}^{\mathrm{an}}_{x-2}) = \mathrm{Symm}^{x-2}(\mathrm{H}_E)$, $\omega^y \subset \mathrm{Fil}_{y-2}(\mathbb{W}^{\mathrm{an}}_{y-2}) = \mathrm{Symm}^{y-2}(\mathrm{H}_E)$, $\omega^z \subset \mathrm{Fil}_{z-2}(\mathbb{W}^{\mathrm{an}}_{z-2}) = \mathrm{Symm}^{z-2}(\mathrm{H}_E)$ respectively.

If we fix embeddings of $\overline{\mathbb{Q}}$ in $\mathbb{C}$ and $\mathbb{C}_p$ respectively, using the identifications between the p-adic overconvergent projection and the complex holomorphic one and between the Gauss-Manin connection and the Shimura-Maass differential operator on the one hand and the classical expressions of the special values of the complex triple product L-functions on the other, we obtain:

$$|\mathcal{L}_p^f(\alpha_f, \alpha_g, \alpha_h)(x, y, z)|_p = (\text{explicit constant}) \times \Big(\mathrm{L}^{\mathrm{alg}}(f_x, g_y, h_z, \frac{x+y+z-2}{2})\Big)^{\frac{1}{2}}.$$

In particular for $x = k, y = \ell, z = m$ we have $\mathcal{L}_p^f(\alpha_f, \alpha_g, \alpha_h)(k, \ell, m) \neq 0$ which implies that $\mathcal{L}_p^f(\alpha_f, \alpha_g, \alpha_h) \neq 0$.

6 Higher coherent cohomology

The purpose of this last section is to explain how the higher coherent cohomology of automorphic bundles enters the picture and how this is related to irregular motives. Let $K \subset \mathrm{GSp}_{2g}(\mathbb{A}_f)$ be a compact open subgroup. Let $X_K \to \operatorname{Spec} \mathbb{C}$ be a toroidal compactification of the Siegel variety of genus g and level K. For any classical weight $k = (k_1, \cdots, k_g)$, we can consider the cuspidal cohomology $\mathrm{H}^i(X_K, \omega^k(-D))$, as well as the usual cohomology $\mathrm{H}^i(X_K, \omega^k)$. They don't depend on the choice of the toroidal compactification. Let us define the interior coherent cohomology

$$\overline{\mathrm{H}}^i(X_K, \omega^k) = \mathrm{Im}(\mathrm{H}^i(X_K, \omega^k(-D)) \to \mathrm{H}^i(X_K, \omega^k))$$

Recall that $\lim_K \overline{\mathrm{H}}^i(X_K, \omega^k)$ is an admissible $\mathrm{GSp}_{2g}(\mathbb{A}_f)$-representation. We first recall the following result, saying that a generic weight has only cohomology in one degree.

Theorem 6.0.1 (Harris [1990], Li and Schwermer [2004], Lan [2016]). *There is an (explicit) constant C[6] which only depends on g such that if $(k = (k_1, \cdots, k_g))$ and:*

1. *$|k_i - k_{i+1}| \geq C$ for all $1 \leq i \leq g-1$,*
2. *$|k_i + k_j| \geq C$ for all $1 \leq i \leq j \leq g$*

then $\overline{\mathrm{H}}^\star(X_K, \omega^k)$ is concentrated in one degree.

Let us explain how one should think about this theorem. Identify $\mathbb{Z}^g$ with the space of characters of the maximal diagonal torus of the group Sp_{2g}. We make a choice of positive roots R^+ to be the union of the compact positive roots $R_c^+ = \{e_i - e_j\}_{1 \leq i < j \leq g}$ and non-compact positive roots $R_{nc}^+ = \{e_i + e_j\}_{1 \leq i \leq j \leq g}$.

We can associate to k the g-uple $\lambda = (\lambda_1, \cdots, \lambda_g) = (k_1 - 1, \cdots, k_g - g) = k + \rho_c - \rho_{nc} \in \mathbb{Z}^g$ where ρ_c is half the sum of the positive compact roots, and ρ_{nc} is half the sum of the positive non-compact roots. We see that k is dominant if and only if λ is R_c^+ regular: $\langle \lambda, \alpha \rangle > 0$ for all $\alpha \in R_c^+$.

The theorem above says that if k is such that λ is far enough from all the walls perpendicular to all the roots, then $\overline{\mathrm{H}}^\star(X, \omega^k)$ is concentrated in one single degree which can be determined as follows: let $C \subset \mathbb{Z}^g$ be the chamber defined by $\lambda_1 > \ldots > \lambda_g \geq 0$; the cohomological degree is the minimum of the length of the elements of the Weyl group $W_{Sp_{2g}} = (\mathbb{Z}/2\mathbb{Z})^g \rtimes S_g$ that take λ to an element of C. Let λ be far enough from the

[6] One can be more precise. For example, if $g = 1$, $\overline{\mathrm{H}}^\star(X_K, \omega^k)$ is concentrated in degree 0 if $k \geq 2$ and in degree 1 if $k \leq 0$. If $g = 2$, $\overline{\mathrm{H}}^i(X_K, \omega^k)$ is concentrated in degree 0 if $k_2 \geq 4$; degree 1 if $k_2 \leq 0$ and $k_1 + k_2 \geq 5$; degree 2 if $k_2 + k_1 \leq 1$ and $k_1 \geq 3$; degree 3 if $k_1 \leq -1$.

walls and let w be an element of the Weyl group of minimal length such that $w.\lambda \in C$. Although the Hecke modules $\overline{\mathrm{H}}^{\ell(w)}(X_K, \omega^{\lambda-\rho_c+\rho_{nc}})$ and $\overline{\mathrm{H}}^0(X_{\mathbb{C}}, \omega^{w.\lambda-\rho_c+\rho_{nc}})$ are rarely isomorphic (except for $g = 1$), they are closely related [7].

So from that perspective, a generic weight has cohomology in one single degree, and moreover, one can often reduce to degree 0 cohomology. In that sense, Theorem 3.1 is optimal as long as we want to work over the total weight space.

We'd now like to consider "singular" weights λ that lie on the walls $\langle\lambda, \alpha\rangle = 0$ for $\alpha \in R^+_{nc}$. The main reason is that the corresponding cohomology groups of weight $\lambda - \rho_c + \rho_n$ are conjecturally related to irregular motives. Moreover, they don't admit a Betti cohomology realization and can only be seen in the coherent cohomology. In one direction, one knows how to attach compatible systems of Galois representations to automorphic forms realized in the coherent cohomology [8] (Deligne and Serre [1974], Taylor [1991], Goldring [2014], Pilloni and Stroh [2016], Boxer [2015], Goldring and Koskivirta [2017]). The method is to establish congruences with automorphic forms which are holomorphic discrete series at infinity and whose Galois representations can (often) be constructed in the étale cohomology of a Shimura variety.

Example 1 (Limits of discrete series). Let π be an automorphic representation for the group $\mathrm{GSp}_{2g}/\mathbb{Q}$ for which π_∞ is a limit of discrete series with infinitesimal character λ lying on such non-compact wall. Then π_f is realized in $\lim_K \overline{\mathrm{H}}^i(X_K, \omega^{\lambda-\rho_c+\rho_{nc}})$. Moreover, it will often be realized (for instance if the associated parameter has trivial centralizer) in several consecutive degrees (the number of consecutive degrees is the number of non-compact roots $\alpha \in R^+_{nc}$ such that $\langle\lambda, \alpha\rangle = 0$). For the standard $2g+1$ dimensional representation of the L-group $\mathrm{GSp}^L_{2g} \to \mathrm{GL}_{2g+1}$, the associated compatible system has (conjectural) Hodge-Tate weights $(\lambda_1, -\lambda_1, \cdots, \lambda_g, -\lambda_g, 0)$. The simplest situation is $g = 1$, $\lambda = 0$, $k = 1$. There is an isomorphism of Hecke modules $\overline{\mathrm{H}}^0(X_K, \omega^1) = \overline{\mathrm{H}}^1(X_K, \omega^1)$ and $\lim_K \overline{\mathrm{H}}^i(X_K, \omega^1) = \oplus \pi_f$ where π_f runs over all admissible $\mathrm{GL}_2(\mathbb{A}_f)$-modules for which $\pi_\infty \otimes \pi_f$ is cuspidal automorphic for π_∞ the unique limit of discrete series of $\mathrm{GL}_2(\mathbb{R})$ [9]. For the tautological 2-dimensional representation of the L-group, the associated compatible system arises from an Artin motive (Deligne and Serre [1974]).

When $g = 1$ we have the following theorem (a particular case of Artin's conjecture):

[7] If λ is far enough from the walls, all the cohomology is represented by automorphic forms $\pi_\infty \otimes \pi_f$ which are discrete series at infinity. The L-packet corresponding to π_∞ contains a holomorphic discrete series π^h_∞. It the global Langlands parameter associated to π has trivial centralizer, then $\pi^h_\infty \otimes \pi_f$ is still automorphic and realized in the degree 0 cohomology

[8] For automorphic forms which are not holomorphic limits of discrete series, they are very "weak" compatible systems since they are not known to be de Rham.

[9] π is normalized by imposing that the central character of is $|.| \times \chi$ where χ is a finite character

Theorem 6.0.2 (Langlands [1980], Tunnell [1981], Buzzard, Dickinson, Shepherd-Barron, and Taylor [2001], Khare and Wintenberger [2009], Kisin [2009], Kassaei [2013], Kassaei, Sasaki, and Tian [2014], Pilloni and Stroh [2016], Calegari and Geraghty [2018]**).** *There is a bijective correspondence between isomorphism classes of continuous irreducible odd Galois representations* $\rho : G_{\mathbb{Q}} \to \mathrm{GL}_2(\mathbb{C})$ *and cuspidal automorphic forms* $\pi = \pi_\infty \otimes \pi_f$ *on* $\mathrm{GL}_2/\mathbb{Q}$ *such that* π_∞ *is a limit of discrete series. This bijection satisfies* $L(\rho, s) = L(\pi \otimes |\,|^{-\frac{1}{2}}, s)$.

Remark 6.0.3. The theorem holds also for totally odd irreducible two dimensional representations of the Galois group G_F of a totally real finite field extension F of $\mathbb{Q}$. Under mild technical hypothesis one can also prove that a representation $\rho : G_F \to \mathrm{GL}_2(\overline{\mathbb{Q}}_p)$ which is totally odd, irreducible and geometric with Hodge-Tate weights all equal to 0 is an Artin representation. See Pilloni and Stroh [2016].

The case $g = 2$ is also particularly interesting. Let $A \to \operatorname{Spec} \mathbb{Q}$ be a simple abelian surface and denote by $\mathrm{H}^1(A)$ the associated motive. For every prime p, we can define a Weil-Deligne representation $WD_p(\mathrm{H}^1(A)) : \mathrm{WD}_{\mathbb{Q}_p} \to \mathrm{GSp}_4(\mathbb{C})$. By Gan and Takeda [2011] there is a local L-packet $\Pi_p(A)$ whose Langlands parameter is $WD_p(\mathrm{H}^1(A)) \otimes |\,|^{\frac{3}{2}}$. This local L-packet contains at most two elements and exactly one generic element π_p^g. At the infinite place there is a local L-packet $\Pi_\infty(A)$ which consists of the two limits of discrete series (respectively holomorphic and generic) $\{\pi_\infty^h, \pi_\infty^g\}$ with infinitesimal character $\lambda = (1, 0)$[10]. We let $\Pi(A) = \prod_p \Pi_p(A) \times \Pi_\infty(A)$. The following is a particular example of Langlands's conjectures:

Conjecture 2. *The global L-packet* $\Pi(A)$ *contains a cuspidal automorphic form. As a consequence the complex L-function* $L(\mathrm{H}^1(A), s)$ *extends to an entire function over* $\mathbb{C}$ *and satisfies a functional equation as predicted in Serre [1970].*

Remark 6.0.4. 1) If $\mathrm{End}(A) \neq \mathbb{Z}$ (the GL_2-type case), the conjecture is known thanks to the works Khare and Wintenberger [2009], Kisin [2009] and Yoshida [1984].

2) $\pi_f = \otimes_p \pi_p \in \prod_p \Pi_p(A)$ is realized (with multiplicity one) in $\lim_K \overline{\mathrm{H}}^0(X_K, \omega^{(2,2)})$ provided $\pi_\infty^h \otimes \pi_f$ is automorphic, and in $\lim_K \overline{\mathrm{H}}^1(X_K, \omega^{(2,2)})$ provided $\pi_\infty^g \otimes \pi_f$ is automorphic.

3) The character formula of Labesse and Langlands [1979] describes which elements of $\Pi(A)$ should be cuspidal automorphic. If $\mathrm{End}(A) = \mathbb{Z}$, all elements of $\Pi(A)$ should be cuspidal automorphic. If $\mathrm{End}(A) \neq \mathbb{Z}$ an element $\pi_\infty \otimes \pi_p$ should be automorphic if and only if the number of non-generic representations occurring in the product is even. If $\mathrm{End}(A) = \mathbb{Z}$ we can choose the particular element of $\Pi(A)$ which is generic at all finite

[10] we normalize here $\{\pi^h, \pi^g\}$ by asking that the central character is $|\,|^2$ on the connected component of the center

places and π_∞^h at infinity. This representation has a unique line which is generated by a lowest weight vector at ∞ and is invariant under the paramodular group of a certain level $N(A)$ at all finite places. Therefore there should be a well determined (up to scalar) holomorphic weight $(2,2)$ cuspform of paramodular level $N(A)$ with rational Hecke eigenvalues attached to A. This is the paramodular conjecture of Brumer and Kramer [2014].

Theorem 6.0.2 and Conjecture 2 share high similarities: the Hodge-Tate weights of the motives considered have multiplicity two and the relevant automorphic forms contribute to two coherent cohomology degrees of the same automorphic sheaf. We will now explain how these singular weights behave in p-adic families: this appears to be a crucial tool in the proof of Theorem 6.0.2 and in the approaches to Conjecture 2.

6.1 Modular curves and weight one forms. We slightly change notations. Let p be a prime integer and $N \geq 3$ an integer prime to p. Let X be the modular curve of level $\Gamma_1(N)$ over Spec $\mathbb{Z}_p$ and X_{Iw} the modular curve of level $\Gamma_1(N) \cap \Gamma_0(p)$. We now examine the behaviour of p-adic families at weight one. We restrict ourselves to ordinary families because weight one modular forms of finite slope at p are necessarily ordinary.

Theorem 6.1.1 (Hida [1986]). *There is a finite projective $\Lambda = \mathbb{Z}_p[\![\mathbb{Z}_p^\times]\!]$-module M* [11] *such that for all $k \in \mathbb{Z}_{\geq 2}$,*

$$M \otimes_{\Lambda,k} \mathbb{Z}_p = \mathrm{ordH}^0(X_{\mathrm{Iw}}, \omega^k(-D)).$$

Here $\mathrm{ord} = \lim_n U_p^{n!}$ is the ordinary projector for U_p. There is a control theorem in weight 1, but it is more complicated to state. By construction of M, there is an injective map $\mathrm{H}^0(X_{Iw}, \omega(-D)) \to M \otimes_{\Lambda,1} \mathbb{Z}_p$. In order to state the classicity theorem in weight 1, we need to look at the Galois representation picture. For any $k \in \mathbb{Z}$, and any eigenform f in $M \otimes_{\Lambda,k} \overline{\mathbb{Z}}_p$, there is an associated two dimensional Galois representation ρ_f whose restriction to inertia at p is nearly ordinary (χ_p is the p-adic cyclotomic character):

$$\rho_f|_{I_{\mathbb{Q}_p}} \simeq \begin{pmatrix} 1 & \star \\ 0 & \chi_p^{1-k} \end{pmatrix}$$

If $k \geq 2$ the representation ρ_f is automatically de Rham which is consistent with the control theorem. If $k = 1$, the representation is de Rham if and only if it is unramified at p and the classicity theorem in weight 1 states:

Theorem 6.1.2 (Buzzard and Taylor [1999], Pilloni and Stroh [2016]). *An eigenclass $f \in M \otimes_{\Lambda,1} \overline{\mathbb{Z}}_p$ is classical if and only if the associated Galois representation is unramified at p.*

[11] Moreover, M carries an action of the Hecke algebra and the control isomorphism is Hecke equivariant.

This classicity theorem is one of the key steps towards the proof of Theorem 6.0.2 via the strategy envisionned in Buzzard and Taylor [1999][12]: establish a congruence between an icoashedral artin representation and a modular elliptic curve modulo 5, and prove a modular lifting theorem. There is a difficulty to prove a modular lifting theorem with weight one forms because congruences are obstructed (since $\mathrm{H}^1(X, \omega) \neq 0$) and the usual Taylor-Wiles method doesn't apply. The strategy is to prove the modular lifting theorem with the module of ordinary p-adic modular forms of weight one instead (that is the module $M \otimes_{\Lambda,1} \mathbb{Z}_p$, for which the usual Taylor-Wiles method applies) and then argue via this classicity theorem. In order to obtain a full proof of Theorem 6.0.2, it is necessary to combine this strategy with solvable base change, and therefore one needs an extension of theorem Theorem 6.1.2 over totally real fields (Pilloni and Stroh [2016]). Observe that Theorem 6.0.2 was first proved in full generality as a consequence of Serre's modularity conjecture. Calegari and Geraghty [2018] found a way to modify the Taylor-Wiles method in order to apply it directly to weight one forms, therefore eliminating the use of Theorem 6.1.2. This method is very promising but as its application depends on certain conjectural inputs it has not yet given a complete new proof of Theorem 6.0.2.

6.2 The group GSp_4 and potentially modular abelian surfaces. We now let $X \to \operatorname{Spec} \mathbb{Z}_p$ be the Siegel threefold of hyperspecial level at p (and some fixed level away from p). We let $X_{\mathrm{Iw}} \to X_{\mathrm{Kli}} \to X$ be the Siegel threefolds of Iwahori and Klingen level at p. As we have seen, for all weights $k = (k_1, k_2)$ with $k_1 \geq k_2$, we have an automorphic vector bundle ω^k. The tempered part (at infinity) of the cohomology $\overline{\mathrm{H}}^{\star}(X_{\mathbb{C}}, \omega^{(k_1,k_2)})$ is concentrated in degree 0 if $k_2 \geq 3$ while there is cohomology in degree 0 and 1 if $k_2 = 2$. The situation resembles that of modular curves and weight one forms, except that there are now infinitely many singular weights: all those of the form $(k, 2)$ for $k \geq 2$.

Let $\Lambda_1 = \mathbb{Z}_p[\![\mathbb{Z}_p^\times]\!]$ and $\Lambda_2 = \mathbb{Z}_p[\![(\mathbb{Z}_p^\times)^2]\!]$. We first state the main theorem of classical Hida theory:

Theorem 6.2.1 (Hida [1986], Pilloni [2011]). *There exists a finite projective Λ_2-module M such that for (k_1, k_2) with $k_1 \geq k_2 \geq 4$*

$$M \otimes_{\Lambda_2,(k_1,k_2)} \mathbb{Z}_p = \mathrm{ordH}^0(X_{\mathrm{Iw}}, \omega^{(k_1,k_2)}(-D))$$

Here ord is the ordinary projector for the operator $U_{p,1}U_{p,2}$. The bound $k_2 \geq 4$ is an accident and the expected optimal bound is $k_2 \geq 3$. It is instructive to look at the Galois representation picture. For all eigenclasses $f \in M \otimes_{\Lambda_2,(k_1,k_2)} \overline{\mathbb{Z}}_p$ there is an associated nearly ordinary Galois representation $\rho_f : G_{\mathbb{Q}} \to \mathrm{GSp}_4(\overline{\mathbb{Q}}_p)$ such that:

[12] Granting the fact that it is known in the solvable image case by automorphic methods

$$\rho_f|_{I_{\mathbb{Q}_p}} \simeq \begin{pmatrix} 1 & \star & \star & \star \\ 0 & \chi_p^{-k_2+2} & \star & \star \\ 0 & 0 & \chi_p^{-k_1+1} & \star \\ 0 & 0 & 0 & \chi_p^{-k_1-k_2+3} \end{pmatrix}$$

Such a representation is automatically geometric if $k_1 \geq k_2 \geq 3$. It is tempting to believe that an eigenclass of weight $k_1 \geq k_2 = 2$ is classical if and only if

$$\rho_f|_{I_{\mathbb{Q}_p}} \simeq \begin{pmatrix} 1 & 0 & \star & \star \\ 0 & 1 & \star & \star \\ 0 & 0 & \chi_p^{-k_1+1} & 0 \\ 0 & 0 & 0 & \chi_p^{-k_1+1} \end{pmatrix}$$

(the analogue of Theorem 6.1.2). The techniques of Theorem 6.1.2 which crucially depend on the explicit relation between q-expansion and Hecke eigenvalues don't appear to generalize to this case. In particular, it seems impossible to generalize the strategy of Buzzard and Taylor [1999] to Conjecture 2.

We now state the main theorem of Higher Hida theory which deals with the singular weights:

Theorem 6.2.2 (Pilloni [2017]). *There exists a perfect complex $M^\bullet$*[13] *of Λ_1-modules of amplitude $[0,1]$ such that for all $k \in \mathbb{Z}_{\geq 2}$:*

$$M^\bullet \otimes^L_{(k,2)} \mathbb{Q}_p = \mathrm{ord}' \mathrm{R}\Gamma\big(X_{\mathrm{Kli}}, \omega^{(k,2)}(-D) \otimes \mathbb{Q}_p\big).$$

Here ord' is the ordinary projector for the operator $U_{p,1}$. The control theorem is sharp. Let us explain briefly the construction of $M^\bullet$. Let $X \to \operatorname{Spec} \mathbb{Z}_p$ be the Siegel threefold of level prime to p. We let $\mathfrak{X}$ be the p-adic completion of X and denote by $\mathfrak{X}^{\geq i}$ the p-rank stratification on $\mathfrak{X}$. As we have seen in Section 3, over the ordinary locus $\mathfrak{X}^{\geq 2}$ we have a multiplicative subgroup of rank 2 of $G[p^\infty]$ which provides the extra structure on ω_G allowing for the interpolation property. Over $\mathfrak{X}^{\geq 1}$ there is still an extra structure as we can choose a multiplicative Barsotti-Tate group of height 1, $H_\infty \hookrightarrow G[p^\infty]$ and for such a choice we have an exact sequence

$$0 \to \omega_{G[p^\infty]/H_\infty} \to \omega_{G[p^\infty]} \to \omega_{H^\infty} \to 0$$

and the Hodge-Tate map realizes an isomorphism $T_p(H_\infty^D) \otimes \mathcal{O}_{\mathfrak{X}^{\geq 1}(p^\infty)} \to \omega_{H_\infty}$. Thus, we end up with half the extra structure we had over the ordinary locus and, this allows the interpolation of the automorphic sheaves in one direction. It is quite important to work

[13] $M^\bullet$ carries an action of the Hecke algebra and the control theorem is Hecke equivariant

over this larger base since $\mathfrak{X}^{\geq 1}$ is morally of cohomological dimension 1, while $\mathfrak{X}^{\geq 2}$ is of cohomological dimension 0[14].

The projective module M is obtained by considering the (degree 0) ordinary cohomology of an interpolation sheaf over $\mathfrak{X}^{\geq 2}$ as explained in Section 3, while the complex $M^\bullet$ is obtained by considering the ordinary cohomology of an other interpolation sheaf, whose weight is parametrized by Λ_1 over $\mathfrak{X}^{\geq 1}$.

The cohomology $M^\bullet \otimes^L_{\Lambda_1,2} \mathbb{Z}_p$ is an integral modification of $\mathrm{ord}'\mathrm{R}\Gamma\big(X_{\mathrm{Kli}}, \omega^{(2,2)}(-D)\big)$. One important property of $M^\bullet$ is that it is concentrated in two degrees, while this is not known to hold for $\mathrm{R}\Gamma\big(X, \omega^{(2,2)}(-D)\big)$. In Boxer, Calegari, Gee, and Pilloni [2018] we manage to study the Galois representation supported by $M^\bullet$ and prove under some technical assumptions that it is ordinary. As a corollary, $M^\bullet \otimes^L_{\Lambda_1,2} \mathbb{Z}_p$ can be used to construct modified Taylor-Wiles systems in the sense of Calegari and Geraghty [2018]. It is an important ingredient in the proof of the following theorem:

Theorem 6.2.3 (Boxer, Calegari, Gee, and Pilloni [2018])**.** *Let $A/\mathbb{Q}$ be an abelian surface. Then there is a finite field extension F of $\mathbb{Q}$ such that $\mathrm{H}^1(A|_F)$ is automorphic. In particular $L(\mathrm{H}^1(A), s)$ has a meromorphic continuation to $\mathbb{C}$.*

The theorem holds also when $\mathbb{Q}$ is replaced by a totally real field.

PERFECTOID SPACES AND THE HOMOLOGICAL CONJECTURES

Yves André

Abstract

This is a survey of recent advances in commutative algebra, especially in mixed characteristic, obtained by using the theory of perfectoid spaces. An explanation of these techniques and a short account of the author's proof of the direct summand conjecture are included. One then portrays the progresses made with these (and related) techniques on the so-called homological conjectures.

1 The direct summand conjecture

Let R be a Noetherian (commutative) ring and S a finite ring extension, and let us consider the exact sequence of finitely generated R-modules

$$0 \to R \to S \to S/R \to 0. \tag{1-1}$$

When does this sequence split? Equivalently, when is $R \to S$ *pure*, *i.e.* remains injective after any base change? This holds for instance when $R \to S$ is flat, or when R is a normal $\mathbb{Q}$-algebra, but not in general (the embedding of $\mathbb{Q}[x, y]/(xy)$ in its normal closure gives a counter-example, since it is no longer an embedding modulo $x + y$).

The direct summand conjecture, formulated by M. Hochster around 1969, claims that (1-1) splits whenever R is regular. Hochster proved it when R contains a field Hochster [1973]. R. Heitmann proved it in dimension ≤ 3 R. C. Heitmann [2002].

Recently, the author proved it in general André [2016a]:

1.0.1 Theorem. (1-1) *splits if R is regular.*

This has many (non trivially) equivalent forms. One of them is that *every ideal of a regular ring R is contracted from every finite (or integral) extension of R*. Another (more

MSC2010: primary 13D22; secondary 13H05, 14G20.
Keywords: homological conjectures, big Cohen–Macaulay algebra, perfectoid algebra, purity.

indirect) equivalent form is the following statement, which settles a question raised by L. Gruson and M. Raynaud Raynaud and Gruson [1971, p. 1.4.3][1]:

1.0.2 Theorem. *Any integral extension of a Noetherian ring descends flatness of modules.*

We will see one more equivalent form below in the framework of the so-called homological conjectures (4.2).

2 The role of perfectoid spaces

2.1 Some heuristics. After Hochster's work Hochster [1983], it is enough to prove the direct summand conjecture in the case when R is a complete unramified local regular ring of mixed characteristic $(0, p)$ and perfect residue field k. By Cohen's structure theorem, one may thus assume $R = W(k)[[x_1, \dots, x_n]]$.

In characteristic p, all proofs of the direct summand conjecture use the Frobenius endomorphism F in some way. In mixed characteristic, $R = W(k)[[x_1, \dots, x_n]]$ carries a Frobenius-like endomorphism (acting as the canonical automorphism of $W(k)$ and sending x_i to x_i^p), which however does not extend to general finite extensions S of R. To remedy this, p-adic Hodge theory suggests to "ramify deeply", by adjoining iterated p^{th} roots of $p, x_1, \dots, x_n$. Doing this, one leaves the familiar shore of Noetherian commutative algebra for perfectoid geometry, recently introduced by P. Scholze [2012].

To begin with, $W(k)$ is replaced by the non-Noetherian complete valuation ring $\mathcal{K}^o := \widehat{W(k)[p^{\frac{1}{p^\infty}}]}$. The valuation ring $\mathcal{L}^o$ of any finite extension $\mathcal{L}$ of the field $\mathcal{K}[\frac{1}{p}]$ satisfies:
(2-1)

$$F : \mathcal{L}^o/p \overset{x \mapsto x^p}{\to} \mathcal{L}^o/p \;\; \textit{is surjective, and } \mathcal{L}^o \textit{ is } p^{\frac{1}{p^\infty}}\textit{-almost finite etale over } \mathcal{K}^o,$$

this being understood in the context of almost ring theory, introduced by G. Faltings and developped by Gabber and Ramero [2003], which gives precise meaning to "up to $p^{\frac{1}{p^\infty}}$-torsion"; for instance, $p^{\frac{1}{p^\infty}}$-almost etaleness means that $p^{\frac{1}{p^\infty}}\Omega_{\mathcal{L}^o/\mathcal{K}^o} = 0$. Actually, Gabber and Ramero [ibid.] is much more general: it deals with modules over a commutative ring up to $\mathfrak{k}$-torsion, for some idempotent ideal $\mathfrak{k}$. Going beyond the case of a valuation ideal $\mathfrak{k}$ will be crucial: beside "$p^{\frac{1}{p^\infty}}$-almost" modules, we will have to consider "$(pg)^{\frac{1}{p^\infty}}$-almost" modules for some "geometric" discriminant g.

[1] *cf.* Ohi [1996] for the equivalence. Gruson and Raynaud settled the case of a finite extension and outlined that the transition to integral extensions is not a routine exercise.

2.2 Perfectoid notions. In perfectoid geometry, one works with certain Banach[2] $\mathcal{K}$-algebras $\mathfrak{A}$. One denotes by $\mathfrak{A}^o$ the $\mathcal{K}^o$-subalgebra of power-bounded elements. One says that $\mathfrak{A}$ is *uniform* if $\mathfrak{A}^o$ is bounded, and that $\mathfrak{A}$ is *perfectoid* if it is uniform and $F : \mathfrak{A}^o/p \overset{x\mapsto x^p}{\to} \mathfrak{A}^o/p$ is surjective. An example which plays a crucial role in the sequel is $\hat{\cup}_i W(k)[p^{\frac{1}{p^i}}][[x_1^{\frac{1}{p^i}}, \dots, x_n^{\frac{1}{p^i}}]][\frac{1}{p}]$, a deeply ramified avatar of R. Morphisms of perfectoid algebras $\mathfrak{A} \to \mathfrak{B}$ are continuous algebra homomorphisms (one then says that $\mathfrak{B}$ is a perfectoid $\mathfrak{A}$-algebra).

Perfectoid algebras enjoy three fundamental stability properties Scholze [2012]:

2.2.1 ***Tensor product.*** *If $\mathfrak{B}$ and $\mathfrak{C}$ are perfectoid $\mathfrak{A}$-algebras, so is $\mathfrak{B}\hat{\otimes}_{\mathfrak{A}}\mathfrak{C}$, and $(\mathfrak{B}\hat{\otimes}_{\mathfrak{A}}\mathfrak{C})^o$ is $p^{\frac{1}{p^\infty}}$-almost isomorphic to $\mathfrak{B}^o\hat{\otimes}_{\mathfrak{A}^o}\mathfrak{C}^o$.*

2.2.2 ***Localization.*** *The ring of functions $\mathfrak{A}\{\frac{f}{g}\}$ on the subset of the perfectoid space* $\mathrm{Spa}(\mathfrak{A}, \mathfrak{A}^o)$ *where $|f| \le |g|$ holds is perfectoid, and $\mathfrak{A}\{\frac{f}{g}\}^o$ is $p^{\frac{1}{p^\infty}}$-almost isomorphic to $\mathfrak{A}^o\langle(\frac{f'}{g'})^{\frac{1}{p^\infty}}\rangle$ for some approximations f', g' of f, g which admit iterated p^{th}-roots in $\mathfrak{A}$.*

2.2.3 ***Finite etale extension.*** *Any finite etale extension $\mathfrak{B}$ of $\mathfrak{A}$ is perfectoid, and $\mathfrak{B}^o$ is a $p^{\frac{1}{p^\infty}}$-almost finite etale extension of $\mathfrak{A}^o$.*

This generalization of 2-1 to perfectoid algebras is Faltings's "almost purity theorem" Faltings [2002] as revisited by Scholze [2012] and Kedlaya and Liu [2015].

Let us explain how the second assertion of 2.2.3 follows from the first following André [2016b, p. 3.4.2]. The idea is to reduce to the case when $\mathfrak{B}$ is Galois over $\mathfrak{A}$ with Galois group G, *i.e.* $\mathfrak{B}^G = \mathfrak{A}$ and $\mathfrak{B} \otimes_{\mathfrak{A}} \mathfrak{B} \overset{\sim}{\to} \prod_G \mathfrak{B}$. This implies $\mathfrak{B}^{oG} = \mathfrak{A}^o$. On the other hand, since $\mathfrak{B}$ is a finitely generated projective $\mathfrak{A}$-module, $\mathfrak{B} \otimes_{\mathfrak{A}} \mathfrak{B} = \mathfrak{B}\hat{\otimes}_{\mathfrak{A}}\mathfrak{B}$, and one deduces from 2.2.1 (assuming $\mathfrak{B}$ perfectoid) that $\mathfrak{B}^o\hat{\otimes}_{\mathfrak{A}^o}\mathfrak{B}^o \to \prod_G \mathfrak{B}^o$ is a $p^{\frac{1}{p^\infty}}$-almost isomorphism. To get rid of the completion, one passes modulo p^m: $\mathfrak{B}^o/p^m$ is almost Galois over $\mathfrak{A}^o/p^m$, hence almost finite etale, and a variant of Grothendieck's "équivalence remarquable" Gabber and Ramero [2003, p. 5.3.27] allows to conclude that $\mathfrak{B}^o$ it itself almost finite etale over $\mathfrak{A}^o$.

2.3 Direct summand conjecture: the case when $S[\frac{1}{p}]$ is etale over $R[\frac{1}{p}]$. Let us go back to the direct summand conjecture for $R = W(k)[[x_1, \dots, x_n]]$. The special case

[2]here and in the sequel, one can work with any perfectoid field $\mathcal{K}$ (of mixed char. $(0, p)$), - *i.e.* complete, non-discretely valued, and such that F is surjective on $\mathcal{K}^o/p$. An extensive dictionary between the langage of commutative algebra and the language of non-archimedean functional analysis is presented in André [2016b, p. 2.3.1].

when $S[\frac{1}{p}]$ is etale over $R[\frac{1}{p}]$ was settled by B. Bhatt [2014] and by K. Shimomoto [2016], using 2.2.3. Here is a slightly different account, suitable to the sequel.

Let us consider the perfectoid algebra $\mathfrak{A} = \hat{\cup}_i W(k)[p^{\frac{1}{p^i}}][[x_1^{\frac{1}{p^i}}, \dots, x_n^{\frac{1}{p^i}}]][\frac{1}{p}]$ and notice that $\mathfrak{A}^o = \hat{\cup}_i W(k)[p^{\frac{1}{p^i}}][[x_1^{\frac{1}{p^i}}, \dots, x_n^{\frac{1}{p^i}}]]$ is a faithfully flat extension of R. By assumption $\mathfrak{B} := S \otimes_R \mathfrak{A}$ is finite etale over $\mathfrak{A}$, hence by 2.2.3, $\mathfrak{B}^o$ is $p^{\frac{1}{p^\infty}}$-almost finite etale, hence almost pure (in the sense: almost universally injective) over $\mathfrak{A}^o$. A fortiori, (1-1) almost splits after tensoring with $\mathfrak{A}^o$. In other words, if $e \in \mathrm{Ext}^1_R(S/R, R)$ denotes the class corresponding to (1-1), then $p^{\frac{1}{p^\infty}}(e \otimes 1) = 0$ in $\mathrm{Ext}^1_R(S/R, R) \otimes_R \mathfrak{A}^o \cong \mathrm{Ext}^1_{\mathfrak{A}^o}((S \otimes_R \mathfrak{A}^o)/\mathfrak{A}^o, \mathfrak{A}^o)$. One concludes that $e = 0$ by the following general elementary lemma (applied to $M = Re$ and $\mathfrak{K} = p^{\frac{1}{p^\infty}}\mathfrak{A}^o$):

2.3.1 Lemma. *André [2016a, p. 1.1.2] Let R be a local Noetherian ring, M a finitely generated R-module, A a faithfully flat R-algebra. Let $\mathfrak{K}$ be an idempotent ideal of A such that $\mathfrak{K}.M_A = 0$ and $R \cap \mathfrak{K} \neq 0$. Then $M = 0$.*

2.4 The perfectoid Abhyankar lemma. In the general case, $S \otimes_R \mathfrak{A}$ is no longer etale over $\mathfrak{A}$: one must take into account a discriminant $g \in R$ of $S[\frac{1}{p}]$ over $R[\frac{1}{p}]$. This suggests to try to generalize 2.2.3 to *ramified* extensions of perfectoid algebras. It turns out that this is possible, provided one extracts suitable roots of g in the spirit of Abhyankar's lemma.

This leads to replace everywhere "$p^{\frac{1}{p^\infty}}$-almost" by "$(pg)^{\frac{1}{p^\infty}}$-almost", thereby extending the basic setting of almost ring theory beyond the usual situation of a non-discrete valuation ring. This also leads to introduce the notion of *almost perfectoid algebra*, where $F : \mathfrak{A}^o/p \overset{x\mapsto x^p}{\to} \mathfrak{A}^o/p$ is only assumed to be $(pg)^{\frac{1}{p^\infty}}$-almost surjective André [2016b, p. 3.5.4].

2.4.1 Theorem. *André [ibid.] Let $\mathfrak{A}$ be a perfectoid $\mathfrak{K}$-algebra, which contains a compatible system of p-power roots $g^{\frac{1}{p^j}}$ of some non-zero-divisor $g \in \mathfrak{A}^o$. Let $\mathfrak{B}'$ be a finite etale $\mathfrak{A}[\frac{1}{g}]$-algebra. Let $\mathfrak{B}$ be the integral closure of $g^{-\frac{1}{p^\infty}}\mathfrak{A}$ in $\mathfrak{B}'$, so that $\mathfrak{B}[\frac{1}{g}] = \mathfrak{B}'$.*

Then $\mathfrak{B}$ is almost perfectoid, and for any n, $\mathfrak{B}^o/p^m$ is $(pg)^{\frac{1}{p^\infty}}$-almost finite etale (hence $(pg)^{\frac{1}{p^\infty}}$-almost flat) over $\mathfrak{A}^o/p^m$.

(If $g = 1$, one may use Gabber and Ramero [2003, p. 5.3.27] again to conclude that $\mathfrak{B}^o$ is itself almost finite etale over $\mathfrak{A}^o$ and recover 2.2.3).

The basic idea is to look at the pro-system of algebras of functions $\mathfrak{A}^j := \mathfrak{A}\{\frac{p^j}{g}\}$ on complements of tubular neighborhoods of the hypersurface $g = 0$ in the perfectoid space $\mathrm{Spa}(\mathfrak{A}, \mathfrak{A}^o)$, *resp.* at the pro-system $\mathfrak{B}^j := \mathfrak{B}' \otimes_{\mathfrak{A}[\frac{1}{g}]} \mathfrak{A}\{\frac{p^j}{g}\}$. Each $\mathfrak{A}^j$ is perfectoid

(2.2.2), and each $\mathfrak{B}^j$ is finite etale over $\mathfrak{A}^j$, hence perfectoid; moreover $\mathfrak{B}^{jo}$ is $p^{\frac{1}{p^\infty}}$-almost finite etale over $\mathfrak{A}^{jo}$ by almost purity (2.2.3). One can show that $\mathfrak{B}^o$ is isomorphic to $\lim \mathfrak{B}^{jo}$, and that the latter has the asserted properties,

However, in the sequel, the identification of $(\lim \mathfrak{B}^{jo})[\frac{1}{p}]$ with the integral closure of $g^{-\frac{1}{p^\infty}}\mathfrak{A}$ in $\mathfrak{B}'$ plays no role; changing notation, we will set $\mathfrak{B} := (\lim \mathfrak{B}^{jo})[\frac{1}{p}]$, which is a uniform Banach algebra, and sktech the *proof that $\mathfrak{B}$ is almost perfectoid and that for every m, $\mathfrak{B}^o/p^m$ is $(pg)^{\frac{1}{p^\infty}}$-almost finite etale over $\mathfrak{A}^o/p^m$.*

The proof involves six steps.

1) For any $r \in \mathbb{N}[\frac{1}{p}]$, *$\lim(\mathfrak{A}^{jo}/p^r)$ is $(pg)^{\frac{1}{p^\infty}}$-almost isomorphic to $\mathfrak{A}^o/p^r$.* This is essentially Scholze's perfectoid version of Riemann's extension theorem Scholze [2015, p. II.3.1] (hint: if R denotes $\mathfrak{A}^o/p^r$ for short, $\mathfrak{A}^{jo}/p^r$ is $p^{\frac{1}{p^\infty}}$-almost isomorphic to $R^j := R[(\frac{p^j}{g})^{\frac{1}{p^\infty}}]$; the key idea is that for $j' \geq j + rp^k$, $R^{j'} \to R^j$ factors through $R^{jk} := \sum_{s\leq \frac{1}{p^k}} R(\frac{p^j}{g})^s$, so that $\lim R^j \cong \lim R^{jk}$; on the other hand, the kernel and cokernel of $R \to R^{jk}$ are killed by g raised to a power which tends to 0 when $j,k \to \infty$). Passing to the limit $r \to \infty$, it follows that $\lim \mathfrak{A}^{jo} = g^{-\frac{1}{p^\infty}}\mathfrak{A}$, and this also holds under the weaker assumption that $\mathfrak{A}$ is almost perfectoid, *cf.* André [2016b, p. 4.2.2].

2) *$\lim^1(\mathfrak{B}^{jo}/p^r)$ is $(pg)^{\frac{1}{p^\infty}}$-almost zero.* The technique is similar to the one in 1), *cf.* André [ibid., p. 4.4.1].

3) *$\lim(\mathfrak{B}^{jo}/p) \xrightarrow{F} \lim(\mathfrak{B}^{jo}/p)$ is $(pg)^{\frac{1}{p^\infty}}$-almost surjective.* Indeed, taking the limit of the exact sequence $0 \to \mathfrak{B}^{jo}/p^{\frac{p-1}{p}} \to \mathfrak{B}^{jo}/p \to \mathfrak{B}^{jo}/p^{\frac{1}{p}} \to 0$, one deduces from 2) (for $r = \frac{p-1}{p}$), that $\lim(\mathfrak{B}^{jo}/p) \to \lim(\mathfrak{B}^{jo}/p^{\frac{1}{p}})$ is $(pg)^{\frac{1}{p^\infty}}$-almost surjective; on the other hand, $\mathfrak{B}^{jo}/p^{\frac{1}{p}} \to \mathfrak{B}^{jo}/p$ is an isomorphism because $\mathfrak{B}^j$ is perfectoid.

4) *$\mathfrak{B}$ is almost perfectoid.* From 3), it suffices to show that the natural map $\mathfrak{B}^o/p = (\lim \mathfrak{B}^{jo})/p \to \lim(\mathfrak{B}^{jo}/p)$ is a $(pg)^{\frac{1}{p^\infty}}$-almost isomorphism. It is easy to see that it is injective André [ibid., p. 2.8.1], and on the other hand, the composition $\lim_{F,j}(\mathfrak{B}^{jo}/p) = \mathfrak{B}^{\flat o} \to (\lim \mathfrak{B}^{jo})/p \to \lim(\mathfrak{B}^{jo}/p)$ is almost surjective by 3).

5) *$\mathfrak{B} \to \mathfrak{B}^j$ factors through a $g^{\frac{1}{p^\infty}}$-almost isomorphism $\mathfrak{B}\{\frac{p^j}{g}\} \overset{a}{\cong} \mathfrak{B}^j$.* The factorization comes from the fact that $\mathfrak{B}^j \cong \mathfrak{B}^j\{\frac{p^j}{g}\}$, and one constructs an almost inverse to $\mathfrak{B}\{\frac{p^j}{g}\} \overset{a}{\to} \mathfrak{B}^j$ as follows (*cf.* André [ibid., p. 4.4.4]): the integral closure of $\mathfrak{A}^o$ in $\mathfrak{B}'$ maps to the integral closure $\mathfrak{A}^{jo}$ in $\mathfrak{B}^j$, which is $p^{\frac{1}{p^\infty}}$-almost $\mathfrak{B}^{jo}$ (by almost purity). Passing to the limit and inverting pg, one gets a morphism $\mathfrak{B}' \xrightarrow{\delta} \mathfrak{B}[\frac{1}{g}]$, and the sought for inverse is induced by $\delta \otimes 1_{\mathfrak{A}^j}$.

6) *for every m, $\mathfrak{B}^o/p^m$ is $(pg)^{\frac{1}{p^\infty}}$-almost finite etale over $\mathfrak{A}^o/p^m$.* This is the decisive step: how to keep track of the almost finite etaleness of $\mathfrak{B}^{jo}$ over $\mathfrak{A}^{jo}$ at the limit? As in 2.2.3, the idea is to reduce to the case when $\mathfrak{B}'$ is Galois over $\mathfrak{A}[\frac{1}{g}]$ with Galois group G, *i.e.* $(\mathfrak{B}')^G =$

$\mathfrak{A}[\frac{1}{g}]$ and $\mathfrak{B}' \otimes_{\mathfrak{A}[\frac{1}{g}]} \mathfrak{B}' \xrightarrow{\sim} \prod_G \mathfrak{B}'$. It follows that $\mathfrak{B}^j$ is G-Galois over $\mathfrak{A}^j$, and (as in 2.2.3) that $\mathfrak{B}^{jo} \hat{\otimes}_{\mathfrak{A}^{jo}} \mathfrak{B}^{jo} \to \prod_G \mathfrak{B}^{jo}$ is a $p^{\frac{1}{p^\infty}}$-almost isomorphism. Passing to the limit, (and taking into account that by 4) and 5), $\mathfrak{B} \hat{\otimes}_{\mathfrak{A}} \mathfrak{B}$ is an almost perfectoid algebra, and $\mathfrak{B} \hat{\otimes}_{\mathfrak{A}} \mathfrak{B}\{\frac{p^j}{g}\} \cong \mathfrak{B}^j \hat{\otimes}_{\mathfrak{A}^j} \mathfrak{B}^j$, so that one can apply 1)), one concludes that $\mathfrak{A}^o \to \mathfrak{B}^{oG}$ and $\mathfrak{B}^o \hat{\otimes}_{\mathfrak{A}^o} \mathfrak{B}^o \to \prod_G \mathfrak{B}^o$ are $(pg)^{\frac{1}{p^\infty}}$-almost isomorphisms. To get rid of the completion, one passes modulo p^m: $\mathfrak{B}^o/p^m$ is almost Galois over $\mathfrak{A}^o/p^m$, hence $(pg)^{\frac{1}{p^\infty}}$-almost finite etale (in constrast to 2.2.3, one cannot conclude that $\mathfrak{B}^o$ is $(pg)^{\frac{1}{p^\infty}}$-almost finite etale over $\mathfrak{A}^o$ since p may not belong to $(pg)^{\frac{1}{p^\infty}}$). □

2.5 Infinite Kummer extensions. In order to extend the strategy of 2.3 to the general case by means of the perfectoid Abhyankar lemma, one has first to adjoin to the perfectoid algebra $\hat{\cup}_i W(k)[p^{\frac{1}{p^i}}][[x_1^{\frac{1}{p^i}}, \ldots, x_n^{\frac{1}{p^i}}]][\frac{1}{p}]$ the iterated p^{th}-roots of a discriminant g. At finite level i, it seems very difficult to control the extension

$$(W(k)[p^{\frac{1}{p^i}}][[x_1^{\frac{1}{p^i}}, \ldots, x_n^{\frac{1}{p^i}}]][g^{\frac{1}{p^i}}, \frac{1}{p}])^o$$

which is bigger than $W(k)[p^{\frac{1}{p^i}}][[x_1^{\frac{1}{p^i}}, \ldots, x_n^{\frac{1}{p^i}}]][g^{\frac{1}{p^i}}]$, but things turn easier at the infinite level, thanks to the perfectoid theory.

2.5.1 Theorem. *André [2016a, p. 2.5.2] Let $\mathfrak{A}$ be a perfectoid $\mathcal{K}$-algebra, and let $g \in \mathfrak{A}^o$ be a non-zero divisor. Then for any n, $\mathfrak{A}\langle g^{\frac{1}{p^\infty}}\rangle^o/p^m$ is $p^{\frac{1}{p^\infty}}$-almost faithfully flat over $\mathfrak{A}^o/p^m$.*

The basic idea is to add one variable T, consider the perfectoid algebra $\mathfrak{C} := \mathfrak{A}\langle T^{\frac{1}{p^\infty}}\rangle$ and look at the ind-system of algebras of functions $\mathfrak{C}_i := \mathfrak{C}\{\frac{T-g}{p^i}\}$ on tubular neighborhoods of the hypersurface $T = g$ in the perfectoid space Spa$(\mathfrak{C}, \mathfrak{C}^o)$.

The proof involves three steps.

7) *$\mathfrak{A}\langle g^{\frac{1}{p^\infty}}\rangle^o$ is $p^{\frac{1}{p^\infty}}$-almost isomorphic to $\widehat{\operatorname{colim}}_i\, \mathfrak{C}_i^o$.* This is an easy consequence of the general fact that for any uniform Banach algebra $\mathfrak{B}$ and $f \in \mathfrak{B}^o$, $\widehat{\operatorname{colim}}_i \mathfrak{B}\{\frac{f}{p^i}\}^o$ is $p^{\frac{1}{p^\infty}}$-almost isomorphic to $(\mathfrak{B}/f\mathfrak{B})^o$, *cf.* André [2016b, p. 2.9.3].

8) *$\mathfrak{C}^o$ contains a compatible system of p-power roots of some non-zero-divisor f_i such that $\mathfrak{C}_i^o$ is $p^{\frac{1}{p^\infty}}$-almost isomorphic to $\widehat{\operatorname{colim}}_j\, \mathfrak{C}\langle U\rangle^o/(p^{\frac{1}{p^j}}U - f_i^{\frac{1}{p^j}})$.* This is one instance of Scholze's approximation lemma Scholze [2012, p. 6.7]; one may assume $f_i \equiv T - g \mod p^{\frac{1}{p}}$.

9) *$\mathfrak{C}\langle U\rangle^o/(p^{\frac{1}{p^j}}U - f_i^{\frac{1}{p^j}}, p^m)$ is faithfully flat over $\mathfrak{A}^o/p^m$.* One may replace p^m by any positive power of p, *e.g.* $p^{\frac{1}{p^{j+1}}}$. Since $\mathfrak{C}$ is perfectoid, there is $g_{ij} \in \mathfrak{C}^{\frac{1}{p^\infty}}\rangle^o$ such that $g_{ij}^{p^j} \equiv$

$g \mod p$. Then $f_i^{\frac{1}{p^j}} \equiv T^{\frac{1}{p^j}} - g_{ij} \mod p^{\frac{1}{p^{j+1}}}$, and $\mathcal{C}\langle U\rangle^o/(p^{\frac{1}{p^j}}U - f_i^{\frac{1}{p^j}}, p^{\frac{1}{p^{j+1}}}) \cong (\mathfrak{A}^o/p^{\frac{1}{p^{j+1}}})[T^{\frac{1}{p^\infty}}, U]/(T^{\frac{1}{p^j}} - g_{ij})$, a free $\mathfrak{A}^o/p^{\frac{1}{p^{j+1}}}$-module. □

2.6 Conclusion of the proof of the direct summand conjecture. One chooses $g \in R$ such that $S[\frac{1}{pg}]$ is etale over $R[\frac{1}{pg}]$. One then follows the argument of 2.3, replacing $\mathfrak{A} = \hat{\cup}_i W(k)[p^{\frac{1}{p^i}}][[x_1^{\frac{1}{p^i}}, \dots, x_n^{\frac{1}{p^i}}]][\frac{1}{p}]$ by the "infinite Kummer extension" $\mathfrak{A} := (\hat{\cup}_i W(k)[p^{\frac{1}{p^i}}][[x_1^{\frac{1}{p^i}}, \dots, x_n^{\frac{1}{p^i}}]][\frac{1}{p}])\langle g^{\frac{1}{p^\infty}}\rangle$. One introduces the finite etale extension $\mathfrak{B}' := S \otimes_R \mathfrak{A}[\frac{1}{g}]$ of $\mathfrak{A}[\frac{1}{g}]$, and one replaces $\mathfrak{B} = S \otimes_R \mathfrak{A}$ in 2.3 by $\mathfrak{B} := (\lim \mathfrak{B}^{jo})[\frac{1}{p}]$, noting that $\mathfrak{B}^o$ is the S-algebra $\lim \mathfrak{B}^{jo}$. Translating Th. 2.4.1 and Th. 2.5.1 in terms of almost purity modulo p^m, and reasoning as in 2.3 (using the same lemma), one obtains that (1-1) splits modulo p^m for any n André [2016a, §3]. A Mittag-Leffler argument (retractions of $R/p^m \to S/p^m$ form a torsor under an artinian R/p^m-module Hochster [1973, p. 30]) shows that (1-1) itself splits. □

2.7 Derived version. In , B. Bhatt revisits this proof and proposes a variant, which differs in the analysis of the pro-system $\mathfrak{A}^{jo}/p^r$ occurring in the proof of Th. 2.4.1: he strengthens step 1) by showing that the pro-system of kernels and cokernels of $(\mathfrak{A}/p^r)_j \to (\mathfrak{A}^{jo}/p^r)_j$ is pro-isomorphic to a pro-system of $(pg)^{\frac{1}{p^\infty}}$-torsion modules; this allows to apply various functors before passing to the limit $j \to \infty$, whence a gain in flexibility. More importantly, he obtains the following derived version of the direct summand conjecture, which had been conjectured by J. de Jong:

2.7.1 Theorem. *Bhatt [n.d.] Let R be a regular Noetherian ring, and $f : X \to \operatorname{Spec} R$ be a proper surjective morphism. Then the map $R \to R\Gamma(X, \mathcal{O}_X)$ splits in the derived category $D(R)$.*

3 Existence of (big) Cohen–Macaulay algebras

3.1 Cohen–Macaulay rings and Cohen–Macaulay algebras for the non-Cohen-Macaulay rings. Let S be a local Noetherian ring with maximal ideal $\mathfrak{m}$ and residue field k. Recall that a sequence $\underline{x} = (x_1, \dots, x_n)$ in $\mathfrak{m}$ is *secant*[3] if $\dim S/(\underline{x}) = \dim S - n$, and *regular* if for every i, multiplication by x_i is injective in $S/(x_1, \dots, x_{i-1})S$. Any regular sequence

[3] following Bourkaki's terminology (for instance); it is also often called "part of a system of parameters", although $\operatorname{gr}_{\underline{x}} S$ may not be a polynomial ring in the "parameters" x_i (it *is* if $\underline{x}$ is regular).

is secant, and if the converse holds, S is said to be *Cohen–Macaulay*. Regular local rings have a secant sequence generating $\mathfrak{m}$, and are Cohen–Macaulay.

Cohen–Macaulay rings form the right setting for Serre duality and the use of local homological methods in algebraic geometry, and have many applications to algebraic combinatorics Bruns and Herzog [1993]. When confronted with a non-Cohen–Macaulay ring S, one may try two expedients:

1) *Macaulayfication*: construct a proper birational morphism $X \to \operatorname{Spec} S$ such that all local rings of X are Cohen–Macaulay. This weak resolution of singularities, introduced by Faltings, has been established in general by T. Kawasaki [2000]. Hovever, secant sequences in S may not remain secant (hence not become regular) in the local rings of X; this motivates the second approach:

2) *Construction of a Cohen–Macaulay algebra*[4]: an S-algebra C such that any secant sequence of S becomes regular in C, and $\mathfrak{m}C \neq C$.

The existence of Cohen–Macaulay algebras implies the direct summand conjecture: indeed, if C is a Cohen–Macaulay algebra for a finite extension S of a regular local ring R, it is also a Cohen–Macaulay R-algebra; this implies that $R \to C$ is faithfully flat, hence pure, and so is $R \to S$.

3.2 Constructions of Cohen–Macaulay algebras. The existence of a (big) Cohen–Macaulay algebra was established by Hochster and C. Huneke under the assumption that S contains a field Hochster and Huneke [1995]. One may assume that S is a complete local domain. In char. $p > 0$, one may then take C to be the *total integral closure of* S (*i.e.* the integral closure of S in an algebraic closure of its field of fractions). This is no longer true in the case of equal char. 0, which can nevertheless be treated by reduction to char. $p >> 0$ using ultraproduct techniques.

The remaining case of mixed characteristic was settled in André [2016a], using the same perfectoid methods, so that one has:

3.2.1 Theorem. *Any local Noetherian ring S admits a (big) Cohen–Macaulay algebra C.*

In the case of a complete local domain S of char $(0, p)$ and perfect residue field k (to which one reduces), one proceeds as follows. Cohen's theorem allows to present S as a finite extension of $R = W[[x_1, \dots, x_n]]$. One first considers the R-algebra

$$\mathfrak{A} := (\hat{\cup}_i W(k)[p^{\frac{1}{p^i}}][[x_1^{\frac{1}{p^i}}, \dots, x_n^{\frac{1}{p^i}}]][\frac{1}{p}])\langle g^{\frac{1}{p^\infty}}\rangle^o$$

[4]since it would be too restrictive to impose that C is Noetherian, one often speaks of "big" Cohen–Macaulay algebra.

and the S-algebra $\mathfrak{B}^o = \lim \mathfrak{B}^{jo}$ as above 2.6. It follows from Th. 2.4.1 and Th. 2.5.1 that $\mathfrak{B}^o$ is $(pg)^{\frac{1}{p^\infty}}$-almost isomorphic to a faithfully flat R algebra modulo any power of p. From there, one deduces that the sequence $(p, x_1, \ldots, x_n)$ is "$(pg)^{\frac{1}{p^\infty}}$-almost regular" in $\mathfrak{B}^o$.

To get rid of "almost", Lemma 2.3.1 is no longer sufficient: instead, one uses Hochster's technique of monoidal modifications Hochster [2002]Hochster and Huneke [1995]. After $\mathfrak{m}$-completion, one gets a S-algebra C in which $(p, x_1, \ldots, x_n)$, as well as any other secant sequence of S, becomes regular. □

Subsequently, using the tilting equivalence between perfectoid algebras in char. 0 and in char. p and applying Hochster's modifications in char. p rather than in char.0, K. Shimomoto [2017] shows that *in Th. 3.2.1, in mixed characteristic, C can be taken to be perfectoid. In particular, if S is regular, it admits a perfectoid faithfully flat algebra* (one may speculate about the converse).

3.3 Finite and fpqc covers. Since Cohen–Macaulay algebras for regular local rings are faithfully flat, Th. 3.2.1 implies André [2016a]:

3.3.1 Theorem. *Any finite cover of a regular scheme is dominated by a faithfully flat quasi-compact cover.*

If regularity is omitted, Spec$(\mathbb{Q}[x, y]/(xy))$ and its normalization provide a counter-example.

4 Homological conjectures

4.1 Origins from intersection theory. Under the influence of M. Auslander, D. Buchsbaum and J.-P. Serre, commutative algebra has shifted in the late 50s from the study of ideals of commutative rings to the homological study of modules (*cf.* their characterization of regular local rings by the existence of finite free resolutions for any finitely generated module, *resp.* for the residue field).

Serre proved that for any three prime ideals $\mathfrak{p}, \mathfrak{q}, \mathfrak{r}$ of a regular local ring R such that $\mathfrak{r}$ is a minimal prime of $\mathfrak{p}+\mathfrak{q}$, ht $\mathfrak{r} \leq$ ht $\mathfrak{p}+$ht $\mathfrak{q}$ Serre [1965]. The special case $\mathfrak{r} = \mathfrak{m}$ can be amplified: for any ideals I, J of R such that $I + J$ is $\mathfrak{m}$-primary, $\dim R/I + \dim R/J \leq \dim R$.

This is no longer true if R is not regular, and attempts to understand the general situation led to the so-called homological conjectures *cf.* Bruns and Herzog [1993, ch. 9], Hochster [2007].

4.2 Intersection conjectures. Let $(R, \mathfrak{m})$ be local Noetherian ring.

The first "intersection conjecture" was proposed by Peskine and Szpiro [1973], proved by them when R contains a field by reduction to char. p and Frobenius techniques, and later proved in general by P. Roberts using K-theoretic methods Roberts [1987]. It states that *if M, N are finitely generated R-modules such that $M \otimes N$ has finite length, then* $\dim N \leq \operatorname{pd} M$. It implies that *$R$ is Cohen–Macaulay if and only if there is an R-module M of finite length and finite projective dimension* (in the spirit of Serre's characterization of regular rings, which is the case $M = k$), resp. *if there is an R-module M of finite injective dimension*.

Indeed, one may take $N = R$ and deduce that $\dim R \leq \operatorname{pd} M$; by the Auslander-Buchsbaum formula, $\operatorname{pd} M = \operatorname{depth} R - \operatorname{depth} M$, so that the inequality $\operatorname{depth} R \leq \dim R$ is an equality. The second assertion follows from the fact that $\operatorname{id} M = \operatorname{depth} R$ Bass [1963].

The "new intersection conjecture", also proved by Peskine and Szpiro [1973] and Roberts [1987], states that *for any non exact complex $F_\bullet$ of free R-modules concentrated in degrees $[0, s]$ with finite length homology, $s > \dim R$.*

The "improved new intersection conjecture" is a variant due to E. Evans and P. Evans and Griffith [1981], in which the condition on $F_\bullet$ is "slightly" relaxed: the $H_{i>0}$ are of finite length and there exists a primitive cyclic submodule of H_0 of finite length. They proved it, assuming the existence of (big) Cohen–Macaulay algebras[5], and showed that it implies their "syzygy conjecture". In spite of appearances, the passage from the new intersection conjecture to its "improved" variant is no small step[6]: in fact, according to Hochster [2007] and S. Dutta [1987], the latter is *equivalent to the direct summand conjecture*.

On the other hand, in the wake of the new intersection conjecture (and motivated by the McKay correspondence in dimension 3 and the "fact" that threefold flops induce equivalences of derived categories), T. Bridgeland and S. Iyengar obtained a refinement of Serre's criterion for regular rings assuming the existence of Cohen–Macaulay algebras Bridgeland and Iyengar [2006, p. 2.4].

By Th. 1.0.1 and Th. 3.2.1, the improved new intersection conjecture and the Bridgeland-Iyengar criterion thus hold inconditionally:

4.2.1 Theorem. *Let R be a Noetherian local ring and $F_\bullet$ be a complex of finitely generated free R-modules concentrated in degree $[0, s]$, such that $H_{>0}(F_\bullet)$ has finite length.*

1. *If $H_0(F_\bullet)$ contains a cyclic R-submodule of finite length not contained in $\mathfrak{m} H_0(F_\bullet)$, then $s \geq \dim R$.*

[5] if R is Cohen–Macaulay, the Buchsbaum-Eisenbud criterion gives a condition for the exactness of $F_\bullet$ in terms of codimension of Fitting ideals of syzygies. In general, the same condition guarantees that $F_\bullet \otimes C$ is exact for any Cohen–Macaulay R-algebra C Bruns and Herzog [1993, p. 9.1.8].

[6] K-theoretic techniques failed to make the leap.

2. *If $H_0(F_\bullet)$ has finite length and contains k as a direct summand, and $s = \dim R$, then R is regular.*

And so does the syzygy conjecture:

4.2.2 Theorem. *Let R be a Noetherian local ring and M a finitely generated R-module of finite projective dimension s. Then for $i \in \{1, \dots, s-1\}$, the i-th syzygy module of M has rank $\geq i$.*

4.3 Further work around the homological conjectures using perfectoid spaces.

4.3.1 . In 2017, Heitmann and L. Ma show that Cohen–Macaulay algebras can be constructed in a way compatible with quotients $S \to S/\mathfrak{p}$ by primes of height one[7]. Using arguments similar to Bhatt's derived techniques, they deduce the vanishing conjecture for maps of Tor Hochster and Huneke [1995]:

4.3.1 Theorem. R. Heitmann and Ma [2017a] *Let $R \to S \to T$ be morphisms such that the composed map is a local morphism of mixed characteristic regular local rings, and S is a finite torsion-free extension of R. Then for every R-module M and every i, the map $\mathrm{Tor}_i^R(M, S) \to \mathrm{Tor}_i^R(M, T)$ vanishes.*

They obtain the following corollary, which generalizes results by Hochster and J. Roberts, J.-F. Boutot et al.:

4.3.2 Corollary. R. Heitmann and Ma [ibid.] *Let $R \hookrightarrow S$ be a pure, local morphism, with S regular. Then R is pseudo-rational, hence Cohen–Macaulay.*

4.3.2 . In 2017, Ma and K. Schwede define and study perfectoid multiplier/test ideals in mixed characteristic, and use them to bound symbolic powers of ideals in regular domains in terms of ordinary powers:

4.3.3 Theorem. Ma and Schwede [2017] *Let R be a regular excellent Noetherian domain and let $I \subset R$ be a radical ideal such that each minimal prime of I has height $\leq h$. Then for every n, $I^{(hn)} \subset I^n$.*

Here $I^{(hn)}$ denotes the ideal of elements of R which vanish generically to order hn at I. When R contains a field, the result was proved in Ein, Lazarsfeld, and Smith [2001] and Hochster and Huneke [1990].

[7] weak functoriality of Cohen–Macaulay algebras in general has been since announced by the author Andre [2018].

4.3.3 . An efficient and unified way of dealing with questions related to the homological conjectures in char. p is provided by "tight closure theory", which has some flavor of almost ring theory. Using Th. 2.4.1 and Th. 2.5.1 above, Heitmann and Ma give evidence that the "extended plus closure" introduced in R. C. Heitmann [2001] is a good analog of tight closure theory in mixed characteristic R. Heitmann and Ma [2017b].

LA COURBE

Laurent Fargues

Résumé

On présente un résumé de nos travaux sur la courbe que nous avons introduite avec Jean-Marc Fontaine et ses applications en théorie de Hodge p-adique ainsi qu'au programme de Langlands.

Introduction

La courbe fondamentale en théorie de Hodge p-adique a été introduite par Jean-Marc Fontaine et l'auteur dans Fargues et Fontaine [2017]. On présente d'abord celle-ci, l'étude des fibrés vectoriels et de leurs modifications dans la Section 1. Dans la Section 2 on explique nos résultats sur l'étude des G-fibrés et leurs applications aux espaces de périodes p-adiques. Enfin, on conclut dans la Section 3 par des résultats récents sur les familles de fibrés et le lien conjectural avec la correspondance de Langlands locale. Ce texte est en quelque sorte un récit du parcours qui nous a mené des filtrations de Harder-Narasimhan des schémas en groupes finis et plats (Fargues [2010b]) à la conjecture de géométrisation de la correspondance de Langlands locale (Section 3).

1 Courbe et fibrés vectoriels

1.1 Fonctions holomorphes de la variable p. Soient E un corps local de corps résiduel le corps fini $\mathbb{F}_q$ et π une uniformisante de E. On a donc soit $[E : \mathbb{Q}_p] < +\infty$, soit $E = \mathbb{F}_q((\pi))$. Soit $F|\mathbb{F}_q$ un corps perfectoïde. On note $\varpi \in F$ une pseudo-uniformisante i.e. $0 < |\varpi| < 1$. Considérons l'anneau de Fontaine (Fontaine [1979], Fontaine [1994a])

$$\mathbf{A} = \begin{cases} W_{\mathcal{O}_E}(\mathcal{O}_F) \text{ si } E|\mathbb{Q}_p \\ \mathcal{O}_F[\![\pi]\!] \text{ si } E = \mathbb{F}_q((\pi)). \end{cases}$$

L'auteur a bénéficié du support des projets ANR-14-CE25 "PerCoLaTor" et ERC Advanced Grant 742608 "GeoLocLang".
MSC2010 : primary 11S31 ; secondary 11S37, 11G18, 14K10.

La théorie de la courbe schématique ne nécessite pas la théorie des espaces perfectoïdes qu'elle prédate ou des espaces adiques. Néanmoins il est plus naturel maintenant de l'exposer en introduisant ces objets. Considérons donc l'espace adique

$$Y = \mathrm{Spa}(\mathbf{A}, \mathbf{A}) \setminus V(\pi[\varpi]).$$

Si $E = \mathbb{F}_q(\!(\pi)\!)$ il s'agit d'un disque ouvert épointé de la variable π, $\mathbb{D}_F^* = \{0 < |\pi| < 1\} \subset \mathbb{A}_F^1$ qui est exactement celui qui apparaît dans les travaux de (Hartl et Pink [2004]). Néanmoins on ne le considère pas ici comme un espace adique sur F mais sur E,

$$\begin{array}{ccc} & Y = \mathbb{D}_F^* & \\ {}^{\text{loc. de type fini}}\swarrow & & \searrow^{\text{pas loc. de type fini}} \\ \mathrm{Spa}(F) & & \mathbb{D}_{\mathbb{F}_q}^* = \mathrm{Spa}(\mathbb{F}_q(\!(\pi)\!)). \end{array}$$

Il est préperfectoïde, si $E|\mathbb{Q}_p$ et E_∞ est le complété de l'extension engendrée par les points de torsion d'un groupe de Lubin-Tate, l'espace $Y \hat{\otimes}_E E_\infty$ est perfectoïde de basculé le même espace associé à $E_\infty^\flat$ i.e. $\mathbb{D}_F^{*,1/p^\infty}$ un disque perfectoïde épointé (Fargues [2015c] sec. 2.2).

L'algèbre de Fréchet $\mathcal{O}(Y)$ est obtenue par complétion des fonctions holomorphes sur Y, méromorphes le long des diviseurs (π) et $([\varpi])$,

$$\mathbf{A}[\tfrac{1}{\pi}, \tfrac{1}{[\varpi]}],$$

relativement aux normes de Gauss $|.|_\rho$ pour des rayons $\rho \in]0,1[$

$$\Big| \sum_{n \gg -\infty} [x_n]\pi^n \Big|_\rho = \sup_n |x_n|\rho^n.$$

Un élément $\xi = \sum_n [x_n]\pi^n \in \mathbf{A}$ est dit primitif de degré $d > 0$ si $x_0 \neq 0$, $x_0, \dots, x_{d-1} \in \mathfrak{m}_F$ et $x_d \in \mathcal{O}_F^\times$. Le produit d'un élément primitif de degré d par un de degré d' est primitif de degré $d + d'$ et on a donc une bonne notion d'élément primitif irréductible. Deux tels éléments sont équivalents s'ils sont multiples par une unité dans $\mathbf{A}^\times$. Le résultat suivant est un un résultat clef pour toute la suite (on renvoie également aux articles de revue Fargues et Fontaine [2012], Fargues et Fontaine [2011] et Fargues et Fontaine [2014]).

Théorème 1.1 (Fargues et Fontaine [2017] théo. 2.4, coro. 2.2.23, théo. 3.1.11)**.**

1. *Si F est algébriquement clos alors tout élément primitif dans $\mathbf{A}$ irréductible est de degré 1, équivalent à $\pi - [a]$ avec $0 < |a| < 1$. En d'autres termes, tout ξ primitif a une factorisation (de Weierstrass)*

$$\xi = u(\pi - [a_1]) \dots (\pi - [a_d]),\ u \in \mathbf{A}^\times, 0 < |a_i| < 1.$$

2. *Pour ξ primitif irréductible dans* $\mathbf{A}$*,* $\mathbf{A}[\frac{1}{\pi}]/(\xi) = \mathcal{O}(Y)/(\xi)$ *est un corps perfectoïde de basculé une extension de degré* $\deg(\xi)$ *de* F *via* $x \mapsto [x]$ *mod* ξ*. Cela induit une équivalence*

$$\{\text{éléments primitifs irréductibles de degré 1}\}/\sim \xrightarrow{\sim} \text{débasculements de } F \text{ sur } E.$$

Par définition les points classiques de Y, $|Y|^{cl}$, sont les zéros des éléments primitifs de $\mathbf{A}$. Les normes de Gauss $|.|_\rho$ sont multiplicatives et *on dispose donc d'une bonne notion de polygone de Newton pour les fonctions holomorphes* f *sur* Y ainsi que sur ses couronnes, ceci par application d'une transformée de Legendre inverse appliquée à la fonction concave $]0,+\infty[\ni r \mapsto -\log|f|_{q^{-r}}$. Par « bonne notion de polygone de Newton » on entend typiquement le fait que le polygone d'un produit est le concaténé des polygones (Fargues et Fontaine [ibid., sec. 1], Fargues et Fontaine [2014, sec. 1]). Par exemple, le polygone de Newton de $\sum_{n\gg 0}[x_n]\pi^n \in \mathbf{A}[\frac{1}{\pi}, \frac{1}{[\varpi]}]$ est l'enveloppe convexe décroissante des points $(n, v(x_n))_{n\in\mathbb{Z}}$. Si $\xi = \sum_n [x_n]\pi^n$ est primitif de degré d on définit sa valuation (la « distance à l'origine $\pi = 0$ dans le disque épointé Y ») comme étant $\frac{1}{d}v(x_0)$.

Théorème 1.2 (Fargues et Fontaine [2017, théo. 3.4.4])**.**

1. *Pour* $f \in \mathcal{O}(Y)$ *non nul les pentes de son polygone de Newton sont les valuations des zéros de* f *dans* $|Y|^{cl}$*,* $f(y) = 0$ *avec* $y \in |Y|^{cl}$*, comptées avec multiplicité* $\mathrm{ord}_y(f)\deg(y)$ *où la valuation* ord_y *est celle de l'anneau de périodes de Fontaine* $\widehat{\mathcal{O}}_{Y,y} = B_{dR}^+(k(y))$ *associé au corps perfectoïde* $k(y)$*.*
2. *L'algèbre de Banach des fonctions holomorphes sur une couronne compacte* $\{\rho_1 \leq |\pi| \leq \rho_2\}$ *de* Y *est un anneau principal de spectre maximal les éléments de* $|Y|^{cl}$ *dans cette couronne (à une unité près tout élément irréductible est primitif irréductible dans* $\mathbf{A}$*).*

Concrètement, si F est algébriquement clos et si λ est une pente du polygone de f alors $f = (\pi - [a])g$ avec $v(a) = \lambda$ et la multiplicité de λ dans le polygone de g est une de moins. L'analyse p-adique d'une fonction d'une variable développée dans Lazard [1962] s'étend à ce cadre. On peut typiquement former des produits de Weierstrass et vérifier ainsi que tout $f \in \mathcal{O}(Y)$ se met sous la forme

$$\prod_{n\geq 0}\left(1 - \frac{[x_n]}{\pi}\right) \times g$$

avec $x_n \to 0$, g sans zéros au voisinage de $\pi = 0$ et donc méromorphe en $\pi = 0$, de la forme $\sum_{n\gg 0}[x_n]\pi^n$ avec $x_n \in F$ et pour tout $\rho \in]0,1[$, $\lim_{n\to+\infty}|x_n|\rho^n = 0$ (Fargues et Fontaine [2017] sec. 1.2). Cela permet de rendre concret les éléments de $\mathcal{O}(Y)$ puisqu'*en général, sauf si bien sûr si* $E = \mathbb{F}_q((\pi))$*, un tel élément n'admet pas de développement unique en série de Laurent de la forme* $\sum_{n\in\mathbb{Z}}[x_n]\pi^n$.

1.2 La courbe schématique. L'espace Y est muni d'un Frobenius φ induit par le Frobenius $x \mapsto x^q$ de F. *Les théorèmes de factorisation précédents permettent d'analyser les périodes p-adiques*. Typiquement un élément de $\mathcal{O}(Y)^{\varphi=\pi^d}$ a un polygone de Newton satisfaisant une équation fonctionnelle qui se résout facilement. On peut alors lui appliquer les résultats de factorisation précédent. Utilisant ces résultats on obtient le théorème clef suivant.

Théorème 1.3 (Fargues et Fontaine [2017, théo. 6.2.1])**.** *Si le corps F est algébriquement clos l'algèbre de périodes $P = \bigoplus_{d\geq 0} \mathcal{O}(Y)^{\varphi=\pi^d}$ est graduée factorielle i.e. le monoïde abélien $\coprod_{d\geq 0} P_d \setminus \{0\}/E^\times$ est libre de base $P_1 \setminus \{0\}/E^\times$.*

Concrètement, si $f \in P_d \setminus \{0\}$, $f = f_1 \dots f_d$ avec $f_i \in P_1$ et une telle écriture est unique à des scalaires dans $E^\times$ près. Ce théorème (qui se formule et se démontre sans espaces adiques) s'est récemment retrouvé de nouveau au coeur de résultats plus complexes à priori, cf. proposition 3.2. *Il est au coeur même de la courbe.*

De la même façon, en utilisant ces résultats d'analyse concernant les fonctions de $\mathcal{O}(Y)$ et leurs zéros, on donne une démonstration rapide de la suite exacte fondamentale de la théorie de Hodge p-adique dans (Fargues et Fontaine [ibid., théo. 6.4.1]). En combinant ces divers résultats on obtient la construction de la courbe schématique.

Théorème 1.4 (Fargues et Fontaine [ibid., théo. 6.5.2, 7.3.3])**.** *Le schéma $X = Proj(P)$ est noethérien régulier de dimension 1, i.e. de Dedekind. De plus*

1. *Il y a un morphisme d'espaces annelés $Y \to X$ qui induit une bijection $|Y|^{cl}/\varphi^{\mathbb{Z}} \to |X|$ (points fermés de X) tel que si $y \mapsto x$ alors $k(y) = k(x)$ et $B_{dR}^+(k(y)) = \widehat{\mathcal{O}}_{Y,y} = \widehat{\mathcal{O}}_{X,x}$.*
2. *La courbe est « complète » au sens où si pour $x \in |X|$ on pose $\deg(x) := [k(x)^\flat : F]$, alors pour tout $f \in E(X)^\times$, $\deg(\div f) = 0$.*
3. *Si F est algébriquement clos alors tout point est de degré 1, $P_1 \setminus \{0\}/E^\times \xrightarrow{\sim} |X|$ via $t \mapsto V^+(t)$. De plus $\mathcal{O}_X(D^+(t)) = \mathcal{O}(Y)[\frac{1}{t}]^{\varphi=Id} = B_{cris}(C_t)^{\varphi=Id}$ est un anneau principal où C_t est le corps résiduel en $V^+(t)$, $C_t^\flat = F$.*

1.3 La courbe adique. Comme on l'a dit précédemment l'espace Y est adique préperfectoïde. On définit alors la courbe adique comme étant

$$X^{ad} = Y/\varphi^{\mathbb{Z}}.$$

C'est un espace adique quasicompact partiellement propre (mais pas de type fini) sur $\mathrm{Spa}(E)$. Il y a un morphisme d'espaces annelés $X^{ad} \to X$ qui identifie les points classiques de X^{ad} et les points fermés de X ainsi que les complétés des anneaux locaux correspondants. Bien que non localement de type fini on sait que Y *et* X^{ad} *sont localement* *noethériens* (Fargues [2015c] conjecture 1 démontrée par Kedlaya [2016a]). L'un des intérêts de ce résultat est que du coup Y et X^{ad} rentrent dans le cadre de la théorie « classique » développée par Huber [1996]. Ainsi, par exemple, si Z est un E-espace rigide de Tate, i.e. un E-espace adique localement de type fini, on peut former l'espace adique $X^{ad} \times Z$ et regarder les faisceaux cohérents dessus lorsque Z varie (cf. Kedlaya, Pottharst et Xiao [2014] pour une exemple d'une version non perfectoïde de cela).

1.4 Fibrés vectoriels. Bien que l'algèbre graduée de périodes P utilisée pour définir X dépende du choix de π, X n'en dépend canoniquement pas. Ceci dit, le choix de π définit un fibré « très ample » $\mathcal{O}(1) = \widetilde{P[1]}$ sur X tel que

$$P = \bigoplus_{d \geq 0} H^0(X, \mathcal{O}(d)).$$

On suppose maintenant que F contient une clôture algébrique $\overline{\mathbb{F}}_q$ de $\mathbb{F}_q$. On note E_n l'extension non ramifiée de degré n de E et $\breve{E} = \widehat{E^{nr}}$ muni de son Frobenius σ. On a une identification (l'indice E signifie la courbe associée au choix de E)

$$X_E \otimes_E E_n = X_{E_n}$$

et le revêtement cyclique $X^{ad}_{E_n} \to X^{ad}_E$ s'identifie à

$$Y/\varphi^{n\mathbb{Z}} \longrightarrow Y/\varphi^{\mathbb{Z}}.$$

Ainsi,

trivialisation du revêtement $Y \to Y/\varphi^{\mathbb{Z}}$

X^{ad} — ext. des scalaires non ramifiées $\nearrow$

X^{ad} — ext. des scalaires ramifiées $\searrow$

monde perfectoïde.

Pour tout $\lambda = \frac{d}{h} \in \mathbb{Q}$, $(d,h) = 1$, on définit $\mathcal{O}_X(\lambda)$ comme étant le poussé en avant par le revêtement étale fini $X_{E_h} \to X_E$ de $\mathcal{O}_{X_{E_h}}(d)$. Un des points fondamentaux de la théorie est maintenant le suivant : puisque la courbe est complète (théorème 1.4) on peut définir naturellement le degré d'un fibré en droites et *on dispose en particulier du formalisme des filtrations de Harder-Narasimhan* (Fargues et Fontaine [2017] sec. 5.5). Ainsi *le fibré $\mathcal{O}(\lambda)$ est stable de pente λ.*

Théorème 1.5 (Fargues et Fontaine [ibid.] théo. 8.2.10)**.** *Supposons F algébriquement clos.*

1. *Pour tout $\lambda \in \mathbb{Q}$, un fibré sur X est semi-stable de pente λ si et seulement si il est isomorphe à une somme directe de $\mathcal{O}(\lambda)$.*
2. *La filtration de Harder-Narasimhan d'un fibré sur X est scindée.*
3. *L'application $(\lambda_i)_i \mapsto \oplus_i \mathcal{O}(\lambda_i)$ induit une bijection entre suites décroissantes de nombres rationnels et classes d'isomorphisme de fibrés sur X.*

Ce résultat ressemble fortement à une généralisation du théorème de Grothendieck concernant la droite projective. Néanmoins sa preuve est beaucoup plus complexe car contrairement à $\mathbb{P}^1$, $H^1(X, \mathcal{O}(-1)) \neq 0$: si $V^+(t) = \infty$ avec $t \in P_1 \setminus \{0\}$ alors *l'anneau principal* $\mathcal{O}(Y)[1/t]^{\varphi=Id}$ *muni du stathme* $-\mathrm{ord}_\infty$ *n'est pas euclidien !* La démonstration de ce résultat utilise des résultats fins de théorie de Hodge p-adique concernant les périodes de groupes p-divisibles et leurs liens avec les modifications de fibrés (cf. Section 1.7.2).

Lorsque le corps F n'est plus algébriquement clos des *phénomènes monodromiques apparaissent.* On vérifie typiquement que pour $t \in P_1 \setminus \{0\}$

$$\mathrm{Cl}(\mathcal{O}(Y)[1/t]^{\varphi=Id}) = \mathrm{Pic}^0(X) = \mathrm{Hom}(\mathrm{Gal}(\overline{F}|F), E^\times).$$

On a plus généralement le résultat suivant.

Théorème 1.6 (Fargues et Fontaine [2017] théo. 9.3.1, du type Narasimhan Narasimhan et Seshadri [1965])**.** *Via le foncteur $\mathcal{E} \mapsto H^0(X_{\widehat{\overline{F}}}, \mathcal{E}_{|X_{\widehat{\overline{F}}}})$, la catégorie des fibrés semi-stables de pente 0 sur X_F est équivalente à celle des représentations p-adiques de* $\mathrm{Gal}(\overline{F}|F)$ *à coefficients dans E.*

Enfin, venons en au théorème GAGA.

Théorème 1.7 (GAGA, Fargues [2015c] théo. 3.5, Kedlaya et Liu [2015] théo. 8.5.5)**.** *L'image réciproque par le morphisme d'espaces annelés $X^{ad} \to X$ induit une équivalence entre faisceaux cohérents sur X et X^{ad}.*

La première démonstration de ce résultat (Fargues [2015c]) consistait à comparer le théorème de classification 1.4 avec celui de Kedlaya [2004] lorsque $E|\mathbb{Q}_p$ ou bien le théorème d'Hartl Pink en égales caractéristiques (Hartl et Pink [2004]). Plus précisément, les fibrés vectoriels sur X^{ad} s'identifient aux fibrés φ-équivariants sur Y, qui eux-même s'identifient aux germes de fibrés vectoriels φ-équivariants au voisinage de $\pi = 0$ sur Y (si U est un tel voisinage alors $Y = \cup_{n \geq 0} \varphi^n(U)$). *L'anneau des germes de fonctions holomorphes au voisinage de $\pi = 0$ s'identifie à l'anneau de Robba* associé à F, et donc les fibrés vectoriels sur X^{ad} s'identifient aux φ-modules sur cet anneau de Robba.

Kedlaya et Liu [2015] ont donné une autre démonstration reposant sur leur preuve du fait que $\mathcal{O}(1)$ *est ample sur X^{ad}* : pour tout fibré $\mathcal{E}$ sur X^{ad}, pour $d \gg 0$, $\mathcal{E}(d)$ est engendré par ses sections globales (bien sûr ce résultat est tautologique sur la courbe schématique, c'est une des raisons pour laquelle elle est plus simple à manipuler, ce résultat est intégré dans sa construction). Il s'agit de construire suffisamment de sections de $\mathcal{E}(d)$, $d \gg 0$, par un processus itératif convergeant (KEDLAYA et LIU [ibid.] sec. 6.2), les méthodes usuelles de séries de Poincaré (CARTAN [1958]) sur Y ne semblant pas fonctionner (de plus, si F est algébriquement clos, on ne sait pas à l'avance que le tiré en arrière à Y d'un fibré sur X^{ad} est trivial, i.e. qu'un tel fibré est donné par un facteur d'automorphie, alors que c'est une conséquence du théorème de classification).

Une façon plus intrinsèque d'exposer le théorème de classification des fibrés est d'utiliser les isocristaux tels qu'ils apparaissent dans le théorème de Dieudonné-Manin ; $\varphi\text{−Mod}_{\breve{E}}$ qui est la catégorie des couples (D, φ) où D est un $\breve{E}$–espace vectoriel de dimension finie et φ un automorphisme σ-linéaire. L'espace Y vit au dessus de $\text{Spa}(\breve{E})$. Dès lors on peut construire pour un tel isocristal

$$\mathcal{E}(D, \varphi) = Y \times_{\varphi^{\mathbb{Z}}} D \longrightarrow Y/\varphi^{\mathbb{Z}} = X^{ad}$$

qui est un fibré trivialisé de fibre D sur Y ayant pour facteur d'automorphie φ agissant sur D. Via GAGA cela correspond au fibré associé au P-module gradué $\oplus_{d \geq 0}(D \otimes \mathcal{O}(Y))^{\varphi \otimes \varphi = \pi^d}$. Dès lors le théorème 1.5 s'énonce en disant que

$$\mathcal{E}(-) : \varphi\text{−Mod}_{\breve{E}} \longrightarrow \text{Fibrés sur } X$$

est essentiellement surjectif.

1.5 Simple connexité géométrique de la courbe.

Du théorème de classification des fibrés on peut déduire le résultat suivant.

Théorème 1.8 (FARGUES et FONTAINE [2017] théo. 8.6.1)**.** *Si F est algébriquement clos le schéma $X_{\overline{E}}$ est simplement connexe : tout revêtement étale fini est scindé.*

En d'autres termes $\pi_1(X) = \text{Gal}(\overline{E}|E)$. Plus généralement, pour F quelconque, $\pi_1(X) = \text{Gal}(\overline{F}|F) \times \text{Gal}(\overline{E}|E)$ (FARGUES et FONTAINE [ibid.] théo. 9.5.1). On dispose du même résultat, soit par la même méthode soit par GAGA, sur la courbe adique : les revêtements étales finis de $\text{Spa}(E)$ correspondent à ceux de X^{ad}. Ce résultat a d'importantes applications. Il se réinterprète de façon formelle en disant que si F est algébriquement clos alors le diamant au sens de SCHOLZE [p. d., 2014] (cf. FARGUES [2017] par exemple pour ce diamant en particulier et la Section 3.3)

$$\text{Div}^1_F = \text{Spa}(F) \times \text{Spa}(E)^{\diamond}/\varphi^{\mathbb{Z}}_{E^{\diamond}}$$

a pour π_1 le groupe de Galois $\mathrm{Gal}(\overline{E}|E)$ ($X_F^{ad,\diamond}$ et Div_F^1 ont même catégorie de revêtements étales). On a

$$\mathrm{Spa}(F) \times \mathrm{Spa}(E)^\diamond = \mathbb{D}_F^{*,1/p^\infty}/\mathcal{O}_E^\times$$

un disque perfectoïde épointé divisé par l'action de Lubin-Tate de $\mathcal{O}_E^\times$ (Fargues [2015c] sec.2 et Scholze [2014]). Dès lors, si $F = \mathbb{C}_p^\flat$ on trouve comme corollaire du théorème 1.8 que *le groupe de Galois* $\mathrm{Gal}(\overline{E}|E)$ *classifie les revêtements étales finis* $\mathcal{O}_E^\times$-*équivariants de* $\mathbb{D}_{\mathbb{C}_p}^*/\varphi^{\mathbb{Z}}$ (Weinstein [2017]). Ce résultat a motivé l'article Kucharczyk et Scholze [2016] de Kucharczyk et Scholze qui est la recherche d'un résultat analogue sur les corps de nombres.

Le théorème 1.8 est également à la base de la preuve du *lemme de Drinfeld-Scholze* (Scholze [2014]) qui affirme que « $\pi_1\big((\mathrm{Div}^1)^d\big) = \pi_1(\mathrm{Div}^1)^d$ » (cf. Fargues [2017] sec. 4 pour une signification précise de cet énoncé en termes de Div^1).

1.6 Fibrés et espaces de Banach-Colmez. La découverte de la courbe remonte à l'étude par Fontaine et l'auteur des résultats de Colmez sur les espaces de Banach de dimension finie (Colmez [2002], Colmez [2008]). C'est en définissant des filtrations de Harder-Narasimhan sur ceux-ci et en tentant de les classifier que nous sommes tombés sur la courbe. Maintenant, le lien entre fibrés vectoriels sur la courbe et espaces de Banach-Colmez est complètement clarifié par le théorème suivant.

Théorème 1.9 (Le Bras [2017])**.** *Supposons que* $F = C^\flat$ *avec* C *algébriquement clos.*

1. *La catégorie des espaces de Banach-Colmez est la plus petite sous-catégorie abélienne de la catégorie des faisceaux pro-étales de* E*-espaces vectoriels sur* $\mathrm{Spa}(C)$ *contenant* $\mathbb{G}_a$, $\underline{E}$ *et stable par extensions.*
2. *Le foncteur cohomologie relative induit une équivalence entre le coeur dans* $\mathbb{D}^b_{coh}(\mathcal{O}_X)$ *de la* t*-structure*
   - *dont la partie* ≤ 0 *est formée des complexes* $\mathcal{E}^\bullet$ *satisfaisant* $\mathcal{H}^i(\mathcal{E}^\bullet) = 0$ *si* $i > 0$ *et* $\mathcal{H}^0(\mathcal{E}^\bullet)$ *est à pentes de HN* ≥ 0,
   - *la partie* ≥ 0 *des complexes satisfaisant* $\mathcal{H}^i(\mathcal{E}^\bullet) = 0$ *si* $i < -1$ *et* $\mathcal{H}^{-1}(\mathcal{E}^\bullet)$ *est à pentes de HN* < 0,

   et la catégorie des espaces de Banach-Colmez.
3. *L'équivalence précédente s'étend en une équivalence dérivée.*

Ici par cohomologie relative on entend la chose suivante. On peut définir un morphisme de (gros) topos pro-étales

$$\tau : (X_{C^\flat}^{ad})^\sim_{\text{pro-ét}} \longrightarrow \mathrm{Spa}(C^\flat)^\sim_{\text{pro-ét}} = \mathrm{Spa}(C)^\sim_{\text{pro-ét}}$$

grâce à la fonctorialité de la courbe adique : $S \mapsto X_S^{ad}$ (cf. Section 3.1) où S est un espace perfectoïde sur $\mathrm{Spa}(\mathbb{F}_q)$. Dès lors, si $\mathcal{E}^\bullet$ est un complexe de faisceaux cohérents sur $X_{C^\flat}^{ad}$ on peut définir $R\tau_*\mathcal{E}^\bullet$.

Certains de ces faisceaux de cohomologie relative, ceux associés aux fibrés vectoriels à pentes dans $[0,1]$, sont représentables par des C-espaces perfectoïdes du type $\varprojlim_{\times p} \mathcal{G}^{rig}$ où $\mathcal{G}$ est un groupe formel p-divisible sur $\mathcal{O}_C$ (cf. sec. 4 de FARGUES et FONTAINE [2017], c'est ce que Scholze et Weinstein ont appelé plus tard le revêtement universel d'un groupe p-divisible (SCHOLZE et WEINSTEIN [2013]). Néanmoins en général ils ne sont représentables que par des diamants (et ces espaces de Banach-Colmez ont probablement été une forte source d'inspiration pour l'introduction par Scholze de la théorie des diamants).

Via le théorème de classification des fibrés 1.5 cela fournit une classification des espaces de Banach-Colmez. Remarquons que la t-structure intervenant dans ce dernier théorème est analogue à celle utilisée par Bridgeland (BRIDGELAND [2006]) qui a été une inspiration pour ce résultat.

Dans ce cadre là, Fontaine a récemment fait le lien entre le coeur de la t-structure analogue sur les fibrés Galois équivariants et sa théorie des presque $\mathbb{C}_p$-représentations (FONTAINE [2003]). Cela permet de boucler la boucle puisque cette théorie a été une forte inspiration pour la théorie des espaces de Banach-Colmez (FONTAINE [ibid.] sec. 4.1 par exemple).

Enfin, les résultats de BERGER [2008a] clarifient complètement le lien entre fibrés Galois équivariants et la théorie « classique » des (φ, Γ)-modules : si K est de valuation discrète à corps résiduel parfait, $C = \widehat{\overline{K}}$ et $F = C^\flat$ alors la catégorie des fibrés $\mathrm{Gal}(\overline{K}|K)$-équivariants sur la courbe est équivalente à celle des (φ, Γ)-modules.

1.7 Modifications de fibrés et théorie de Hodge p-adique.

1.7.1 Faiblement admissible implique admissible. La première application que nous avons donnée de la courbe avec Fontaine dans FARGUES et FONTAINE [2017], sec. 10, est une nouvelle preuve du théorème « faiblement admissible équivalent à admissible » de COLMEZ et FONTAINE [2000], BERGER [2008b]). C'était la seconde fois, après la preuve du théorème de classification des fibrés, que sont apparues naturellement les modifications de fibrés qui sont devenues essentielles dans la suite (dans l'exposé FARGUES [2010a], p.53, on dit appliquer une correspondance de Hecke lorsqu'on modifie un fibré).

Plus précisément, prenons $E = \mathbb{Q}_p$ et soit $K|\breve{\mathbb{Q}}_p$ une extension de degré fini. On note $C = \widehat{\overline{K}}$ et $\Gamma = \mathrm{Gal}(\overline{K}|K)$. La courbe associée à $C^\flat$ est munie d'une action de Γ et d'un point fermé ∞ de corps résiduel C invariant sous l'action de Γ. Cette action « arithmétique » de Γ rigidifie complètement la situation. On a en effet les propriétés suivantes :

1. ∞ est le seul point fermé dont la Γ-orbite soit finie et donc la catégorie des fibrés Γ-équivariants sur $X \setminus \{\infty\}$ est abélienne (FARGUES et FONTAINE [2017] 10.1.1, 10.1.3)
2. si $(D,\varphi) \in \varphi\text{−Mod}_{\breve{\mathbb{Q}}_p}$ alors les sous-fibrés Γ-invariants de $\mathcal{E}(D,\varphi)_{|X\setminus\{\infty\}}$ sont en bijection avec les sous-isocristaux de (D,φ) (FARGUES et FONTAINE [ibid.] théo. 10.2.14).

Soit donc $(D,\varphi) \in \varphi\text{−Mod}_{\breve{\mathbb{Q}}_p}$ un isocristal. On s'intéresse aux modifications Γ-équivariantes de $\mathcal{E}(D,\varphi)$ en ∞. Ce fibré est trivialisé en ∞ et $\widehat{\mathcal{E}(D,\varphi)}_\infty = D \otimes B_{dR}^+ = D_K \otimes_K B_{dR}^+$. On dispose maintenant de l'énoncé suivant : pour W un K-espace vectoriel de dimension finie il y a une bijection

$$\begin{aligned}\text{Filtrations de W} &\xrightarrow{\sim} \text{réseaux } \Gamma\text{-invariants dans } W \otimes B_{dR}\\ \text{Fil}^\bullet W &\longmapsto \text{Fil}^0(W \otimes B_{dR}).\end{aligned}$$

Du point de vue « de la grassmanienne affine » (SCHOLZE [2014] où Scholze montre que l'on peut mettre une structure de ind-diamant sur ces objets), si μ est un cocaractère diagonal dominant à valeurs dans GL_n et

$$\text{Gr}_\mu = \text{GL}_n(B_{dR}^+)\mu(t)\text{GL}_n(B_{dR}^+)/GL_n(B_{dR}^+)$$

est une cellule de Schubert affine (comme ensemble), il y a une application de Bialynicki-Birula (CARAIANI et SCHOLZE [2017, prop. 3.4.3] pour la version en familles pour n'importe quel groupe)

$$\text{Gr}_\mu \longrightarrow \text{GL}_n(C)/P_\mu(C).$$

Le résultat précédent dit que cela induit une bijection

$$\text{Gr}_\mu^\Gamma \xrightarrow{\sim} \text{GL}_n(K)/P_\mu(K).$$

Il s'agit là d'un résultat analogue au résultat « classique » sur $\mathbb{C}$ qui dit que pour l'action de $\mathbb{G}_m$ sur la cellule affine Gr_μ, avec ici $\text{Gr}(\mathbb{C}) = \text{GL}_n\big(\mathbb{C}(\!(t)\!)\big)/\text{GL}_n\big(\mathbb{C}[\![t]\!]\big)$, induite par $\lambda.t = \lambda t$ avec $\lambda \in \mathbb{G}_m$, alors

$$\text{Gr}_\mu^{\mathbb{G}_m} \xrightarrow{\sim} G/P_\mu.$$

Du point de vue des espaces de lacets cette action algébrique de $\mathbb{G}_m$ correspond à l'action de $U(1)$ de rotation des lacets. *Il y a donc une forte analogie entre $U(1)$ et Γ.* Par exemple, pour $\sigma \in \Gamma$, $\sigma(t) = \chi_{cyc}(\sigma)t$ où ici t est le $2i\pi$ p-adique de Fontaine.

Il résulte de cela que les modifications Γ-équivariantes de $\mathcal{E}(D,\varphi)$ sont en bijection avec les filtrations de D_K. Partant donc d'un φ-module filtré $(D,\varphi,\text{Fil}^\bullet D_K)$ au sens de Fontaine (Fontaine [1994b]) on en déduit par modification un fibré Γ-équivariant $\mathcal{E}(D,\varphi,\mathrm{Fil}^\bullet D_K)$. Sa filtration de Harder-Narasimhan est Γ-invariante et provient donc d'une filtration de (D,φ). Partant de là « le théorème faiblement admissible » implique admissible est une conséquence facile du théorème de classification des fibrés qui implique que $\dim_E H^0(X,\mathcal{F}) = \mathrm{rg}(\mathcal{F})$ ssi $\mathcal{F}$ est semi-stable de pente 0.

On donne également dans Fargues et Fontaine [2017], sec. 10.6, une preuve du théorème de la monodromie p-adique (de Rham implique potentiellement semi-stable (Colmez [2003])) en utilisant la courbe.

1.7.2 Modifications de fibrés et groupes p-divisibles. La preuve du théorème de classification des fibrés utilise de façon fondamentale deux résultats sur les modifications de fibrés qui se déduisent de résultats sur les périodes de groupes p-divisibles. C'est au cours de cette preuve que l'auteur a commencé à s'intéresser aux liens entre groupes p-divisibles et modifications de fibrés. Plus précisément, supposons que $E = \mathbb{Q}_p$ et $F = C^\flat$ avec $C|\mathbb{Q}_p$ algébriquement clos. Si $\mathrm{BT}_{\mathcal{O}_C}$ désigne les groupes de Barsotti-Tate sur $\mathcal{O}_C$ il y a un foncteur

$$\mathfrak{M} : \mathrm{BT}_{\mathcal{O}_C} \otimes \mathbb{Q} \longrightarrow \left\{ \begin{array}{c} \text{modifications minuscules de fibrés en } \infty \\ \mathcal{F} \hookrightarrow \mathcal{E} \text{ avec } \mathcal{F} \text{ semi-stable de pente 0 i.e. trivial} \end{array} \right\}.$$

Ce foncteur admet les deux descriptions suivantes, si $\mathcal{G} \mapsto [\mathcal{F} \hookrightarrow \mathcal{E}]$,

— **[Périodes de de Rham]** On a $\mathcal{F} = V_p(\mathcal{G}) \otimes \mathcal{O}_X$ et $\mathcal{E} = \mathcal{E}(D, p^{-1}\varphi)$ où (D,φ) est le module de Dieudonné covariant de $\mathcal{G}_{k_C}$. Le morphisme $\mathcal{F} \hookrightarrow \mathcal{E}$ est alors donné par une application linéaire

$$V_p(\mathcal{G}) \to H^0(\mathcal{E}(D, p^{-1}\varphi)) = (D \otimes \mathcal{O}(Y))^{\varphi = p}$$

qui est une application de périodes cristallines de Fontaine. Le faisceau $\mathrm{coker}(\mathcal{F} \to \mathcal{E})$ est alors le faisceau gratte-ciel $\mathrm{Lie}(\mathcal{G})[\frac{1}{p}]$ en ∞.

— **[Périodes de Hodge-Tate]** Il y a un morphisme de Hodge-Tate $\alpha_{\mathcal{G}^D} : V_p(\mathcal{G}^D) \to \omega_{\mathcal{G}}[\frac{1}{p}]$ (Fontaine [1981], Fargues [2008], Fargues [2011]) qui induit une surjection $V_p(\mathcal{G}^D) \otimes \mathcal{O}_X \twoheadrightarrow i_{\infty *}\omega_{\mathcal{G}}[\frac{1}{p}]$ et donc une modification. La modification duale de cette modification est $[\mathcal{F} \hookrightarrow \mathcal{E}]$.

Ces deux types de périodes ont été unifiées plus tard via l'introduction des φ-modules sur A_{inf} (cf. Section 1.7.3). Le théorème de classification des fibrés utilise les deux résultats suivants :

1. *(Lafaille/Gross-Hopkins)* Tout élément de $\mathbb{P}^{n-1}(C)$ est la période de de Rham d'un groupe formel de hauteur n et de dimension 1

2. *(Drinfeld)* Tout élément de $\mathbb{P}^{n-1}(C) \setminus \bigcup_{H \in \check{\mathbb{P}}^{n-1}(\mathbb{Q}_p)} H(C)$ est la période de de Rham d'un $\mathcal{O}_D$-module formel spécial et donc (principe des tours jumelles, cf. Section 2.3) la période de Hodge-Tate d'un groupe formel de hauteur n et de dimension 1.

Via le foncteur $\mathfrak{M}$ le point (1) implique que toute modification de degré 1 de $\mathcal{O}(\frac{1}{n})$ est isomorphe à $\mathcal{O}^n$. Le point (2) implique que tout modification de degré -1 de $\mathcal{O}^n$ est isomorphe à $\mathcal{O}^{n-r} \oplus \mathcal{O}(\frac{1}{r})$, $1 \leq r \leq n$ (cf. sec. 8.3 de Fargues et Fontaine [2017]). Réciproquement, le théorème de classification fournit de nouveaux résultats concernant les espaces de périodes p-adiques (cf. Section 2.3). Ainsi, *la courbe est une machine qui recycle les deux résultats précédents pour en produire de nouveaux.*

La catégorie de modifications précédente dans le but de $\mathfrak{M}$ s'identifie (du point de vue des périodes de Hodge-Tate) à celle des couples (V, W) où : V est un $\mathbb{Q}_p$-espace vectoriel de dimension finie et $W \subset V_C$ est un sous-espace. On introduit dans Fargues [2013] la notion de *groupes rigides analytiques de type p-divisible.* Il s'agit de groupes rigides analytiques abéliens G sur C tels que

— $\times p : G \to G$ est surjectif de noyau fini
— $\times p : G \to G$ est topologiquement nilpotent i.e. « G est topologiquement de p^∞-torsion ».

On a alors le théorème suivant.

Théorème 1.10 (Fargues [ibid.]). *1. Le foncteur $\mathcal{G} \mapsto \mathcal{G}^{rig}$ de la catégorie des groupes formels p-divisibles sur $\mathcal{O}_C$ vers les groupes rigides analytiques de type p-divisible est pleinement fidèle, d'image essentielle les groupes G tels que $G \simeq \mathring{\mathbb{B}}^d_C$ comme espaces rigide pour un entier d.*

2. La catégorie des groupes rigides analytiques p-divisibles s'identifie à celle des triplets (Λ, W, u) où Λ est un $\mathbb{Z}_p$-module libre de rang fini, W un C-espace vectoriel de dimension finie et $u : W \to \Lambda_C$ est C-linéaire.

Dans le point (2), au triplet (Λ, W, u) on associe le groupe rigide analytique $(\log \otimes Id)^{-1}(W \otimes \mathbb{G}_a)$ dans la suite exacte

$$0 \longrightarrow \big(\Lambda[\tfrac{1}{p}]/\Lambda\big)(1) \longrightarrow \widehat{\mathbb{G}}_m^{rig} \otimes_{\mathbb{Z}_p} \Lambda \xrightarrow{\log \otimes Id} \mathbb{G}_a \otimes \Lambda_C \longrightarrow 0.$$

Les groupes G associés aux triplets (Λ, W, u) avec u injectif correspondent aux groupes G « hyperboliques » i.e. tels que tout morphisme rigide analytique $\mathbb{A}^1 \to G$ soit constant. Les groupes rigides analytiques de type p-divisible hyperboliques à isogénie près sont donc équivalents aux modifications minuscules dans le but du foncteur $\mathfrak{M}$. Ce même foncteur $\mathfrak{M}$ est donc de plus pleinement fidèle d'après le point (1) du théorème précédent. Scholze et Weinstein on complété ce résultat en montrant qu'il est en fait essentiellement surjectif.

Théorème 1.11 (Scholze et Weinstein [2013]). *Le foncteur $\mathfrak{M}$ est une équivalence de catégories.*

Leur preuve consiste à montrer que si C est sphériquement complet avec comme groupe de valuations $\mathbb{R}$, alors pour tout groupe rigide analytique de type p-divisible G « hyperbolique » on a $G \simeq \mathring{\mathbb{B}}_C^d$. Ils montrent ensuite que l'on peut descendre du cas C sphériquement complet au cas C quelconque en utilisant le fait que les orbites de Hecke, comme fibres des applications de périodes de de Rham de Rapoport-Zink, sont des espaces rigides de dimension 0.

1.7.3 φ-modules sur A_{inf} et modifications de fibrés. Il s'est alors posé la question de savoir comment faire le lien par un objet intermédiaire entre périodes de Hodge-Tate et de de Rham. Le point de départ est la remarque suivante qui résulte du théorème de factorisation 1.3 : les modifications de $\mathcal{O} \hookrightarrow \mathcal{O}(d)$ sont toutes obtenues par un procédé itératif qui est le suivant. Partant de ξ primitif de degré d tel que $\xi = \sum_{n\geq 0}[x_n]\pi^n$ avec $x_d \in 1 + \mathfrak{m}_F$ on peut former le produit de Weierstrass

$$\prod_{n\geq 0} \frac{\varphi^n(\xi)}{\pi^d} \cdot « \prod_{n<0} \varphi^n(\xi) » \in \mathcal{O}(Y)^{\varphi=\pi^d}$$

le produit entre guillemets n'étant pas convergeant mais pouvant être défini comme solution de l'équation fonctionelle $\varphi(x) = \xi x$ dans $\mathbf{A}$ (cf. Fargues et Fontaine [2017] sec. 6.3). Cela a conduit (Fargues [2015c]) à la « version perfectoïde » suivante des φ-modules de Breuil-Kisin (Kisin [2006]). Soit ξ primitif de degré 1 qui engendre le noyau de $\theta : \mathbf{A} \to \mathcal{O}_C$. Par définition un φ-module sur $\mathbf{A}$ est un couple (M, φ) où M est un $\mathbf{A}$-module libre et $\varphi : M \to M$ est semi-linéaire de conoyau annulé par une puissance de ξ. On a alors le résultat suivant.

Théorème 1.12 (Fargues [2015c], Scholze [2014]). *Il y a une anti-équivalence entre $\varphi-\mathrm{Mod}_{\mathbf{A}}$ et la catégorie des modifications de fibrés en ∞, $\mathcal{F} \hookrightarrow \mathcal{G}$ avec $\mathcal{F}$ trivial muni d'un réseau dans $H^0(X, \mathcal{F})$.*

Partant d'un φ-module (M, φ) on construit un *« Shtuka »* $(\mathfrak{M}, \varphi) = (M \otimes \mathcal{O}_Y, \varphi \otimes \varphi)$ sur Y dont le zéro est localisé en $V(\xi)$, coker$(\mathfrak{M} \xrightarrow{\varphi} \mathfrak{M})$ est supporté en $V(\xi)$. On forme alors (Fargues [2015c] sec. 4.4)

$$\mathfrak{M}_\infty = \varprojlim_{n\geq 0} \varphi^{n*}\mathfrak{M} \ \text{ et } \ \mathfrak{M}^\infty = \varinjlim_{n\leq 0} \varphi^{n*}\mathfrak{M},$$

(opération qui est l'analogue du produit de Weierstrass précédent pour GL_1). Puisque φ « dilate sur le disque épointé Y » les deux limites précédentes sont essentiellement

constantes sur tout ouvert quasicompact de Y, et $\mathfrak{M}_\infty$ et $\mathfrak{M}^\infty$ sont donc des fibrés φ-équivariants i.e. des fibrés sur X^{ad}. La modification associée à (M,φ) est alors la duale de $\mathfrak{M}_\infty \hookrightarrow \mathfrak{M}^\infty$.
Dans l'autre sens une telle modification fournit par un procédé inverse un tel Shtuka $(\mathfrak{M},\varphi)$ sur Y. On utilise alors la compactification par deux diviseurs (Scholze [2014])

$$\mathcal{Y} = \mathrm{Spa}(\mathbf{A},\mathbf{A}) \setminus V(\pi,[\varpi]) = Y \cup V(\pi) \cup V([\varpi]).$$

En utilisant le théorème 11.1.7 de Fargues et Fontaine [2017] on vérifie que $\mathfrak{M}$ s'étend automatiquement grâce à la structure de Frobenius le long du diviseur $([\varpi])$. En utilisant la condition de trivialité de $\mathscr{F}$ couplée au choix du réseau dans $H^0(X,\mathscr{F})$ on vérifie que $\mathfrak{M}$ s'étend en $\pi = 0$. Le fibré $\mathfrak{M}$ s'étend donc canoniquement à $\mathcal{Y}$. On peut alors appliquer le résultat GAGA de Kedlaya (Kedlaya [2016b]) qui dit que les fibrés sur $\mathrm{Spec}(\mathbf{A}) \setminus V(\pi,[\varpi])$ et $\mathrm{Spa}(\mathbf{A},\mathbf{A}) \setminus V(\pi,[\varpi])$ s'identifient et que ceux-ci sont triviaux pour conclure ($\mathbf{A}$ se comporte en quelque sorte comme un anneau local régulier de dimension 2).

Partant de $(M,\varphi) \in \varphi\text{-}\mathrm{Mod}_{\mathbf{A}}$, si $(\mathfrak{N},\varphi) = (M,\varphi)\otimes \mathcal{O}_{\mathfrak{Y}}$:
- si $V(\pi) = \{y_{\text{ét}}\}$ (diviseur étale) : $(\mathfrak{N}_{y_{\text{ét}}},\varphi)$ fournit le fibré trivial $\mathscr{F}^\vee$ ainsi que le réseau dans $H^0(X,\mathscr{F}^\vee)$,
- si $V([\varpi]) = \{y_{\text{cris}}\}$ (diviseur cristallin) : $(\mathfrak{N}_{y_{\text{cris}}},\varphi)$ fournit le fibré $\mathscr{G}^\vee$ qui est associé à l'isocristal $(\mathfrak{N}_{y_{\text{cris}}}\otimes k(y_{cris}),\varphi)$,
- si $V(\xi) = \{y_{\text{dR}}\}$ (diviseur de de Rham) : l'inclusion de B_{dR}^+-réseaux $\varphi : \widehat{\mathfrak{N}}_{\varphi(y_{\text{dR}})} \hookrightarrow \widehat{\mathfrak{N}}_{y_{\text{dR}}}$ fournit la filtration de Hodge i.e. la modification $\mathscr{G}^\vee \hookrightarrow \mathscr{F}^\vee$.

C'est en ce sens là que l'on a unifié les différentes périodes. On renvoie à Scholze [2014] pour plus de détails.

Comme corollaire du théorème précédent on déduit comme dans Kisin [2006] que la catégorie des groupes p-divisibles sur $\mathcal{O}_C$ s'identifie à celle des φ-modules sur $\mathbf{A}$, (M,φ), tels que coker φ soit annulé par ξ (Fargues [2015c] sec 4.8). Ce résultat a été repris par Lau sur des bases affinoïdes perfectoïdes plus générales dans Lau [2016] par les méthodes de Displays/Windows de Zink. Remarquons enfin que sur $\mathcal{O}_C$ l'hypothèse $p \neq 2$ de Fargues [2015c] et Lau [2016] n'est en fait pas nécessaire puisque tout groupe p-divisible $\mathcal{G}$ sur $\mathcal{O}_C$ est somme directe d'un groupe étale et d'un groupe connexe.

Si X est un schéma propre et lisse sur $\mathcal{O}_K$ de valuation discrète à corps résiduel parfait avec $C = \widehat{\overline{K}}$, les différents théorèmes de comparaison cristallins/semi-stables (Fontaine et Messing [1987], Tsuji [1999], Niziol [2008] par exemple) fournissent automatiquement de telles modifications de fibrés avec $\mathscr{F} = H^\bullet_{\text{ét}}(X_{\overline{K}},\mathbb{Q}_p)\otimes \mathcal{O}_X$ et $\mathscr{G} = \mathscr{E}(D,\varphi)$,

(D, φ) étant la cohomologie cristalline de la fibre spéciale X_{k_K}. On peut donc définir grâce à 1.12 une théorie cohomologique sur de tels X à valeurs dans les φ-modules sur $\mathbf{A}$.

À la suite de cela Bhatt, Morrow et Scholze (Bhatt, Morrow et Scholze [2015], Bhatt, Morrow et Scholze [2016]) ont défini de manière géométrique une telle théorie cohomologique sur les schémas formels propres et lisses sur $\mathcal{O}_C$, à valeurs dans des complexes de φ-modules sur $\mathbf{A}$ et ont donné des applications à l'étude de la torsion dans la cohomologie étale de ces variétés. Le point est qu'ils ne construisent pas seulement des φ-modules sur $\mathbf{A}$ mais plutôt un *complexe de cohomologie*, ce qui raffine la construction précédente et donne des informations sur la torsion. En effet, l'équivalence du théorème 1.12 n'est pas une équivalence exacte et ne passe pas aux complexes de cohomologie.

Notons également que Niziol a interprété la cohomologie syntomique géométrique en termes de fibrés sur la courbe dans Niziol [p. d.]. Plus précisément, la cohomologie de Deligne s'interprète parfois comme groupes d'extensions de structures de Hodge mixtes, les régulateurs archimédiens envoyant une extension de motifs mixtes sur l'extension correspondante de structures de Hodge. Niziol donne une interprétation similaire dans Niziol [ibid.] pour la cohomologie syntomique en termes d'extensions de modifications de fibrés vectoriels.

Enfin concluons par la conjecture suivante, apparue au cours de nombreuses discussions avec Le Bras et Scholze, également inspirée par les travaux de Colmez et Niziol (Colmez et Niziol [2017] sec. 5.2 où les espaces de Banach-Colmez apparaissent naturellement) qui devrait généraliser la cohomologie de Hyodo-Kato des schémas propres et lisses à réduction semi-stable.

Conjecture 1.13. *Soit $C|\mathbb{Q}_p$ complet et algébriquement clos. On peut définir une théorie cohomologique sur les C-espaces rigides lisses quasicompacts séparés, à valeurs dans les fibrés vectoriels sur la courbe associée à $C^\flat$ qui généralise la cohomologie de Hyodo-Kato des schémas propres et lisses à réduction semi-stable. Cette théorie cohomologique devrait se factoriser par la catégorie des motifs rigides de Ayoub (Ayoub [2015]).*

On espère même la construction d'un complexe de cohomologie dans $\mathbb{D}^b_{coh}(\mathcal{O}_X)$. Par semi-simplification de la filtration de Harder-Narasimhan cela fournirait une théorie cohomologique à valeurs dans les isocristaux. Cependant la conjecture précédente est plus subtile puisqu'on prédit l'existence d'un relèvement au niveau des fibrés. Bien sûr si $C = \widehat{\overline{K}}$ cela devrait définir une théorie cohomologique sur de tels K-espaces rigides à valeurs dans les fibrés Galois équivariants.

2 Géométrisation de l'ensemble de Kottwitz et applications

2.1 Géométrisation. Dans cette section X est la courbe associée à un corps F algébriquement clos et E comme précédemment. Soit G un groupe réductif sur E. On considère l'ensemble de Kottwitz $B(G) = G(\breve{E})/\sigma$-conj. des classes d'isomorphismes de G-isocristaux. Ici par σ-conjugaison on entend $b \sim gbg^{-\sigma}$. Si $b \in G(\breve{E})$ on peut lui associer un G-fibré sur X par composition

$$\begin{aligned} \mathrm{Rep}(G) &\longrightarrow \varphi\mathrm{-Mod}_{\breve{E}} \xrightarrow{\mathcal{E}(-)} \text{fibrés sur } X \\ (V,\rho) &\longmapsto \big(V_{\breve{E}}, \rho(b)\sigma\big). \end{aligned}$$

On le note $\mathcal{E}_b$ et on le voit également comme un G-torseur étale. Tiré en arrière sur la courbe adique il s'agit du G^{an}-torseur localement trivial pour la topologie adique

$$Y \times_{\varphi^{\mathbb{Z}}} G^{an}_{\breve{E}}$$

où φ agit sur $G_{\breve{E}}$ via $b\sigma$. Le théorème principal de Fargues [2016a] est alors le suivant (cf. Anschütz [2017] pour le cas $E = \mathbb{F}_q((\pi))$). Il s'agit d'une généralisation du théorème de classification 1.5.

Théorème 2.1 (Fargues [2016a], Anschütz [2017]). *Il y a une bijection d'ensembles pointés*

$$\begin{aligned} B(G) &\xrightarrow{\sim} H^1_{\text{ét}}(X,G) \\ [b] &\longmapsto [\mathcal{E}_b]. \end{aligned}$$

Ce résultat est utilisé dans Caraiani et Scholze [2017] afin de construire des applications de périodes de Hodge-Tate pour des variétés de Shimura de type Hodge et stratifier par un ensemble de Kottwitz la variété de drapeaux au but de ces applications de périodes.

Cette bijection satisfait des propriétés très agréables :

- Il y a un *dictionnaire entre théorie de la réduction de Harder-Narasimhan/ Atiyah-Bott et la description par Kottwitz de* $B(G)$. Par exemple :
  - b est basique ssi $\mathcal{E}_b$ est semi-stable
  - le polygone de Harder-Narasimhan $\{\nu_{\mathcal{E}_b}\}$ vu comme classe de conjugaison géométrique de cocaractère $\mathbb{D} \to G_{\overline{F}}$ est égal à $\{\nu_b^{-1}\}$ l'inverse du polygone de Newton.
- L'application $\kappa : B(G) \to \pi_1(G)_\Gamma$ de Kottwitz s'interprète comme l'opposé d'une *première classe de Chern d'un G-fibré.*
- On dispose d'un *analogue du théorème de Drinfeld-Simpson* : lorsque G est quasi-déployé, pour tout point fermé $\infty \in |X|$, $\mathcal{E}_{|X\setminus\{\infty\}}$ est trivial. Les fibrés sur X s'obtiennent ainsi par recollement « à la Beauville-Laszlo » et donc si $\{\infty\} = V^+(t)$, de corps résiduel C, le groupoïde des G-fibrés sur X s'identifie au groupoïde quotient

$$\big[G\big(\mathcal{O}(Y)[\tfrac{1}{t}]^{\varphi=Id}\big)\backslash G(B_{dR}(C))/G(B^+_{dR}(C))\big].$$

2.2 Interprétation géométrique de certains résultats de Tate. On suppose dans cette section que $E|\mathbb{Q}_p$. Durant la démonstration du théorème 2.1 est apparu un lien intéressant entre théorie du corps de classe et fibrés sur la courbe. Par exemple, si B est une algèbre à division sur E, d'après la théorie du corps de classe (calcul du groupe de Brauer), il existe un isocristal isocline (D, φ) tel que $B \simeq End(D, \varphi)$. On a alors

$$B \otimes_E \mathcal{O}_X \xrightarrow{\sim} \mathcal{E}nd(\mathcal{E}(D, \varphi)).$$

Il en résulte que le morphisme $\mathrm{Br}(E) \to \mathrm{Br}(X)$ est nul. Partant de ce résultat on démontre dans Fargues [2016a] que *le groupe de Brauer* $\mathrm{Br}(X)$ *est nul.* On conjecture même en fait que le corps des fonctions de X est (C1) (Fargues [ibid.]).

On peut aller plus loin dans les liens entre corps de classe et cohomologie de la courbe. On note $\Gamma = \mathrm{Gal}(\overline{E}|E)$. D'après le théorème 1.8 les systèmes locaux étales finis sur X correspondent par tiré en arrière via $X \to \mathrm{Spec}(E)$ aux Γ-modules discrets finis. On a alors le résultat suivant.

Théorème 2.2 (Fargues [ibid.]). *Soit M un Γ-module discret fini et $\mathcal{F}$ le faisceau étale localement constant associé sur X par tiré en arrière via $X \to \mathrm{Spec}(E)$. On a alors :*

1. $H^\bullet(E, M) \xrightarrow{\sim} H^\bullet_{\text{ét}}(X, \mathcal{F})$.
2. *Via cet isomorphisme pour $M = \mathbb{Z}/n\mathbb{Z}(1)$, la classe fondamentale de la théorie du corps de classe correspond à la classe fondamentale de la courbe $\eta_X = c_1(\mathcal{O}(1)) \in H^2_{\text{ét}}(X, \mathbb{Z}/n\mathbb{Z}(1))$, c'est à dire la classe de cycle d'un point fermé sur la courbe.*

On peut ainsi réinterpréter (mais pas redémontrer complètement jusqu'à maintenant i.e. par des méthodes purement géométriques) géométriquement les deux théorèmes suivants de Tate :

1. La dualité de Tate-Nakayama s'interprète comme la *dualité de Poincaré sur la courbe.*
2. La formule de Tate pour la caractéristique d'Euler-Poincaré de la cohomologie galoisienne s'interprète comme une *formule de Grothendieck-Ogg-Shafarevich.*

On espère pouvoir étudier les systèmes locaux sur des ouverts de la courbe ainsi que leur cohomologie (cf. Fargues [ibid.] sec. 3.3 pour des conjectures précises et également Fargues [2015a] sec. 7 pour une description conjecturale du groupe fondamental d'un ouvert).

2.3 Application aux espaces de périodes p-adiques. Rapoport a donné une première application du théorème 2.1 aux espaces de périodes de Rapoport et Zink [p. d.] dans

RAPOPORT [p. d.] en montrant que le lieu admissible coïncide avec toute la variété de drapeaux uniquement dans le cas Lubin-Tate et son dual de Cartier. Il faut faire attention ici que, bien que le théorème de Colmez-Fontaine dise que « admissible est équivalent à faiblement admissible », du point de vue géométrique des espaces de périodes cela dit uniquement que les lieux admissible et faiblement admissible ont mêmes points à valeurs dans des corps p-adiques de valuation discrète, mais ils ne sont pas égaux en général.

Rappelons le contexte de ce type de problème (RAPOPORT et ZINK [p. d.],DAT, ORLIK et RAPOPORT [2010]). On fixe une classe de conjugaison géométrique de cocaractère minuscule $\{\mu\}$ à valeurs dans G et on regarde la variété de drapeaux associée $\mathfrak{F}(G,\mu)$ comme espace adique sur le complété de l'extension maximale non ramifiée du corps de définition de $\{\mu\}$. On fixe un isocristal avec G-structure $[b] \in B(G,\mu)$, l'ensemble de Kottwitz (KOTTWITZ [1997]) qui paramètre les strates de Newton dans les variétés de Shimura dont la donnée induit (G,μ) localement en p (la non vacuité des strates de Newton associées à un élément de $B(G,\mu)$, conjecturée dans FARGUES [2004], est connue dans de très nombreux cas maintenant). On regarde le lieu faiblement admissible $\mathfrak{F}(G,\mu,b)^{\mathrm{fa}}$, un ouvert partiellement propre obtenu en enlevant un nombre fini de $J_b(E)$-orbites de variétés de Schubert où la condition de faible admissibilité de Fontaine n'est pas satisfaite. Rapoport et Zink avaient conjecturé dans RAPOPORT et ZINK [p. d.] l'existence d'un ouvert

$$\mathfrak{F}(G,\mu,b)^{\mathrm{a}} \subset \mathfrak{F}(G,\mu,b)^{\mathrm{fa}}$$

ayant même points classiques de Tate (à valeurs dans un corps de valuation discrète) que $\mathfrak{F}(G,\mu)^{\mathrm{a}}$, ainsi que l'existence d'un E-système local étale avec G-structure dessus qui interpolerait les représentations cristallines à valeurs dans $G(E)$ en les points classiques. Ces dernières représentations sont fournies par Fontaine via le théorème « faiblement admissible équivalent à admissible » en ces points. L'existence de cet ouvert est maintenant connue grâce à la courbe, les travaux de Kedlaya-Liu (KEDLAYA et LIU [2015], cf. le point (1) du théorème 3.1) et de Scholze (SCHOLZE [p. d.]), cf. sec. 3 de CHEN, FARGUES et SHEN [2017] pour un rapide survol. Grâce à cela on peut construire les variétés de Shimura locales associées (RAPOPORT et VIEHMANN [2014]) comme espace de réseaux dans ce système local (de JONG [1995]).

Dans HARTL [2013] Hartl classifie les μ minuscules associés à $G = \mathrm{GL}_n$ tels que $\mathfrak{F}^{\mathrm{a}} = \mathfrak{F}^{\mathrm{fa}}$. Inspirés entre autre par ce résultat, Rapoport et l'auteur ont conjecturé le résultat suivant qui est maintenant démontré.

Théorème 2.3 (CHEN, FARGUES et SHEN [2017])**.** *Pour $[b] \in B(G,\mu)$ basique sont équivalents*

1. $\mathfrak{F}(G,\mu,b)^{\mathrm{a}} = \mathfrak{F}(G,\mu,b)^{\mathrm{fa}}$.
2. *L'ensemble $B(G,\mu)$ est pleinement HN décomposable.*

Par définition l'ensemble $B(G,\mu)$ est pleinement HN décomposable si pour tout $[b'] \in B(G,\mu)$ non basique son polygone de Newton, comme élément d'une chambre de Weyl positive, « touche le polygone de Hodge défini par μ en dehors de ses extrémités ». Les espaces/variétés de Shimura associés aux ensembles $B(G,\mu)$ pleinement HN décomposables jouissent de propriétés tout à fait remarquables (Goertz, He et Nie [2016]). Le premier exemple de tel ensemble qui a intrigué l'auteur remonte à « l'astuce de Boyer » aka la décomposition de Hodge-Newton (Boyer [1999] pour l'astuce originelle, Harris et Taylor [2001] pour sa variante variétés de Shimura, Mantovan [2008], Mantovan et Viehmann [2010], Shen [2014b] pour des généralisations au cas des variétés de Shimura, Goertz, He et Nie [2016] pour le cas de la fibre spéciale, Hansen [2016] and Gaisin et Imai [2016] pour des versions "modernes" dans le cadre des espaces de module de Shtukas locaux).

Voici un exemple de $(2) \Rightarrow (1)$ dans le théorème précédent. Il avait été traité auparavant (Fargues [2015b], appendice de Shen [2016]) et a servi de guide dans la démonstration de $(2) \Rightarrow (1)$.

Corollaire 2.4 (Application de la courbe aux surfaces)**.** *Supposons $p \neq 2$. Soit $\mathcal{F} = \{q = 0\} \subset \P^{20}_{\breve{\mathbb{Q}}_p}$ la variété de drapeaux formées des droites isotropes pour la forme quadratique q telle que $q(x) = \sum_{i=1}^{21} x_i x_{22-i}$. Soit $Z = \{x_{12} = \cdots = x_{21} = 0\} \cap \mathcal{F}$, une variété de Schubert pour $G = SO(q)$. L'espace des périodes p-adiques des surfaces K3 polarisées à réduction supersingulière s'identifie à $\mathcal{F} \setminus G(\mathbb{Q}_p) \cdot Z$.*

La démonstration du théorème 2.3 repose sur la construction suivante. À $x \in \mathcal{F}(G,\mu)(C)$ est associé une modification $\mathcal{E}_{b,x}$ de $\mathcal{E}_b$. En effet, $\mathcal{E}_b$ est canoniquement trivialisé en ∞ et on utilise le fait que μ est minuscule afin d'associer à un tel x une donnée de modification dans $G(B_{dR})/G(B_{dR}^+)$. Via le théorème 2.1 la classe d'isomorphisme de $\mathcal{E}_{b,x}$ fournit un élément de $B(G)$. On peut classifier ces éléments possibles par un autre ensemble (fini) de Kottwitz $B(G, 0, \nu_b\mu^{-1})$ (Rapoport [p. d.] coro. 0.10, Chen, Fargues et Shen [2017] sec. 4). Cela fournit une stratification de $\mathcal{F}(G,\mu)$, la strate ouverte étant celle associée à $[1] \in B(G)$ qui est exactement l'ouvert admissible i.e. le lieu où le G-fibré $\mathcal{E}_{b,x}$ est trivial (cf. Chen, Fargues et Shen [ibid.] sec. 5). C'est l'étude de cette stratification qui mène à la preuve du théorème 2.3. Ce type de stratification apparaît également dans Caraiani et Scholze [2017] par le même type de construction. En effet, les périodes de Hodge-Tate et de de Rham de la Section 1.7.2 s'interprètent agréablement au sens où si $\mathcal{E}_b \rightsquigarrow \mathcal{E}_1$ est une modification minuscule de type μ en ∞ :

— sa *période de de Rham* est donnée par l'élément $x \in \mathcal{F}(G,\mu)(C)$ qui identifie la modification à $\mathcal{E}_b \rightsquigarrow \mathcal{E}_{b,x}$

— sa *période de Hodge-Tate* est donnée par l'élément $y \in \mathcal{F}(G,\mu^{-1})(C)$ qui identifie la modification à $\mathcal{E}_{1,y} \rightsquigarrow \mathcal{E}_b$.

Ces périodes de Hodge-Tate et de de Rham sont l'ombre de deux pattes du champ de Hecke des modifications des G-fibrés (cf. Section 3.3). Ce type de considérations sur les périodes de Hodge-Tate et de de Rham a été une très forte inspiration pour l'introduction de la conjecture de géométrisation de la Section 3.

Puisque nous l'utilisons dans la preuve du théorème 2.3, remarquons que la considération des G-fibrés sur la courbe, pour G quelconque, clarifie complètement *l'isomorphisme entre les tours jumelles* de Faltings [2002] et Faltings [2004] (cf. également Fargues [2008] et Scholze et Weinstein [2013]). Plus précisément, pour $[b] \in B(G)$ basique le groupe réductif J_b devient une forme intérieure pure de G après extension des scalaires à la courbe : *$J_b \times X$ est la torsion intérieure de $G \times X$ par le G-torseur $\mathcal{E}_b$.* Il en résulte une équivalence de groupoïdes entre J_b-fibrés sur X et G-fibrés sur X qui respecte les modifications. À partir de là les espaces de modules de modifications sont identifiés. On renvoie à la section 5.1 de Chen, Fargues et Shen [2017] pour plus de détails.

Enfin, l'auteur a commencé à s'intéresser aux filtrations du type Harder-Narasimhan en théorie de Hodge p-adique lors de la découverte de l'existence de telles filtrations sur les schémas en groupes finis et plats (Fargues [2010b]). Ces filtrations permettent de définir des domaines fondamentaux dans les espaces de modules de groupes p-divisibles (Fargues [ibid.] coro. 11 et Shen [2014a]). On a alors la conjecture suivante concernant l'existence de « domaines fondamentaux de Siegel » dans les espaces de périodes p-adiques. Cette conjecture est liée au théorème 2.3 via le fait que lorsque $B(G,\mu)$ est pleinement HN décomposé alors $\mathcal{F}(G,\mu) \setminus \mathcal{F}(G,\mu,b)^{\mathrm{a}}$ est « paraboliquement induit » (Chen, Fargues et Shen [2017] sec. 7).

Conjecture 2.5 (Chen, Fargues et Shen [ibid.] sec. 7)**.** *Pour $[b] \in B(G,\mu)$ basique, sont équivalents :*

1. $\mathcal{F}(G,\mu,b)^{\mathrm{a}} = \mathcal{F}(G,\mu,b)^{\mathrm{fa}}$
2. *Il existe un ouvert quasicompact $U \subset \mathcal{F}(G,\mu,b)^{\mathrm{a}}$ tel que $\mathcal{F}(G,\mu,b)^{\mathrm{a}} = J_b(E)\cdot U$.*

Si $\underline{G}$ est un modèle entier de G, les filtrations de Harder-Narasimhan des schémas en groupes finis et plats s'étendent aux φ-modules de Breuil-Kisin avec $\underline{G}$-structure (Levin et Wang-Ericksson [2016], Peche Irissarry [p. d.]) ainsi qu'aux φ-modules sur A_{inf} de la Section 1.7.3. En étudiant les $\underline{G}$-Shtukas sur $\mathfrak{Y}$ il est probable que l'on puisse généraliser la preuve de 1.12 à cadre là. On peut donc espérer des constructions générales de tels domaines fondamentaux grâce à ces techniques.

3 Géométrisation de la correspondance de Langlands locale

3.1 La courbe en familles. Soit $\mathrm{Perf}_{\mathbb{F}_q}$ la catégorie des $\mathbb{F}_q$-espaces perfectoïdes (Scholze [2012]). On ne s'intéresse désormais qu'à la courbe adique et on note X ce que l'on notait auparavant X^{ad}. Pour $S \in \mathrm{Perf}_{\mathbb{F}_q}$ on peut construire un E-espace adique X_S que l'on peut voir comme étant « la famille de courbes adiques $(X_{k(s),k(s)^+})_{s\in S}$ ». Comme dans le cas d'un point base

$$X_S = Y_S/\varphi^{\mathbb{Z}}$$

où Y_S est « Stein ». Par exemple, si $E = \mathbb{F}_q((\pi))$, $Y_S = \mathbb{D}_S^* = \{0 < |\pi| < 1\} \subset \mathbb{A}_S^1$ et le Frobenius φ est donné par celui de S. Lorsque $S = \mathrm{Spa}(R, R^+)$ est affinoïde perfectoïde l'espace Y_S se définit comme étant

$$\mathrm{Spa}(\mathbf{A}, \mathbf{A}) \setminus V(\pi[\varpi])$$

où $\mathbf{A} = W_{\mathcal{O}_E}(R^+)$ si $E|\mathbb{Q}_p$, $\mathbf{A} = R^+[\![\pi]\!]$ si $E = \mathbb{F}_q((\pi))$ et ϖ est une pseudo-uniformisante de R, $0 < |\varpi| < 1$. Ces E-espaces adiques sont pré-perfectoïdes et on montre que

$$Y_S^{\diamond} = S \times \mathrm{Spa}(E)^{\diamond}$$

où $\varphi \leftrightarrow \varphi_S \times Id$. Ici on utilise la notion de diamant introduite par Scholze (Scholze [2014], Scholze [p. d.]). Si Z est un E-espace adique alors $Z^{\diamond}$ est le faisceau sur $\mathrm{Perf}_{\mathbb{F}_q}$ tel que

$$Z^{\diamond}(T) = \{(T^{\sharp}, \iota, f) \,|T^{\sharp} \text{ est perfectoïde}, \iota : T \xrightarrow{\sim} T^{\sharp,\flat}, f : T^{\sharp} \to Z\}/\sim .$$

Cette formule catégorique, bien que particulièrement élégante, ne dit rien sur la géométrie de Y_S (par exemple elle ne dit rien sur ce qu'est un fibré vectoriel sur X_S).

3.2 Résultats de Kedlaya et Liu sur les familles de fibrés. Kedlaya et Liu ont montré que l'on dispose d'une bonne notion de fibré vectoriel sur des espaces adiques du type X_S (Kedlaya et Liu [2015] sec. 2.7). Ils ont également démontré les trois résultats suivants qui sont au coeur de la structure du champ des G-fibrés sur la courbe (leurs résultats sont énoncés de manière moins « géométrique » en termes de φ-modules sur des anneaux de Robba mais sont équivalents à ceux qui suivent). Dans cet énoncé

$$\tau : \widetilde{(X_S)}_{\text{pro-ét}} \longrightarrow \widetilde{S}_{\text{pro-ét}}$$

est un morphisme de topos pro-étales obtenu par exemple grâce à la fonctorialité de la courbe en la base S.

Théorème 3.1. *Pour S un $\mathbb{F}_q$-espace perfectoïde et $\mathcal{E}$ un fibré vectoriel sur X_S*

1. *La fonction $|S| \ni s \longmapsto \mathrm{HN}(\mathcal{E}_{|X_{k(s),k(s)^+}})$ (polygone de Harder-Narasimhan) est semi-continue supérieurement. En particulier le lieu semi-stable dans S est un ouvert partiellement propre.*

2. *Les foncteurs $R\tau_*$ et $\tau^*(-)\otimes_{\underline{E}}\mathcal{O}_X$ induisent des équivalences inverses entre fibrés vectoriels, fibre à fibre sur S semi-stables de pente 0, et E-systèmes locaux pro-étales sur S.*
3. *Le fibré $\mathcal{O}(1)$ est ample au sens où, si S est affinoïde perfectoïde, alors pour $d \gg 0$ il existe une surjection $\mathcal{O}_{X_S}^n \twoheadrightarrow \mathcal{E}(d)$.*

Le point (1) se reformule de façon agréable de la façon suivante (c'est un exercice de vérifier que les deux sont équivalents). Il y a deux fonctions additives (introduites par Colmez dans Colmez [2002]) sur la catégorie des espaces de Banach-Colmez sur $C|E$ (cf. Section 1.6). Ce sont les fonctions dimension et hauteur déterminées par $\dim \mathbb{G}_a = 1$, $\dim \underline{E} = 0$, $\mathrm{ht}\, \mathbb{G}_a = 0$ et $\mathrm{ht} \underline{E} = 1$ (par référence à la hauteur et la dimension du revêtement universel d'un groupe p-divisible, un cas particulier d'espace de Banach-Colmez). Pour un fibré vectoriel $\mathcal{F}$ sur la courbe X_F associée à $F = C^\flat$ on peut alors définir la dimension et la hauteur des espaces de Banach-Colmez $H^0(X_F, \mathcal{F})$ et $H^1(X_F, \mathcal{F})$ (plus précisément, ces espaces sont définis par troncature via la t-structure du théorème 1.9, la fonction dimension sur le coeur de cette t-structure coïncide alors avec le degré et la hauteur avec le rang, les deux vues comme fonctions additives sur $\mathbb{D}^b_{coh}(\mathcal{O}_{X_F})$). Le point (1) se reformule alors en le fait que pour $\bullet \in \mathbb{N}$, la fonction

$$|S| \longrightarrow \big(\dim H^\bullet(X_{k(s),k(s)^+}, \mathcal{E}_{|X_{k(s),k(s)^+}}), \mathrm{ht}\, H^\bullet(X_{k(s),k(s)^+}, \mathcal{E}_{|X_{k(s),k(s)^+}})\big) \in \mathbb{N}\times\mathbb{Z}$$

est semi-continue supérieurement (puisque $\dim H^0 - \dim H^1 = \deg \mathcal{E}$ et $\mathrm{ht}\, H^0 - \mathrm{ht}\, H^1 = \mathrm{rg} \mathcal{E}$ qui sont localement constants, cela se ramène au même énoncé pour le H^0). Cela replace ce type de résultat dans le cadre conceptuel des résultats de semi-continuité de Grothendieck [1963] (mais malheureusement l'auteur ne sait pas donner un sens au fait que $R\tau_*\mathcal{E}$ soit un « complexe parfait de quoi que ce soit », ce qui donnerait une preuve rapide de cette semi-continuité).

Le point (2) est une vaste généralisation aux $\mathbb{Q}_p$-systèmes locaux du théorème de Lang (qui concerne les $\mathbb{Z}_p$-systèmes locaux). Plus précisément, si $S = \mathrm{Spa}(R, R^+)$ alors d'après Lang,

$$\underline{\mathcal{O}_E}\text{-systèmes locaux pro-étales} \xrightarrow{\sim} \varphi\text{−}\mathrm{Mod}^{\text{ét}}_{\mathbf{A}_{R,R^+}}$$

où les φ-modules sont ceux de la Section 1.7.3 et la condition d'être étale signifie simplement que $\varphi : M \xrightarrow{\sim} M$ est un isomorphisme. Cette condition se réécrit du point de vue du théorème précédent en demandant que pour tout $s \in S$, $(M, \varphi) \otimes_{\mathbf{A}_{R,R^+}} \mathbf{A}_{k(s),k(s)^+}$ soit étale. Le point (2) du théorème précédent remplace donc la condition d'être étale fibre à fibre par la condition d'être semi-stable de pente 0 fibre à fibre et l'anneau $\mathbf{A}$ par un anneau de Robba.

Remarquons que le point (2) est également une généralisation du résultat « du type Narasimhan-Seshadri » 1.6.

Pour le point (3) on renvoie à la discussion après 1.7.

3.3 Le champ Bun_G **et la conjecture de géométrisation.** Motivé par l'apparition systématique des modifications de fibrés vectoriels (Section 1.7.2), le théorème 2.1, les conjectures de Kottwitz décrivant la partie discrète de la cohomologie des espaces de Rapoport-Zink (Rapoport [1995]), les travaux naissants de Scholze sur la construction de L-paramètres via la cohomologie des espaces de Shtukas locaux (Scholze [2014],Lafforgue [p. d.]) et bien sûr ceux de l'école russe autour du programme de Langlands géométrique (Drinfeld [1983], Gaitsgory [2002]), on a formulé une conjecture de géométrisation de la correspondance de Langlands locale (Fargues [2016b], Fargues et Scholze [p. d.]). Puisqu'il s'agit d'un travail en cours nous n'allons pas nous étendre en détail dessus. Indiquons seulement quelques points en lien avec les résultats précédents.

On définit le champ Bun_G sur $\mathrm{Perf}_{\overline{\mathbb{F}}_q}$ comme étant $S \mapsto \{G\text{-fibrés sur } X_S\}$. On le voit comme un champ pour la v-topologie (Scholze [p. d.]). Le point de départ est que le théorème 2.1 donne une identification

$$B(G) = |\mathrm{Bun}_G|.$$

Il faut prendre garde au fait que la topologie quotient sur $B(G) = G(\breve{E})/\sigma$-conj. est la topologie discrète (si les matrices de Frobenius de deux isocristaux sont proches elles sont σ-conjuguées). *Ce n'est pas la topologie qui nous intéresse, on regarde plutôt celle de* $|\mathrm{Bun}_G|$ *induite par les sous-champs ouverts.* L'application première classe de Chern , i.e. $-\kappa$ sur $B(G)$ (cf. Section 2.1), est localement constante (Fargues et Scholze [p. d.]) et fournit une décomposition en sous-champs ouverts/fermés

$$\mathrm{Bun}_G = \coprod_{\alpha \in \pi_1(G)_\Gamma} \mathrm{Bun}_G^\alpha.$$

Il y a une application polygone de Harder-Narasimhan semi-continue à valeurs dans une chambre de Weyl (cet énoncé peut se déduire de 3.1 (1)). Contentons nous seulement de dire que *le lieu semi-stable est ouvert*. Cet énoncé est à mettre en parallèle avec le fait que le lieu basique dans la fibre spéciale d'une variété de Shimura est fermé ; la cohérence entre les deux énoncés provenant du fait que le tube, au sens de la géométrie rigide, au dessus d'un fermé est ouvert. D'après Kottwitz (Kottwitz [1985]) la restriction de κ induit une bijection $B(G)_{basique} \xrightarrow{\sim} \pi_1(G)_\Gamma$. Cela s'interprète géométriquement en : *toute composante de* Bun_G *indexée par un élément de* $\pi_1(G)_\Gamma$ *possède un unique point semi-stable* (l'auteur n'avait jamais vraiment compris la signification de cet énoncé de Kottwitz avant de tomber sur ce simple énoncé géométrique). Soit donc $[b]$ basique et $\alpha = -\kappa(b)$. En utilisant le point (2) de 3.1 on peut démontrer le résultat suivant qui calcule la gerbe résiduelle en l'unique point semi-stable de la composante associée à α :

via le G-fibré $\mathcal{E}_b$, il y a un isomorphisme

$$[\mathrm{Spa}(\overline{\mathbb{F}}_q)/\underline{J_b(E)}] \xrightarrow{\sim} \mathrm{Bun}_G^{\alpha,ss}.$$

(champ classifiant des $J_b(E)$-torseurs pro-étales). *C'est là une des différences majeures avec le champ « classique » des G-fibrés sur une courbe : le groupe des automorphismes du G-fibré trivial est $\underline{G(E)}$ qui est totalement discontinu tandis que dans la situation « classique » c'est le groupe algébrique connexe G.* Cette différence de nature entre champs classifiants, couplée aux travaux de Kaletha et Kottwitz (KALETHA [2016] par exemple), est importante afin de comprendre la conjecture de géométrisation. Plus précisément, si l'on prend la fibre en un point semi-stable d'un faisceau ℓ-adique sur Bun_G on obtient une représentation lisse de $J_b(E)$ (alors que dans la situation « classique », puisque G est connexe, on n'obtiendrait qu'un simple espace vectoriel ℓ-adique).

Venons en maintenant aux modifications de fibrés qui ont joué un rôle très important dans l'intuition de la conjecture. Ici l'intuition vient du point (2) de 1.1. En effet, les débasculements de $S \in \mathrm{Perf}_{\overline{\mathbb{F}}_q}$ sur E, $S^\sharp$ un E-espace perfectoïde avec $S \xrightarrow{\sim} S^{\sharp,\flat}$, fournissent des diviseurs de Cartier

$$S^\sharp \hookrightarrow X_S$$

donnés par $S^\sharp = V(\xi) \hookrightarrow Y_S$ si S est affinoïde perfectoïde et $\xi \in \mathbf{A}_{R,R^+}$ est primitif de degré 1 définissant le débasculement $S^\sharp$. Posons alors

$$\mathrm{Div}^1_S = S \times \mathrm{Spa}(E)^\diamond/\varphi_{E^\diamond}^{\mathbb{Z}}$$

comme S-diamant. Cet objet est en quelque sorte « le miroir » de $X_S^\diamond = S \times \mathrm{Spa}(E)^\diamond/\varphi_S^{\mathbb{Z}}$ (tous deux ont même site étale puisque $\varphi_S \circ \varphi_{E^\diamond}$ est le Frobenius absolu de $S \times \mathrm{Spa}(E)^\diamond$, c'est ce que l'on utilise dans la Section 1.5). Le faisceau Div^1 est alors celui des « diviseurs de Cartier effectifs de degré 1 sur la courbe » (qui n'est pas la courbe elle-même contrairement à la situation « classique »).

Un autre point important est la construction d'un *système de carte perfectoïdes « lisses »* (ℓ-cohomologiquement lisses au sens de SCHOLZE [p. d.] pour être plus précis) sur le champ Bun_G, dont on montre au final qu'il est lisse de dimension 0 (FARGUES et SCHOLZE [p. d.]). Le point de départ a été la remarque suivante liée aux espaces de Banach-Colmez (Section 1.6) : le champ classifiant $[\mathrm{Spa}(\overline{\mathbb{F}}_q)/\underline{\mathrm{GL}_n(\mathbb{Q}_p)}]$ est lisse. En effet, l'espace de module des injections $\mathcal{O}^n \hookrightarrow \mathcal{O}(1)^n$ s'identifie à l'ouvert U du diamant relatif $H^0(\mathcal{O}(1))^{n^2} \to \mathrm{Spa}(\overline{\mathbb{F}}_q)$ formé des matrices de déterminant dans $H^0(\mathcal{O}(n)) \setminus \{0\}$. L'espace de Banach-Colmez relatif $H^0(\mathcal{O}(1)) \to \mathrm{Spa}(\overline{\mathbb{F}}_q)$ est représentable par un disque ouvert perfectoïde (le revêtement universel d'un groupe de Lubin-Tate) et $U \to \mathrm{Spa}(\overline{\mathbb{F}}_q)$ est donc lisse. Le groupe $\underline{\mathrm{GL}_n(\mathbb{Q}_p)}$ agit librement sur U, si $K \subset \mathrm{GL}_n(\mathbb{Q}_p)$ est un sous-groupe compact ouvert pro-p et $F = \overline{\mathbb{F}}_q((T^{1/p^\infty}))$ alors

$$U_F/\underline{K} \longrightarrow \left[\mathrm{Spa}(\overline{\mathbb{F}}_q)/\underline{\mathrm{GL}_n(\mathbb{Q}_p)}\right]$$

est une présentation lisse par un diamant lisse.

Finalement, on peut alors définir des correspondances de Hecke pour μ une classe de conjugaison de cocaractère

$$\begin{array}{ccc} & \mathrm{Hecke}_\mu & \\ \overleftarrow{h} \swarrow & & \searrow \overrightarrow{h} \\ \mathrm{Bun}_G & & \mathrm{Bun}_G \times \mathrm{Div}^1. \end{array}$$

où $\overrightarrow{h}$ est une fibration étale localement triviale en la cellule de Schubert associée à μ dans la B_{dR}-*Grassmanienne de Scholze* au dessus de Div^1 (Scholze [2014], Caraiani et Scholze [2017]). L'étude des modifications de fibrés en lien avec les groupes p-divisibles (Section 1.7.2) et le lien avec les espaces de périodes (Section 2.3) sont une motivation importante pour l'introduction de ce type de diagramme.

La conjecture se formule alors sommairement de la façon suivante. On suppose G quasi-déployé et on fixe une donnée de Whittaker (la construction devrait dépendre de ce choix). On considère le L-groupe ${}^LG = \widehat{G} \rtimes W_E$ de G sur $\overline{\mathbb{Q}}_\ell$ construit canoniquement à partir d'un isomorphisme de Satake géométrique associé à la B_{dR}-grassmanienne affine de Scholze (Fargues et Scholze [p. d.]). Considérons un L-paramètre discret $\varphi : W_E \to {}^LG$. On conjecture alors l'existence d'un faisceau pervers $\mathscr{F}_\varphi$ sur Bun_G muni d'une action de S_φ, propre pour l'action des correspondances de Hecke et dont les fibres en les points semi-stables de Bun_G réalisent des correspondances de Langlands locales pour toutes les formes intérieures pures de G (les J_b lorsque b parcourt les éléments basiques). Sans rentrer dans les détails, outre le fait que cette conjecture construise des correspondances de Langlands locales dans la direction

$$\text{L-paramètre} \longmapsto \text{représentation},$$

l'un de ses points forts est qu'*elle prédit la structure interne des L-paquets associés à φ via l'action de S_φ*. La propriété de Hecke spécialisée aux points semi-stables *implique automatiquement les conjectures de Kottwitz sur la cohomologie des espaces de Rapoport-Zink* (Rapoport [1995]) via le lien entre modifications de fibrés vectoriels et groupes p-divisibles (Section 1.7.2).

On renvoie à FARGUES [2016b] et FARGUES et SCHOLZE [p. d.] pour un énoncé précis de la conjecture et ses conséquences, en espérant avoir expliqué au lecteur quelques éléments de la démarche qui a mené à sa formulation.

3.4 Simple connexité des fibres d'une application d'Abel-Jacobi. Les résultats présentés dans l'article FARGUES [2017] sont un cas particulier de la conjecture de géométrisation qui ne nécessite pas en quelques sortes de l'avoir comprise entièrement. Il s'agit du cas de GL_1 i.e. de la *théorie du corps de classe géométrique.* Dans ce cas là, dans le cadre « classique », il est bien connu que cette même théorie résulte de ce qu'en grand degré le morphisme d'Abel-Jacobi est une fibration localement triviale en variétés algébriques simplement connexes (des espaces projectifs). On démontre que c'est également le cas dans notre cadre dans FARGUES [ibid.].

Voici tout d'abord comment recycler le théorème de factorisation des périodes 1.3 dans un cadre joailler (ce recyclage n'était pas prévu à l'origine mais il montre combien ce théorème de factorisation des périodes est au coeur de la machine). Plus généralement que Div^1, pour $d \geq 1$, on peut définir un un faisceau pro-étale Div^d des diviseurs de Cartier effectifs de degré d sur la courbe.

Proposition 3.2 (FARGUES [ibid.]). *Le faisceau pro-étale* Div^d *est un diamant. De plus le morphisme somme de* d*-diviseurs* $\Sigma^d : (\mathrm{Div}^1)^d \to \mathrm{Div}^d$ *est quasi-pro-étale surjectif et induit un isomorphisme de faisceaux pro-étales* $(\mathrm{Div}^1)^d/\mathfrak{S}_d \xrightarrow{\sim} \mathrm{Div}^d$.

Il y a alors un morphisme d'Abel-Jacobi

$$\mathrm{AJ}^d : \mathrm{Div}^d \longrightarrow \mathcal{P}ic^d = \mathrm{Bun}^d_{\mathrm{GL}_1}.$$

On démontre alors le résultat suivant.

Théorème 3.3 (FARGUES [ibid.]). *Le morphisme* $\mathrm{AJ}^d : \mathrm{Div}^d \to \mathcal{P}ic^d$ *est une fibration pro-étale localement triviale en diamants simplement connexes si* $d > 2$.

D'après le point (2) du théorème théorème 3.1, l'application qui à un fibré en droites, fibre à fibre de degré d, associe le torseur pro-étale des isomorphismes avec $\mathcal{O}(d)$ induit une identification

$$\mathcal{P}ic^d = [\mathrm{Spa}(\overline{\mathbb{F}}_q)/\underline{E}^\times].$$

Le morphisme d'Abel-Jacobi se réécrit alors sous la forme

$$H^0(\mathcal{O}(d)) \setminus \{0\}/\underline{E}^\times \longrightarrow [\mathrm{Spa}(\overline{\mathbb{F}}_q)/\underline{E}^\times].$$

Ici $H^0(\mathcal{O}(d))$, le faisceau $S \mapsto H^0(X_S, \mathcal{O}(d))$, est un « espace de Banach-Colmez absolu » i.e. relatif au dessus de Spa$(\overline{\mathbb{F}}_q)$, l'objet final du topos pro-étale qui n'est pas représentable par un espace perfectoïde (les espaces de Banach-Colmez, qui sont des diamants, tels qu'introduits par Colmez, vivent d'habitude au dessus d'une base perfectoïde fixée, cf. Section 1.6). Bien que $H^0(\mathcal{O}(d))$ ne soit pas un diamant, on montre que $H^0(\mathcal{O}(d)) \setminus \{0\}$ en est un et est simplement connexe lorsque $d > 2$.

MULTIPLICATIVE FUNCTIONS IN SHORT INTERVALS, AND CORRELATIONS OF MULTIPLICATIVE FUNCTIONS

KAISA MATOMÄKI AND MAKSYM RADZIWIŁŁ

Abstract

Our goal in this note is two-fold. In part I, we motivate and explain the ideas behind a recent theorem of ours.

Theorem 1 (Matomäki-Radziwiłł). *Let f be a real-valued multiplicative function with $|f| \leq 1$. Then, for all $X < x \leq 2X$, with at most $o(X)$ exceptions,*

$$\frac{1}{H}\sum_{x<x\leq x+H} f(n) - \frac{1}{X}\sum_{X<n\leq 2X} f(n) = o(1)$$

as soon as $H \to \infty$ with $X \to \infty$.

In part II, which can be read independently, our goal is to survey some of the recent developments connected to Theorem 1. These have been by far and large related to Chowla's conjecture.

Conjecture 1 (Chowla). *Let μ denote the Möbius function. Then, for any set of distinct integers $h_1, \ldots, h_k$,*

$$\sum_{n\leq X} \mu(n+h_1)\ldots\mu(n+h_k) = o(X)$$

as $X \to \infty$.

Part I

We will be interested throughout in *multiplicative* functions, that is $f : \mathbb{N} \to \mathbb{C}$ such that $f(ab) = f(a)f(b)$ for all co-prime a, b. A basic example is the *Möbius function* μ, defined by $\mu(p) = -1$ and $\mu(p^\alpha) = 0$ for all $\alpha > 1$ and primes p. The Möbius function is closely connected to the primes as we now explain. Let Λ denote the von Mangoldt

MSC2010: primary 11N25; secondary 11N37.

function $\Lambda(n)$ defined by setting $\Lambda(n) = \log p$ whenever $n = p^{\alpha}$ and $\Lambda(n) = 0$ otherwise. Then, by inclusion-exclusion,

$$\Lambda(n) = -\sum_{d \mid n} \mu(d) \log d.$$

Using this relationship one can show that,

$$\sum_{n \le x} \Lambda(n) \sim x \iff \sum_{n \le x} \mu(n) = o(x) \tag{1}$$

and

$$\sum_{n \le x} \Lambda(n) = x + O_{\varepsilon}(x^{1/2+\varepsilon}) \quad \text{for all } \varepsilon > 0 \iff \sum_{n \le x} \mu(n) = O_{\varepsilon}(x^{1/2+\varepsilon}) \quad \text{for all } \varepsilon > 0. \tag{2}$$

The statement on the left-hand side of (1) is known as the Prime number theorem, while the statement on the left of (2) is an equivalent reformulation of the Riemann Hypothesis.

An immediate consequence of the Riemann Hypothesis is that the prime number theorem holds in all intervals $[x, x + x^{\alpha}]$ with $\alpha > \frac{1}{2}$. In principle deeper information than the Riemann Hypothesis is contained in the *explicit formula*,

$$\sum_{n \le x} \Lambda(n) = x - \sum_{\rho} \frac{x^{\rho}}{\rho} + O(1)$$

where the sum over ρ corresponds to a sum over zeros of the Riemann zeta-function. However from this formula it is possible to see that without understanding cancellations between zeros of the Riemann zeta-function nothing can be said about intervals with $\alpha \le \frac{1}{2}$. For $\alpha \in (0, \frac{1}{2}]$ it is thus natural to relax the question and ask whether the prime number theorem holds in most intervals $[x, x + x^{\alpha}]$ with $\alpha \in (0, \frac{1}{2}]$. Conditionally on the Riemann Hypothesis, Selberg [1943] succeeded in providing a positive answer to this question. Here we state a weak version of his result.

Theorem 2 (Selberg). *Assume the Riemann Hypothesis. Let $\varepsilon > 0$ be given. The number of integers $x \in [0, X]$ for which*

$$\Big| \sum_{x < n \le x + x^{\alpha}} \Lambda(n) - x^{\alpha} \Big| > x^{\alpha/2+\varepsilon}$$

is $o(X)$ as $X \to \infty$.

The proof of this result is not difficult : Covering the interval $[0, X]$ by dy-adic intervals, the result will follow from Chebyschev's inequality if we can show that,

$$\int_X^{2X} \Big| \sum_{x<n\le x+x^\alpha} \Lambda(n) - x^\alpha \Big|^2 dx \ll_\varepsilon X^{1+\alpha+\varepsilon}.$$

By the explicit formula, for $X \le x \le 2X$,

$$\sum_{x<n\le x+x^\alpha} \Lambda(n) - x^\alpha \approx x^\alpha \sum_{|\rho|\le X^{1-\alpha}} x^{\rho-1}.$$

where ρ is a sum over the zeros of the Riemann zeta-function, and here and later $\approx$ means that the statement is "morally true". Therefore,

$$(3) \qquad \int_X^{2X} \Big| \sum_{x<n\le x+x^\alpha} \Lambda(n) - x^\alpha \Big|^2 dx \approx X^{2\alpha} \int_X^{2X} \Big| \sum_{|\rho|\le X^{1-\alpha}} x^{\rho-1} \Big|^2 dx$$

Expanding the square, and executing the integration over $x \in [X, 2X]$ we obtain that the integral over x is

$$\approx \sum_{\substack{|\rho|\le X^{1-\alpha} \\ |\rho'|\le X^{1-\alpha}}} \frac{X^{\rho+\overline{\rho'}-1}}{\rho+\overline{\rho'}-1}$$

We then bound this trivially by

$$(4) \qquad \sum_{\substack{|\rho|\le X^{1-\alpha} \\ |\rho'|\le X^{1-\alpha}}} \frac{1}{|\rho+\overline{\rho}-1|} \ll X^{1-\alpha+\varepsilon}.$$

Altogether this shows that the left-hand side of (3) is $\ll_\varepsilon X^{1+\alpha+\varepsilon}$, as needed. A similar but more complicated argument establishes a corresponding theorem for the Möbius function.

The Riemann Hypothesis is used crucially in the upper bound (4) which uses that $\Re\rho = \Re\rho' = \frac{1}{2}$. In order to run this argument unconditionally one needs a *zero-density estimate* for the number of zeros of the Riemann zeta function in the strip $\Re s > \sigma$ and with height $|\Im s| \le T$. Using Huxley's zero-density estimate Huxley [1972] allows one to prove the following theorem (see Ramachandra [1976] for details).

Theorem 3 (Huxley). *Let $a(n) = \Lambda(n) - 1$ or $a(n) = \mu(n)$. Then, for $H > X^{1/6+\varepsilon}$, we have, for almost all $X < x < 2X$,*

$$\Big| \sum_{x<n\le x+H} a(n) \Big| \ll_A H(\log X)^{-A}.$$

Two features are worth noticing : Compared to the conditional Theorem 2, the saving that we obtain is weaker, and the range of H is worse. Crucial in the proof of Theorem 3 is the relationship of $\Lambda(n)$ or $\mu(n)$ with the zeros of the Riemann zeta-function.

Until recently this is where things stood. In a recent result we have obtained an improvement of Theorem 3 for arbitrary multiplicative function which is optimal in terms of H. We will begin with a very special case of our result for the Möbius function in the range $H = X^{\varepsilon}$.

Theorem 4 (Matomäki-Radziwiłł). *Let $\varepsilon > 0$ be given. Let $H = X^{\varepsilon}$. Then, for almost all $1 \leq x \leq X$,*

$$\sum_{x<n\leq x+H} \mu(n) = o(H).$$

Unlike Huxley's result our theorem depends directly on the multiplicativity of $\mu(\cdot)$. While the proof that we will give at first will depend on the fact that $\mu(p) = -1$ for all primes p, we will soon see that this is in no way crucial. A complete account of this special case can be found in Matomäki and Radziwiłł [2016a].

0.1 Sketch of the proof of Theorem 4. Consider

$$\int_X^{2X} \Big| \sum_{x<n\leq x+H} \mu(n) \Big|^2 dx \tag{5}$$

Our goal is to show that this is $o(XH^2)$. By an application of Plancherel, (5) is (essentially) equivalent to

$$\int_0^{X/H} \Big| \sum_{X<n\leq 2X} \frac{\mu(n)}{n^{1+it}} \Big|^2 dt = o(1). \tag{6}$$

We have at our disposal two distributional estimates for

$$\sum_{X<n\leq 2X} \frac{\mu(n)}{n^{1+it}}.$$

On the one hand the prime number theorem in the form of Vinogradov-Korobov Korobov [1958] implies that the above Dirichet polynomial is less than $O_A((\log X)^{-A})$ for all $|t| \leq \exp((\log X)^{3/2-\varepsilon})$. On the other hand a result of Montgomery and Vaughan [1974] shows that for arbitrary complex coefficients $a(n)$ and $T, X \geq 1$,

$$\int_0^T \Big| \sum_{X<n\leq 2X} a(n)n^{it} \Big|^2 dt = (T + O(X)) \sum_{X<n\leq 2X} |a(n)|^2. \tag{7}$$

Neither result is directly sufficient for obtaining (6). The first result allows us to only handle the range $|t| \le (\log X)^B$ for any fixed B. This is not sufficient to obtain the result (unless $H > X/(\log X)^B$). However, in any case it allows to reduce our attention to showing that

$$\int_{(\log X)^B}^{X/H} \Big| \sum_{X \le n \le 2X} \frac{\mu(n)}{n^{1+it}} \Big|^2 dt = o(1). \tag{8}$$

for any fixed $B > 0$. Applying (7) to (8) shows that (8) is $O(1)$. This barely fails to be non-trivial. The situation is reminiscent with what one encounters in the proof of the Bombieri-Vinogradov theorem Vaughan [1981] [1]. Similarly, the missing additional input is a bilinear structure.

We create the bilinear structure using *Ramaré's identity*,

$$\mu(n) = \sum_{\substack{n=pm \\ P \le p \le Q \\ (m,p)=1}} \mu(p) \cdot \frac{\mu(m)}{1 + \#\{P \le q \le Q : q|m\}} + \mathbf{1}_{(n, \prod_{P \le p \le Q} p)=1} \cdot \mu(n) \tag{9}$$

valid for any interval $[P, Q]$. If the parameters P, Q are chosen so that

$$\sum_{P \le p \le Q} \frac{1}{p} \to \infty$$

as $X \to \infty$, then all but $o(X)$ of the integers $X < n \le 2X$ have a prime factor in $[P, Q]$. Consequently the second term in Ramaré's identity (9) is typically zero. The point of Ramaré's identity is that it roughly allows us to write

$$\sum_{X < n \le 2X} \frac{\mu(n)}{n^{1+it}} \approx$$
$$\approx \frac{1}{\log \frac{\log Q}{\log P}} \sum_{P \le R = 2^k \le Q} \Big(\sum_{R < p \le 2R} \frac{\mu(p)}{p^{1+it}} \cdot \sum_{X/R < m \le 2X/R} \frac{\mu(m)}{m^{1+it}} \Big) + \text{“small in } L^2\text{''}.$$

[1] If one attempts to prove Bombieri-Vinogradov without a combinatorial decomposition of $\Lambda(n)$ then the available tools turn out to be insufficient: Siegel-Walfisz can handle moduli with $Q \le (\log X)^A$ while the large sieve recovers the trivial bound. This is similar to the situation we are facing here.

where "small in L^2" is a Dirichlet polynomial that is small on average. As a result, we roughly have

$$\int_{(\log X)^B}^{X/H} \Big| \sum_{X<n\le 2X} \frac{\mu(n)}{n^{1+it}} \Big|^2 dt$$
$$\text{“}\ll\text{”} \frac{\log Q}{\log R} \sum_{P\le R=2^k\le Q} \int_{(\log X)^B}^{X/H} \Big| \sum_{R<p\le 2R} \frac{1}{p^{1+it}} \cdot \sum_{X/R<m\le 2X/R} \frac{\mu(m)}{m^{1+it}} \Big|^2 dt + o(1).$$

Now we have a bilinear decomposition and we can use both distributional estimates alluded to above. First of all, if the parameter P is chosen so that $P \ge \exp((\log X)^{2/3+\varepsilon})$, then the prime number theorem of Vinogradov-Korobov applies to the Dirichlet polynomial over the primes, and gives us

$$\sum_{R<p\le 2R} \frac{1}{p^{1+it}} \ll (\log X)^{-B/2}$$

for all $R = 2^k$ in the range $[P, Q]$ and all $|t| > (\log X)^B$. Secondly, (7) shows that,

$$\int_{(\log X)^B}^{X/H} \Big| \sum_{X/R<m\le 2X/R} \frac{\mu(m)}{m^{1+it}} \Big|^2 dt \ll \Big(\frac{X}{H} + \frac{X}{R}\Big) \sum_{X/R<m\le 2X/R} \frac{1}{m^2} \ll \frac{R}{H} + 1.$$

Applying both to (8), we conclude that (8) is

$$\ll \sum_{P\le R=2^k\le Q} (\log X)^{-B} \cdot \Big(\frac{R}{H} + 1\Big) + o(1).$$

This is $o(1)$ as long $R/H \le (\log X)^{B/2}$. We collect all our requirements to see if they can be satisfied at once. We require that

1. $P \ge \exp((\log X)^{2/3+\varepsilon})$ (so that the prime number theorem is applicable).
2. $P/H \ll (\log X)^{B/2}$ (so that the mean-value theorem is efficient).
3. Q is chosen so that $\sum_{P\le p\le Q} p^{-1} \to \infty$ as $X \to \infty$ (so that in Ramaré's identity the second term is negligible).

To meet all these requirements it suffices to pick $Q = H \ge X^{\varepsilon}$ and $P = \exp((\log X)^{2/3+\varepsilon})$.

0.2 General multiplicative functions. The main thrust of the previous argument still came from a harmonious relationship between μ and prime numbers (manifested for example in the property that $\mu(p) = -1$ for all primes p). If one wishes to extend the result to general multiplicative functions, this is a bottleneck. But more generally, before we can proceed we need to understand what is the analogue of the prime number theorem for general multiplicative functions.

Since the prime number theorem can be expressed as

$$\sum_{n \le x} \mu(n) = o(x)$$

it is natural to expect that "having a prime number theorem" for $f(n)$ would amount to knowing the behavior of

$$\sum_{n \le x} f(n).$$

as $x \to \infty$. There is at present a rather well-developed theory of such mean-values. The central result is due to Halász (see also Montgomery and Vaughan [2001] and Granville, Harper, and Soundararajan [2017]).

Theorem 5 (Halász). *Let f be multiplicative with $|f| \le 1$. Then, for all $X, T \ge 1$,*

$$\frac{1}{X} \sum_{X < m \le 2X} f(m) \ll M \exp(-M) + \frac{\log \log X}{\log X} + \frac{1}{T}$$

where

$$M := \min_{|t| \le T} \sum_{p \le X} \frac{1 - \Re f(p) p^{-it}}{p}$$

The quantity M singles out cases in which $f(p)$ is close to p^{it} for most primes p. This is indeed important. If $f = m^{iT}$ then the mean-value is of size approximately X/T showing that the last term is optimal. The other two terms are unfortunately also optimal. For instance the second term takes into account multiplicative functions f such that for example $f(p) = 0$ for $p < X/2$ and $f(p) = 1$ for $X/2 \le p \le X$. In recent literature the function M is frequently denoted by $\mathbb{D}^2(f, p^{it})$ and refered to as a distance function.

Going back to our main problem, we would like to show that for almost all $X \le x \le 2X$,

$$\frac{1}{H} \sum_{x < n \le x + H} f(n) - \frac{1}{X} \sum_{X < n \le 2X} f(n) = o(1). \tag{10}$$

and for H as small as possible, compared to X. Since we aim to prove this for an arbitrary multiplicative function f with $|f| \le 1$ one should think of (10) as a statement about the factorization of the integers, rather than about multiplicative functions. Indeed, (10) states that in most short intervals $[x, x+H]$ integers factorize in a way that is similar to the long interval $[X, 2X]$. Thus in the way that integers factorize in short intervals, there can be no consistently pathological behavior that would work out to still be consistent with, for example, the prime number theorem. An example of such a pathological behavior is the existence of a positive proportion of intervals $[x, x + H]$ on which for instance $\mu(n) = 1$ and a positive proportion of intervals $[x, x + H]$ on which $\mu(n) = -1$. The intervals could be arranged in such a way so that their existence would be consistent with the prime number theorem $\sum_{n \le x} \mu(n) = o(x)$. What (10) achieves is that it rules out such a possibility.

Let us try to prove (10). Expressing both expressions in (10) in terms of Mellin transform and applying Plancherel, reveals that showing (10) amounts to proving that

$$\int_{(\log X)^{\varepsilon}}^{X/H} \Big| \sum_{X<n\le 2X} \frac{f(n)}{n^{1+it}} \Big|^2 dt = o(1).$$

Notice that the integral starts at $(\log X)^{\varepsilon}$, this is important and corresponds to the fact that the Mellin transform of the short sum and the long sum, coincide at the small frequencies $|t| \le (\log X)^{\varepsilon}$.

We now run the same argument as before. The crucial issue is to show that,

(11)
$$\int_{(\log X)^{\varepsilon}}^{X/H} \Big| \sum_{R<p\le 2R} \frac{f(p)}{p^{1+it}} \Big|^2 \cdot \Big| \sum_{X/R<m\le 2X/R} \frac{f(m)}{m^{1+it}} \Big|^2 dt = O\Big((\log X)^{-\varepsilon/2} \cdot \Big(\frac{\log Q}{\log P}\Big)^{-2}\Big)$$

for some $\varepsilon > 0$. One could get away with a smaller saving. Notice that the coefficients $f(p)$ are arbitrary, so there are no point-wise bounds for $\sum_{R<p\le 2R} f(p) p^{-1-it}$. In particular the prime number theorem is of no use!

However the sum over primes is still small for "most" t. Indeed by (7),

$$\int_{0}^{X/H} \Big| \sum_{R<p\le 2R} \frac{f(p)}{p^{1+it}} \Big|^2 dt \sim \frac{X}{H} \cdot \frac{1}{R \log R}.$$

This shows that for "most" t the sum over the primes is of size $R^{-1/2+o(1)}$. Thus for most $t \in [(\log X)^{\varepsilon}, X/H]$ our previous argument works. As a result we can focus on the set $\mathcal{U}$ of those $t \in [(\log X)^{\varepsilon}, X/H]$ for which,

$$\Big| \sum_{R<p\le 2R} \frac{1}{p^{1+it}} \Big|^2 \ge (\log X)^{-\varepsilon} \sum_{R<p\le 2R} \frac{1}{p}.$$

We can find a 1-spaced set $\mathcal{V} \subset U$ such that

$$\int_{t\in\mathcal{U}} \Big| \sum_{R<p\le 2R} \frac{f(p)}{p^{1+it}} \cdot \sum_{X/R<m\le 2X/R} \frac{f(m)}{m^{1+it}} \Big|^2 dt \ll \sum_{t\in\mathcal{V}} \Big| \sum_{R<p\le 2R} \frac{f(p)}{p^{1+it}} \Big|^2 \cdot \Big| \sum_{X/R<m\le 2X/R} \frac{f(m)}{m^{1+it}} \Big|^2 \tag{12}$$

A first task is to understand the cardinality of $\mathcal{V}$. If $Q < \exp((\log X)^{1-2\varepsilon})$ then one can compute moments

$$\int_0^{X/H} \Big| \sum_{R<p\le 2R} \frac{f(p)}{p^{1+it}} \Big|^{2k} dt$$

with a judiciously chosen k, to conclude that $|\mathcal{V}|$ is very small.

On the set $t \in \mathcal{V} \subset [(\log X)^{\varepsilon}, X/H]$ we cannot expect cancellations in the sum over the primes. In fact if there exists a single t for which there are no cancellations in both sums over p and m then we cannot succeed. Thankfully, for real-valued multiplicative functions Halász's theorem ensures that the sum over m is always non-trivially small. In fact we can hope for a saving of a small power of the logarithm in the sum over m. This leads to a bound for (12) of the form,

$$(\log X)^{-\varepsilon} \sum_{t\in\mathcal{V}} \Big| \sum_{R<p\le 2R} \frac{f(p)}{p^{1+it}} \Big|^2 \tag{13}$$

A variant of a distributional result of Halász and Turán [1969] (see Matomäki and Radziwiłł [2016b, Lemma 11]) then shows that once the set $\mathcal{V}$ is small enough, the sum over $t \in \mathcal{V}$ behaves as if there was exactly one term $t \in \mathcal{V}$ at which there are no cancellations. Therefore (13) is

$$\ll (\log X)^{-\varepsilon} \cdot \Big(\frac{1}{\log R}\Big)^2 \ll (\log X)^{-\varepsilon} \cdot (\log Q/\log P)^{-2}$$

provided that P, Q are choosen so that $P \ge \exp(\sqrt{\log Q})$, which we can assume. For instance, simply choose $Q = \exp((\log X)^{1-2\varepsilon})$ and $P = \exp((\log X)^{2/3+\varepsilon})$. This gives (11) and proves

Corollary 1 (Matomäki-Radziwiłł). *Let $f : \mathbb{N} \to [-1, 1]$ be multiplicative. Let $\varepsilon > 0$ be given and set $H = X^{\varepsilon}$. Then for almost all $X < x \le 2X$,*

$$\frac{1}{H} \sum_{x<n\le x+H} f(n) - \frac{1}{X} \sum_{X<n\le 2X} f(n) = o(1)$$

as $X \to \infty$.

0.3 The full result. In our joint work Matomäki and Radziwiłł [2016b] we succeeded in pushing the dependence on H to its optimal form. In particular we obtained the following result.

Theorem 6 (Matomäki-Radziwiłł). *Let $|f| \leq 1$ be multiplicative and real-valued. Let $\delta > 0$ be fixed. Then,*

$$\Big|\frac{1}{H}\sum_{x<n\leq x+H} f(n) - \frac{1}{X}\sum_{X<n\leq 2X} f(n)\Big| < \delta.$$

for all $X < x \leq 2X$ with $\ll X/H^{\delta/30} + X/(\log X)^{1/50}$ exceptions.

This implies that if H goes to infinity with X, no matter how slowly, then,

$$\frac{1}{H}\sum_{x<n\leq x+H} f(n) = \frac{1}{X}\sum_{X\leq n\leq 2X} f(n) + o(1) \tag{14}$$

for almost all $X \leq x \leq 2X$. This is optimal. If H were bounded then (14) is not true: for instance take $H = p+1$ with p prime and, and f equal to a quadratic character $\mod p$. Then the short sum is always equal to $1/H$ in absolute value, while the long sum is tiny. In any case when H is bounded the statement is conjectured to be false for all multiplicative functions f. However such counterexamples are open even for $f = \mu$.

It is not a matter of simple technique to go from $H = X^{\varepsilon}$ to $H \to \infty$. This can be most clearly seen in the fact that previously even on the assumption of the Riemann Hypothesis a result like (6) for $f = \mu$ was only known for $H > (\log X)^A$ for some large A.

There is in fact a very conceptual reason for this. For simplicity let's focus on the case of the Möbius function. After converting the problem to Dirichlet polynomials, for the method to work we have to create bilinear forms with Dirichlet polynomials over primes p in the range of H (or smaller, but for simplicity let's focus on p of size H). Then we have to understand the size of

$$\sum_{H\leq p\leq 2H} \frac{1}{p^{1+it}}$$

Ideally one would like to say that this Dirichlet polynomial is always small. The Riemann Hypothesis guarantees this to be the case for $H > (\log X)^{2+\varepsilon}$. When $(\log X)^{1+\varepsilon} < H < (\log X)^{2+\varepsilon}$ there is a gap in our knowledge: we still expect the Dirichlet polynomial to be always small, but even the Riemann Hypothesis is unable to confirm this. Finally the range $H < (\log X)^{1-\varepsilon}$ is particularly difficult : Using diophantine approximation one can show that there are arbitrarily large $X < t < 2X$, such that,

$$\Big|\sum_{H\leq p\leq 2H} \frac{1}{p^{1+it}}\Big| \geq \frac{1}{4}\sum_{H\leq p\leq H} \frac{1}{p}$$

Moreover the number of such t up to X is expected to be a small power of X. Therefore any argument that works in scales $H < (\log X)^{1-\varepsilon}$ will need to be able to exploit this feature to its advantage. This is not something that arguments in analytic number theory are designed to address!

The main new idea in the proof of Theorem 6 is an iterative scheme, factoring out from the Dirichlet polynomial

$$\sum_{X \le n \le 2X} \frac{f(n)}{n^{1+it}}$$

Dirichlet polynomials supported on the primes in various ranges. The argument is designed to react to the size of the Dirichlet polynomial in each range. If the Dirichlet polynomial exhibits cancellations we are done. If it does not we move to a subsequent range, but retain the information that the Dirichlet polynomial in the previous range was large. Without doing this we would not be able to succeed. For the reader interested in these details we refer to an exposition of Soundararajan [2017] or our original paper Matomäki and Radziwiłł [2016b].

Part II

While analytic number theorists have by now a coherent set of tools to tackle problems about mean-values,

$$\sum_{n \le X} a(n) \tag{15}$$

with $a(n)$ sequences of arithmetical interest, very little is known about *correlations*,

$$\sum_{n \le X} a(n)a(n+h) \tag{16}$$

with $h \neq 0$. To get a sense of the gap in the difficulty set $a(n) = \Lambda(n)$. Then (15) corresponds to the prime number theorem, while (16) is the Hardy-Littlewood 2-tuple conjecture.

If one writes,

$$\Lambda(n) = \sum_{n=ab} \mu(a) \log b \tag{17}$$

then the problem of estimating (16) reduces to that of understanding correlations of the Möbius function. For a few technical reasons we will be interested instead in correlations of the Liouville function, which differs from the Möbius function only on powers of primes. This makes in practice the two interchangeable. The Liouville function $\lambda(n)$ is defined as $\lambda(n) = (-1)^{\Omega(n)}$ where $\Omega(n)$ is the number of prime factors of n counted with multiplicity.

For our approach to succeed, we need to at the very least understand (16) with $a(n) = \mu(n)$ or $a(n) = \lambda(n)$. A conjecture of Chowla [1965] predicts that such sums always exhibit cancellations.

Conjecture 2 (Chowla)**.** *Let $a(n) = \mu(n)$ or $a(n) = \lambda(n)$. Then, for any distinct set of integers $h_1, \dots, h_\ell$,*

$$\sum_{n \le x} a(n + h_1) \dots a(n + h_\ell) = o(x).$$

as $x \to \infty$.

Instead of (17) one could use Linnik's identity,

$$\frac{\Lambda(n)}{\log n} = \sum_{k \ge 1} \frac{d_k^\star(n)}{k} \cdot (-1)^{k+1}$$

where $d_k^\star(n)$ counts the number of solutions to $n = n_1 \dots n_k$ with all $n_i > 1$. Then estimating (16) requires us to understand correlations of the kth divisor function.

Conjecture 3. *Let $h_1, \dots, h_\ell$ be a set of distinct integers and $k_1, \dots, k_\ell \ge 1$ integers. Then,*

$$\sum_{n \le x} d_{k_1}(n + h_1) \dots d_{k_\ell}(n + h_\ell) \sim C(\mathbf{k}, \mathbf{h}) \cdot x (\log x)^{k_1 + \dots + k_\ell - \ell}.$$

as $x \to \infty$, with $C(\mathbf{k}, \mathbf{h})$ a complicated constant depending on the tuples $\mathbf{k} = (k_1, \dots, k_\ell)$ and $\mathbf{h} = (h_1, \dots, h_\ell)$.

Unfortunately for us both conjectures are open. At first the second conjecture appears somewhat more approachable. For instance the problem of estimating,

$$\sum_{n} d(n) d(n+h) W\Big(\frac{n}{X}\Big) \tag{18}$$

with $W(\cdot)$ a smooth function is completely resolved. Following works of Kuznetsov we are able to write down an explicit formula for (18), with the error term involving L-functions associated to eigenfunctions of the hyperbolic Laplacian on $\mathrm{SL}_2(\mathbb{Z})\backslash\mathbb{H}$ ((see Motohashi [1994] for details). The triangle inequality shows that the error term is of size $O(X^{1/2+\varepsilon})$, and moreover this is optimal. One would hope that a similar strategy will work for the estimation of correlations of the third divisor function, and that the error term should involve objects related to $\mathrm{SL}_3(\mathbb{Z})$. So far such attempts have proven unsuccessful Vinogradov and Tahtadžjan [1978], and not even an asymptotic formula is known the mean-value of $d_3(n) d_3(n+1)$.

0.4 Logarithmic Chowla. However it is no longer clear that Conjecture 2 will be the first to fall. At present our understanding of such convolution sums has changed dramatically. For instance we highlight a recent result of Tao [2016b].

Theorem 7 (Tao). *We have,*

(19)
$$\sum_{n \le x} \frac{\lambda(n)\lambda(n+1)}{n} = o(\log x)$$

as $x \to \infty$.

This is refered to as *logarithmic Chowla*.

To see the relevance of Theorem 6 let us start from the very modest goal of obtaining any cancellations at all in correlations of the Liouville function. So let us suppose that

$$\sum_{n \sim X} \lambda(n)\lambda(n+1) = (1 + o(1))X$$

as $X \to \infty$, and see if we can disprove it. The above would mean that for most n, the sign of $\lambda(n)$ and $\lambda(n+1)$ is equal. Therefore there exists an H going to infinity very slowly, so that,

$$\Big| \sum_{x < n < x + H} \lambda(n) \Big| \sim H$$

in at least a positive proportion of the intervals $[x, x + H]$. Theorem 6 rules out such a possibility. In fact a quick consequence of Theorem 6 (see Matomäki and Radziwiłł [2016b, Corollary 2]) is that there exists $\delta > 0$ such that,

$$\Big| \sum_{n \le X} \lambda(n)\lambda(n+1) \Big| \le (1 - \delta)X$$

this resolved an old folklore conjecture (see for instance Hildebrand [n.d.]) and opened the door for further progress on Conjecture 1.

The next natural step is to establish Chowla's conjecture "on average". In joint work with Tao Matomäki, Radziwiłł, and Tao [2015] we obtained such a result.

Theorem 8 (Matomäki-Radziwiłł-Tao). *We have,*

(20)
$$\sum_{|h| \le H} \Big| \sum_{n \le X} \lambda(n)\lambda(n+h) \Big| = o(HX).$$

as soon as $H \to \infty$ with $X \to \infty$.

This was the crucial arithmetic ingredient in Theorem 7. Let us quickly sketch the ideas that go into the proof of Theorem 8. The identity

$$\int_0^1 \Big(\int_{\mathbb{R}} \Big| \sum_{\substack{x \le n < x+H \\ X \le n \le 2X}} \lambda(n) e(n\alpha) \Big|^2 \Big)^2 d\alpha = H \sum_{|h| \le H} (H - |h|) \Big| \sum_{n \le X} \lambda(n) \lambda(n+h) \Big|^2$$

shows that Theorem 8 will follow from

$$\sup_{\alpha \in \mathbb{R}} \sum_{X \le x \le 2X} \Big| \sum_{x \le n \le x+H} \lambda(n) e(n\alpha) \Big| = o(XH) \tag{21}$$

as $X \to \infty$ and $H \to \infty$ with X, arbitrarily slowly. This is a short-interval analogue of a classical result of Davenport (itself a variant of Vinogradov's result for primes),

$$\sup_{\alpha} \Big| \sum_{X \le n \le 2X} \lambda(n) e(n\alpha) \Big| = o(X).$$

Similarly to the proof of Davenport's theorem, the proof of (21) splits depending on the diophantine nature of α. For simplicity let us imagine that α is fixed and we are aiming at obtaining cancellations in

$$\sum_{x \le n \le x+H} \lambda(n) e(n\alpha)$$

in almost all short intervals $X \le x \le 2X$ as $X \to \infty$, and $H \to \infty$ with X. The proof splits into two cases depending on whether $\alpha \in \mathbb{Q}$ or $\alpha \notin \mathbb{Q}$. When $\alpha \notin \mathbb{Q}$ the phase $e(n\alpha)$ oscilates rather randomly, and we succeed by using ideas of Daboussi and Delange [1974], which are a variant of Vinogradov's method. This requires $f(n)$ to be multiplicative only in a certain range $[P, Q]$. [2] On the other hand when $\alpha \in \mathbb{Q}$ the phase $e(n\alpha)$ is predictable and we need to obtain cancellations from $\lambda(n)$. The most extreme case corresponds to $\alpha = 0$. However this is exactly a consequence of Theorem 6! As one might expect the proof for rational α follows by generalizing Theorem 6 to the case of arithmetic progressions. Note that in this case we use the multiplicativity of $f(n)$ in many intervals, and thus this case is significantly more arithmetic.

The estimate (21) is the crucial arithmetic input in the proof of logarithmic Chowla (19). The other input is an ingenious use of entropy allowing to replace the event $\lambda(n+p)\mathbf{1}_{p|n}$ by $\lambda(n+p)/p$, and the creation of a bilinear structure which is possible thanks to the

[2] Daboussi-Delange's work is also often refered to as the Bourgain-Katai-Sarnak-Ziegler criterion (after Bourgain, Sarnak, and Ziegler [2013], Kátai [1986]), however the correct attribution is to Daboussi-Delange who were the first to obtain such a result

logarithmic weights. In fact rather than directly attacking the Chowla conjecture, Tao shows cancellations in

$$\sum_{n \le X} \lambda(n) \Big(\sum_{\substack{p \mid n \\ P \le p \le 2P}} \lambda(n+p) \Big). \tag{22}$$

A feature of the logarithmic weights is that if one can show that (22) is non-trivially small, for any choice of P, then this implies (19). Tao's *entropy decrement argument* shows the existence of a range P on which one can replace the event $\lambda(n+p)\mathbf{1}_{p|n}$ by $\lambda(n+p)/p$. Effectively this shows that (22) is close to

$$\frac{1}{P} \sum_{P \le p \le 2P} \sum_{n \le X} \lambda(n)\lambda(n+p)$$

This is now a ternary problem, that we can hope to address by the circle method. The main ingredient here is (21): The range of P can be quite small with respect to X, and one needs a form of (21) with H of size about P.

0.4.1 Odds and ends. Of course one wonders if logarithmic Chowla has implications for prime numbers. Unfortunately while until recently this was the heuristic expectations of most experts, it turns out that the error terms in (19) are too weak to give back anything about prime numbers. This appears to be a conceptual obstruction rather than a purely technical one. The proof of (19) hinges on Theorem 6 which in turn, in the first step, discards prime numbers from consideration. Thus it seems that these methods cannot be used for a direct attack on the twin prime conjecture.

Nonetheless the logarithmic Chowla conjecture had some dramatic consequence *outside* of number theory. It led for instance to the resolution of the Erdős Discrepancy Problem Tao [2016a] in combinatorics.

Concerning the cases of logarithmic Chowla with more shifts, there has been recent progress due to Tao-Teräväinen Tao and Teräväinen [2017]. It turns out that the case of an odd number of shifts is considerably simpler, and does not require any short interval results. That this is reasonable can be perhaps most easily seen in a result of Elliott according to which, there exists a $\delta > 0$ such that,

$$\Big| \sum_{n \le x} \lambda(n)\lambda(n+1)\lambda(n+2) \Big| \le (1-\delta)X$$

The proof of the above inequality is completely elementary (see Cassaigne, Ferenczi, Mauduit, Rivat, and Sárközy [1999]). This is in stark contrast with the binary case that requires Theorem 6.

0.5 Sarnak's conjecture. One can think of Chowla's conjecture probabilistically, as asserting that if one picks a typical integer n, and we are given $\lambda(n), \lambda(n+1), \ldots, \lambda(n+k-1)$ then we get no discernible advantage in predicting $\lambda(n+k)$.

Such a point of view is appealing from the point of view of information theory: We can think of the "signal" $\lambda = (\lambda(1), \lambda(2), \lambda(3), \ldots)$, and then ask how redundant this signal is? More precisely is knowing the neighborhood of a point $\lambda(n)$ enough to reconstruct $\lambda(n)$ at least with some positive probability? If the sequence $\lambda(n)$ is truly random, then the answer should be no. In particular $\lambda(n)$ should be "orthogonal" to all sequences that have a lot of redundancies, i.e those of entropy 0.

Let us then define what we mean by the entropy of a sequence. Let $f : \mathbb{N} \to \mathbb{C}$ be an arbitrary sequence, and consider the set $S_m = \{(f(n), f(n+1), \ldots, f(n+m-1)) : n > 0\} \subset \mathbb{C}^m$ of m-tuples in $\mathbb{C}^m$. Given ε let $B(m, \varepsilon)$ be the number of m-dimensional balls in $\mathbb{C}^m$ of radius ε that are needed to cover S_m. Then, the *topological entropy of f* is defined as

$$\sigma = \sup_{\varepsilon > 0} \Big(\limsup_{m \to \infty} \frac{1}{m} \log B(m, \varepsilon) \Big).$$

Conjecture 4 (Sarnak). *Let $f : \mathbb{N} \to \mathbb{C}$, have topological entropy zero. Then,*

$$\sum_{n \leq x} \lambda(n) f(n) = o(x).$$

Sarnak's conjecture is a natural generalization of Davenport's theorem. The latter corresponds to the case of $f(n) = e(\alpha n)$ which clearly has entropy 0 (simply cover the m-dimensional unit circle by a finite union of ε balls). Sarnak's conjecture also appears naturally in additive combinatorics. A fundamental step in the proof of the Green-Tao theorem is the orthogonality of the Möbius function to nilsystems Green and Tao [2012], this corresponds to a special case of Sarnak's conjecture.

As one might expect there is a tight link between the conjectures of Chowla and Sarnak. Chowla's conjecture implies Sarnak's conjecture. Moreover if one considers the logarithmic versions of the two conjectures, then they are equivalent Tao [2017] This leads one to believe that Chowla's conjecture and Sarnak's conjecture are equivalent, but this is so far unproven.

There is a large body of literature concerning Sarnak's conjecture (see Ferenczi, Kułaga-Przymus, and Lemańczyk [2017]). There are currently two main tools : When the the sequence f is sufficiently random, one uses a criterion steeming from the work of Daboussi-Delange, also known as the Bourgain-Katai-Sarnak-Ziegler criterion. This says that if, for all fixed primes p, q,

$$\sum_{n \leq x} f(pn)\overline{f(qn)} = o(X), \tag{23}$$

then Sarnak's conjecture holds. Verifying the above condition in practice might require a substantial amount of work depending on the f under consideration. There are also cases for which (23) fails but Sarnak conjecture is expected to hold nonetheless (the simplest example being an f that changes randomly signs on blocks that grow to infinity very slowly). In such a situation one frequently tries to find a way to use Theorem 6. In fact Theorem 6 can be rephrased in purely ergodic terms.

Due to the large number of works on the subject we cannot cover it in great depth, but refer to the recent survey Ferenczi, Kułaga-Przymus, and Lemańczyk [ibid.] for the state of the art.

0.6 The shfited convolution problem on average and L-functions. When the sequence $a(n)$ is of an *automorphic* origin, then the problem of estimating the correlations,

$$\sum_{n \le x} a(n)a(n+h)$$

is often-times refered to as the *shifted convolution problem*. The reason for the different terminology is that the problem occurs frequently and naturally when trying to either estimate moments of L-functions or obtain subconvex bounds.

The prototypical moment problem is the problem of estimating,

$$M_k(T) := \int_T^{2T} |\zeta(\tfrac{1}{2}+it)|^{2k} dt.$$

as $T \to \infty$ where $\zeta(s)$ is the Riemann zeta-function. It is conjectured that $M_k(T) \ll T^{1+\varepsilon}$ for all $k > 0$, and even more precisely that,

$$M_k(T) = TP_k(\log T) + O(T^{1-\delta_k}) \tag{24}$$

with P_k a polynomial of degree k^2 and $\delta_k > 0$ a positive exponent. This is a powerful conjecture that implies the bound $|\zeta(\frac{1}{2}+it)| \ll_\varepsilon 1 + |t|^\varepsilon$. Such a bound (known as the Lindelöf hypothesis) would be a great substitute for the Riemann Hypothesis in many applications.

Unfortunately (24) is known only for $k = 1$ and $k = 2$. While the case of $k = 1$ can be treated with harmonic analysis alone, the estimation for $k = 2$ depends crucially on having a power-saving in the shifted convolution problem. In fact one finds that,

$$\int_T^{2T} |\zeta(\tfrac{1}{2}+it)|^{2k} dt \approx \tag{25}$$

$$\approx TP_k(\log T) + \text{“}\frac{1}{T^{k/2-1}} \sum_{|h| \sim T^{k/2-1+\varepsilon}} e^{ih/T^{k/2-1}} \sum_{n \sim T^{k/2}} d_k(n)d_k(n+h)\text{”}$$

where the meaning of $\sim$ is left vague on purpose. Notice that the error term is trivial when $k = 1$, and is barely non-trivial for $k = 2$. Once $k \geq 3$ the error term is unfortunately too big to be manageable by any known method, and $k > 4$ seems to present extraordinary challenges as even square-root cancellation is no longer sufficient (but see B. Conrey and Keating [2015] for possible ways to circumvent this). Many results on moments focus exactly on the threshold where the sum in the error term is barely non-trivial.

0.6.1 The shifted convolution problem for $d_k(n)$. The shape of the error term in (25) motivates us to understand,

$$\sum_{n \leq X} d_k(n) d_k(n+h)$$

on average over h, or more generally with $d_k(n)$ replaced by coefficients of a $GL(k)$ automorphic form. The literature contains average results when the number of shifts $|h| \leq H$ is substantial, i.e $H > X^{1/3+\varepsilon}$ (and recently for $H > X^{8/33+\varepsilon}$). However using methods related to Theorem 6 one can reduce the number of shifts to be as small as $(\log X)^{O(k \log k)}$.

Theorem 9 (Matomäki-Radziwiłł-Tao)**.** *Let $k \geq \ell \geq 2$ be real numbers. Then, for $H = (\log X)^{10000 k \log k}$,*

$$\sum_{|h| \leq H} \Big| \sum_{n \leq X} d_k(n) d_\ell(n+h) - X P_{k+\ell}(\log X) \Big| = o(HX (\log X)^{k+\ell-2})$$

where $P_{k+\ell}$ is a polynomial of degree $k + \ell - 2$.

Compared to our earlier work multiplicative functions such as $d_k(n)$ present new challenges because they are unbounded. But it is not the fact that they are unbounded in itself which is the main difficulty – it's rather the fact that because they are unbounded, the main contribution to

$$\sum_{n \leq X} d_k(n) d_k(n+h)$$

comes from a thin subset of integers having $(k + o(1)) \log \log x$ prime factors and on which $d_k(n)$ is unusually large. The density of such integers is about $(\log X)^{-k \log k + k - 1}$.

The idea behind the proof of Theorem 9 is to first restrict to a density one subset of integers $\mathfrak{N}$ on which we can construct efficient sieve majorants for $d_k(n)$. Subsequently after some harmonic analysis, we find that the crucial issue is to obtain a non-trivial estimate for

$$\sum_{j=1}^{J} \sum_{X \leq x \leq 2X} \Big| \sum_{\substack{x < n < x+H \\ n \in \mathfrak{N}}} d_k(n) e(n \alpha_j) \Big|$$

where α_j is a set of well-spaced points and J is arbitrary. When J is large one can simply appeal to the large sieve. On the other hand when J is bounded obtaining a non-trivial result amounts to a variant of Theorem 6 for unbounded multiplicative functions (similar variants for other sparse sets of integers were studied in Goudout [2017] and Teräväinen [2016]). It is the intermediate range between bounded and large J which turns out the most subtle. In this range through a use of duality we (essentially) replace $d_k(n)$ by the corresponding sieve majorant $\widetilde{d}_k(n)$, and we are reduced to needing cancellations in

$$\sum_{x<n<x+H} \widetilde{d}_k(n)e(n\alpha_j)$$

after a substantial amount of effort (this would be trivial if $H > X^{\varepsilon}$). We then estimate high moments of such a sum to conclude that it exhibits cancellations for most x.

In fact the argument works quite generally for estimating $d_k(n)b(n+h)$ with $b(n)$ any sequence for which efficient sieve majorants can be constructed. For instance, we obtain results for the higher-order Titchmarsh divisor problem,

$$\sum_{n\leq X} d_k(n)\Lambda(n+h)$$

with an average over $|h| \leq H$ of size at most $H = (\log X)^{10000k\log k}$. For individual h the problem is open for all $k > 2$.

0.6.2 Moments of L-functions. Coming back to the moment problem, our results (such as Theorem 9) say nothing new in the case of the Riemann zeta-function, but they are nonetheless useful in other families. For instance, a q-analogue of moments of the Riemann zeta-function, is the problem of estimating,

$$\sum_{q\leq Q}\sum_{\chi \pmod q}\int_{\mathbb{R}} |L(\tfrac{1}{2}+it,\chi)|^{2k}\cdot\Phi(t)dt \tag{26}$$

where χ is a sum over primitive characters, $L(s,\chi)$ is a Dirichlet L-function and $\Phi(t)$ is a fixed smooth function. This problem (but without the t averaging) is also related to understanding the distribution of $d_k(n)$ in arithmetic progressions.

The large sieve gives sharp upper bound for the above moment problem when $k \leq 4$. A few years ago, J. B. Conrey, Iwaniec, and Soundararajan [2013] devised a method to obtain asymptotic estimates in moments such as (26). They illustrated their method to obtain an asymptotic for (26) when $k = 3$. The case $k = 4$ represents the absolute limit of their method, and also the limit of what should be realistically feasible. In Chandee and Li [2014] it was addressed conditionally on the Generalized Riemann Hypothesis.

Roughly for the solution of the case $k = 4$ one needs to estimate on average a shifted convolution problem in a short interval. It turns out that this problem is amenable to our earlier methods and leads to the following Theorem (the write-up is currently in preparation).

Theorem 10 (Chandee-Li-Matomäki-Radziwiłł). *Let $\Phi(t)$ be a fixed smooth function. Then,*

$$\sum_{q \leq Q} \sum_{\chi \pmod q} \int_{\mathbb{R}} |L(\tfrac{1}{2} + it, \chi)|^8 \cdot \Phi(t) dt \sim C \widehat{\Phi}(0) \cdot Q^2 (\log Q)^{16}.$$

as $Q \to \infty$, where the summation is over primitive characters and $C > 0$ is an absolute constant.

Previously the assumption of the Generalized Riemann Hypothesis was used to estimate non-trivially the shifted convolution problem that arises in this problem.

0.6.3 Gaps between multiplicative sequences. The applications of the shifted convolution problem are not restricted to problems related in one way or another to L-functions. A prominent example is Hooley's Hooley [1971] work on gaps between sums of two squares. Let $1 = s_1 < s_2 < \ldots$ be the sequence of integers representable as sums of two squares. Then the average gap between $s_{n+1} - s_n$ for $s_n \leq x$ is $\asymp \sqrt{\log x}$. Hooley investigated how often the gaps deviate from the mean. He proved that for $\gamma < 5/3$,

$$\sum_{s_n \leq x} (s_{n+1} - s_n)^{\gamma} \asymp x (\log x)^{\frac{1}{2}(\gamma - 1)}. \tag{27}$$

The form of the expression is motivated by Erdős's conjecture that,

$$\sum_{p_n \leq x} (p_{n+1} - p_n)^2 \asymp x \log x.$$

In (27) the lower bound is easy and follows from Holder's inequality against the case $\gamma = 1$. In principle (27) is conjectured to hold for all finite γ, but this is a very deep conjecture. It implies for instance that for any fixed $\varepsilon > 0$ in all intervals of the form $[x, x + x^{\varepsilon}]$ there is a sum of two squares.

The problem of showing (27) is equivalent to obtaining the following frequency bound,

$$\#\Big\{x \leq X : \sum_{x < s_n \leq x + H\sqrt{\log X}} 1 = 0\Big\} \ll \frac{X}{H^{\gamma - 1}} \tag{28}$$

uniformly in $1 \leq H \leq X$. It is the uniformity that is difficult to maintain in this problem.

Hooley's approach goes as follows: In order to obtain (28) he notices that for any weight w_n supported on sums of two squares, and for any constant A, the frequency (28) is

$$\ll \frac{1}{A^2} \sum_{x \leq X} \Big| \sum_{x \leq n \leq x+H} w_n - A \Big|^2 \tag{29}$$

Moreover the estimation of (29) is feasible if we can get a good estimate for the correlations

$$\sum_{|h| \leq H} \sum_{n \leq X} w_n \overline{w_{n+h}}$$

that saves at least a power of H over the trivial bound.

When H is small, Hooley selects $w_n = r(n)\rho(n)$ where $r(n)$ is the number of representations of n as a sums of two squares, and $\rho(n)$ is a sieve weight dampening the size of $r(n)$ so that $r(n)\rho(n) \approx 1$ on average. When H is large (say $H > X^{\varepsilon}$) we can afford to loose powers of the logarithm, and it's enough to choose $w_n = r(n)$. Then we require a shifted convolution on average, with a power-saving. This is possible to obtain because $r(n)$ is roughly similar to the divisor function, and similar techniques that can be used to estimate,

$$\sum_{n \leq x} d(n)d(n+h)$$

will also do the job for the $r(n)$ function.

The sequence of sums of two squares is a norm-form, since $a^2 + b^2$ is the norm of Gaussian integers. It is natural to ask if Hooley's result can be extended to norm forms of higher degree fields. Unfortunately we run right away in a serious difficulty : If K is a number field of degree 3 and $r_K(n)$ is the number of representations of n as a norm of an ideal in K, then there are no results with power-savings for the shifted convolution problem,

$$\sum_{|h| \leq X^{\delta}} \sum_{n \leq X} r_K(n) r_K(n+h)$$

In fact this is of a comparable difficulty as our Conjecture 2 in the case $\ell = 2$ and $k_1 = k_2 = 3$.

It turns out however that we can circumvent these difficulties by using techniques related to Theorem 6. The advantage of using these "more restrictive techniques" (after all we forfeit any possibility of power-savings) is that not only we can extend the result to norm-forms, but more generally to any "multiplicative sequence" (of which norm-forms are an example).

Corollary 2 (Matomäki-Radziwiłł). *Let $\mathcal{P}$ be a set of primes of positive density δ. Let $\mathcal{N}$ be the set of all square-free integers all of whose prime factors belong to $\mathcal{P}$. Denote the elements of $\mathcal{N}$ by $n_1 < n_2 < \dots$. Then, for all $\gamma < \frac{3}{2}$,*

$$\sum_{n_k \le x} (n_{k+1} - n_k)^{\gamma} \asymp_{\mathcal{P},\gamma} x(\log x)^{(1-\delta)(\gamma-1)}. \tag{30}$$

We think it is remarkable that the exponent $\frac{3}{2}$ does not depend on the density of $\mathcal{P}$. Let us very quickly explain the kind of ideas that go into the proof of Corollary (2). The case of H small can be disposed by proving a variant of our Theorem 6 for multiplicative functions that are supported on a set of primes of density $0 < \delta < 1$.

When H is large, the techniques that go into Theorem 6 are not immediately applicable, and need to be modified. Let us highlight the spirit of these modifications in the case of norm forms. What makes the shifted convolution problem (30) difficult are certain specific sets of integers, for instance the integers n that factor into abc with a, b, c roughly of equal size. However if one restricts in the shifted convolution problem to integers of the form $n = abc$ with a, b, c in a certain special configuration then the problem can be solved with a power-saving in X. Unfortunately the set of integers in such a desirable configuration might be of density zero, but this is not a problem when H is large!

The reason is that in the regime H large we can afford to lose some powers of the logarithm, and by restricting to a density zero subset (instead of the full sequence) we are typically loosing at most powers of the logarithm. So we simply run Hooley's method on the subsequence of integers representable as norm forms and that factor as $n = abc$ with abc in certain desirable configurations. In reality the proof of Corollary 2 goes along completely different lines, however what we explained highlights the spirit of the ideas.

0.7 The structure of multiplicative functions.

Our Theorem 6 is of course rather immediately applicable to the study of general multiplicative functions. For instance it immediately implies the following result.

Corollary 3. *Let $f : \mathbb{N} \to \mathbb{R}$ be a multiplicative function which is non-zero for positive proportion of natural numbers. Then f has a positive proportion of sign changes if and only if $f(n) < 0$ for some $n \in \mathbb{N}$.*

This was an improvement even in the case of $f(n) = \mu(n)$. This result has been the starting point of several "rigidity theorems" of Klurman [2017] and Klurman and Mangerel [2017]. We highlight a few of their results. For instance, in Klurman [2017] an old conjecture of Katai is resolved. This asserts that for f taking values on the unit disk,

$$\sum_{n \le x} |f(n+1) - f(n)| = o(x) \tag{31}$$

if and only if, $f(n) = n^{it}$ for some $t \in \mathbb{R}$, or

$$\sum_{n \leq x} |f(n)| = o(x).$$

Notice that if f is assumed to be real-valued and lying on the unit-disk (i.e $f(n) = \pm 1$) then Katai's conjecture is nothing more than a convoluted restatement of Corollary 3.

Moreover in Klurman and Mangerel [2017] appears a solution to an old conjecture of Chudakov. The conjecture states that if f is a multiplicative function such that $f(n)$ takes only finitely many values, and $f(p)$ is zero on only finitely many primes, and

$$\sum_{n \leq x} f(n) = \alpha x + O(1)$$

then f is a Dirichlet character. In a similar vein one can think of the Erdős Discrepancy Problem as a rigidity theorem, since it implies that there are no completely multiplicative functions f with $\sum_{n \leq x} f(n) = O(1)$ for all x.

GAPS BETWEEN PRIMES

James Maynard

Abstract

We discuss recent advances on weak forms of the Prime k-tuple Conjecture, and its role in proving new estimates for the existence of small gaps between primes and the existence of large gaps between primes.

1 Introduction

It follows from the Prime Number Theorem that the *average* gap between primes less than X is of size roughly $\log X$ when X is large. We expect, however, that occasionally these gaps are rather smaller than $\log X$, and occasionally rather larger. Specifically, based on random models and numerical evidence, we believe that the largest and smallest gaps are as described in the following two famous conjectures[1].

Conjecture 1 (Twin Prime Conjecture)**.** *There are infinitely many pairs of primes which differ by exactly 2.*

Conjecture 2 (Cramér's Conjecture, weak form)**.** *Let p_n denote the n^{th} prime. Then*

$$\sup_{p_n \le X} (p_{n+1} - p_n) = (\log X)^{2+o(1)}.$$

Moreover, the Twin Prime Conjecture can be thought of as a special case of the far-reaching Prime k-tuple Conjecture describing more general patterns of many primes.

Conjecture 3 (Prime k-tuple Conjecture)**.** *Let $L_1, \dots, L_k$ be integral linear functions $L_i(n) = a_i n + b_i$ such that for every prime p there is an integer n_p with $\prod_{i=1}^k L_i(n_p)$ coprime to p. Then there are infinitely many integers n such that all of $L_1(n), \dots, L_k(n)$ are primes.*

The author is funded by a Clay Research Fellowship. This article was written whilst the author was a member of the Institute for Advanced Study, Princeton and supported by the National Science Foundation under Grant No. DMS - 1638352.

MSC2010: primary 11N05; secondary 11N35.

[1] The original conjecture of Cramér [1936] was a stronger statement which is no longer fully believed to be true. We expect the weaker version given here to hold.

Unfortunately all these conjectures seem well beyond the current techniques, but we are able to make partial progress by showing that we do have gaps which are smaller or larger than the average gap. A key part of recent progress on results about gaps between primes has been weak versions of Conjecture 3, where one shows there are infinitely many integers n such that *several* (rather *all*) of the linear functions are prime at n.

Theorem 1 (Maynard [2015]). *Let $L_1, \dots, L_k$ be integral linear functions $L_i(n) = a_i n + b_i$ such that for every prime p there is an integer n_p with $\prod_{i=1}^k L_i(n_p)$ coprime to p. Then there is a constant $c > 0$ such that there are infinitely many integers n where at least $c \log k$ of $L_1(n), \dots, L_k(n)$ are primes.*

Variants of Theorem 1 have been important in recent results on small and large gaps between primes, and have proven useful because the method of proof is quite flexible and can generalize to other situations. Specifically, we now know the following approximations to Conjecture 1 and Conjecture 2.

Theorem 2 (Polymath [2014]). *There are infinitely many pairs of primes which differ by at most* 246.

Theorem 3 (Ford, Green, Konyagin, Maynard, and Tao [2018]). *There exists a constant $c > 0$ such that*

$$\sup_{p_n \le X} (p_{n+1} - p_n) \ge c \frac{\log X \cdot \log\log X \cdot \log\log\log\log X}{\log\log\log X}.$$

Moreover, in the case of small gaps between primes, we can show the existence of *many* primes in bounded length intervals.

Theorem 4 (Maynard [2016a]). *There exists a constant $c > 0$ such that, for all $X \ge 2$ there are at least $cX \exp(-\sqrt{\log X})$ integers $x \in [X, 2X]$ such that*

$$\#\{\textit{primes in } [x, x+y]\} \ge c \log y.$$

For example, this shows that there are infinitely many intervals of length $e^{m/c}$ containing m primes, and, for fixed $\epsilon > 0$, infinitely many x such that the interval $[x, x+(\log x)^\epsilon]$ contains $\epsilon c \log\log x$ primes.

2 The GPY sieve method

We aim to prove Theorem 1 by the 'GPY method', which can be interpreted as a first moment method which was introduced to study small gaps between primes by Goldston, Pintz, and Yıldırım [2009]. This takes the following basic steps, for some given set $\{L_1, \dots, L_k\}$ of distinct functions satisfying the hypotheses of Conjecture 3:

1. We choose a probability measure w supported on integers in $[X, 2X]$.

2. We calculate the expected number of the functions $L_i(n)$ which are prime at n, if n is chosen randomly with probability $w(n)$.

3. If this expectation is at least m, then there must be some $n \in [X, 2X]$ such that at least m of $L_1(n), \dots, L_k(n)$ are primes.

4. If this holds for all large X, then there are infinitely many such integers n.

This procedure only works if we can find a probability measure w which is suitably concentrated on integers n where many of the $L_i(n)$ are prime, but at the same time is simple enough that we can calculate this expectation unconditionally. We note that by linearity of expectation, it suffices to be able to calculate the probability that any one of the linear functions is prime. However, any slowly changing smooth function w is insufficient since the primes have density 0 in the integers, whereas any choice of w explicitly depending on the joint distribution of prime values of the L_i is likely to be too complicated to handle unconditionally.

Sieve methods are a flexible set of tools, developed over the past century, which provide natural choices for the probability measure w. The situation of simultaneous prime values of $L_1, \dots, L_k$ is a 'k-dimensional' sieve problem. For such problems when k is large but fixed, the Selberg sieve tends to be the type of sieve which performs best. The standard choice of Selberg sieve weights (which are essentially optimal in closely related situations) are

$$w(n) \propto \Bigg(\sum_{\substack{d \mid \prod_{i=1}^k L_i(n) \\ d<R}} \mu(d) \Big(\log \frac{R}{d}\Big)^k \Bigg)^2, \tag{2-1}$$

where R is a parameter which controls the complexity of the sieve weights, and w is normalized to sum to 1 on $[X, 2X]$.

To calculate the probability that $L_j(n)$ is prime with this choice of $w(n)$, we wish to estimate the sum of $w(n)$ over $n \in [X, 2X]$ such that $L_j(n)$ is prime. To do this we typically expand the divisor sum in the definition (2-1) and swap the order of summation. This reduces the problem to estimating the number of prime values of $L_j(n)$ for $n \in [X, 2X]$ in many different arithmetic progressions with moduli of size about R^2. The Elliott-Halberstam conjecture Elliott and Halberstam [1970] asserts that we should be able to do this when $R^2 < X^{1-\epsilon}$, but unconditionally we only know how to do this when $R^2 < X^{1/2-\epsilon}$, using the Bombieri-Vinogradov Theorem Bombieri [1965] and Vinogradov [1965]. After some computation one finds that, provided we do have suitable estimates for primes in arithmetic progressions, the choice (2-1) gives

$$\mathbb{E}\,\#\{1 \le i \le k : L_i(n) \text{ prime}\} = \Big(2 - \frac{2}{k+1} + o(1)\Big)\frac{\log R}{\log X}. \tag{2-2}$$

In particular, this is less than 1 for all large X, even if we optimistically assume the Elliott-Halberstam conjecture and take $R \approx X^{1/2-\epsilon}$, and so it appears that we will not be able to conclude anything about primes in this manner.

The groundbreaking work of Goldston, Pintz, and Yıldırım [2009] showed that a variant of this choice of weight actually performs much better. They considered

$$w(n) \propto \Big(\sum_{\substack{d \mid \prod_{i=1}^k L_i(n) \\ d<R}} \mu(d)\Big(\log\frac{R}{d}\Big)^{k+\ell}\Big)^2, \tag{2-3}$$

where ℓ is an additional parameter to be optimized over. With the choice (2-3), one finds that provided we have suitable estimates for primes in arithmetic progressions, we obtain

$$\mathbb{E}\,\#\{1 \le i \le k : L_i(n) \text{ prime}\} = \Big(4 + O\Big(\frac{1}{\ell}\Big) + O\Big(\frac{\ell}{k}\Big)\Big)\frac{\log R}{\log X}.$$

This improves upon (2-2) by a factor of about 2 when k is large and $\ell \approx k^{1/2}$. This falls just short of proving that two of the linear functions are simultaneously prime when $R = X^{1/4-\epsilon}$ as allowed by the Bombieri-Vinogradov theorem, but any small improvement allowing $R = X^{1/4+\epsilon}$ would give bounded gaps between primes! By considering additional possible primes, Goldston Pintz and Yıldırım were able to show

$$\liminf_n \frac{p_{n+1} - p_n}{\log p_n} = 0,$$

finally extending a long sequence of improvements to upper bounds for the left hand side Erdős [1940], Rankin [1950], Ricci [1954], Bombieri and Davenport [1966], Pilt'ja [1972], Uchiyama [1975], M. N. Huxley [1973, 1977], M. Huxley [1984], and Maier [1988].

Building on earlier work of Fouvry and Iwaniec [1980] and Bombieri, Friedlander, and Iwaniec [1986, 1987, 1989], Zhang [2014] succeeded in establishing an extended version of the Bombieri-Vinogradov Theorem for moduli with no large prime factors allowing $R = X^{1/4+\epsilon}$, and ultimately this allowed him to show

$$\mathbb{E}\,\#\{1 \le i \le k : L_i(n) \text{ prime}\} > 1,$$

if $k > 3\,500\,000$ and X is sufficiently large. The key breakthrough in Zhang's work was this result on primes in arithmetic progressions of modulus slightly larger than $X^{1/2}$. By choosing suitable linear functions, this then showed that

$$\liminf_n (p_{n+1} - p_n) \leq 7 \cdot 10^7.$$

3 A modified GPY sieve method

An alternative approach to extending the work of Goldston, Pintz and Yıldırım was developed independently by the author Maynard [2015] and Tao (unpublished). The key difference was to consider the multidimensional generalization

$$w(n) \propto \Big(\sum_{\substack{d_1,\dots,d_k \\ d_i | L_i(n) \\ \prod_{i=1}^k d_i < R}} \mu(d) F\Big(\frac{\log d_1}{\log R}, \dots, \frac{\log d_k}{\log R}\Big)\Big)^2, \tag{3-1}$$

for suitable smooth functions $F : \mathbb{R}^k \to \mathbb{R}$ supported on $[0,\infty)^k$. The flexibility of allowing the function F to depend on each divisor $d_1, \dots, d_k$ of $L_1(n), \dots, L_k(n)$ allows us to make $w(n)$ more concentrated on integers n when many of the $L_i(n)$ are prime.

With this choice, after some computation, one finds that

$$\mathbb{E}\,\#\{1 \leq i \leq k : L_i(n) \text{ prime}\} = \Big(\frac{\sum_{i=1}^k J_i(\tilde{F})}{I(\tilde{F})} + o(1)\Big)\frac{\log R}{\log X}, \tag{3-2}$$

provided, as before, we are able to count primes in arithmetic progressions to modulus R^2 on average. Here the $J_i(\tilde{F})$ and $I(\tilde{F})$ are k-dimensional integrals depending on a transform[2] $\tilde{F}$ of F, given by

$$J_\ell(\tilde{F}) = \int \cdots \int_{\sum_{i\neq\ell} t_i \leq 1} \Big(\int_0^{1-\sum_{i\neq\ell} t_i} \tilde{F}(t_1, \dots, t_k) dt_\ell \Big)^2 dt_1 \dots dt_{\ell-1} dt_{\ell+1} \dots dt_k,$$

$$I(\tilde{F}) = \int \cdots \int_{\sum_{i=1}^k t_i \leq 1} \tilde{F}(t_1, \dots, t_k)^2 dt_1 \dots dt_k.$$

For any piecewise smooth choice of $\tilde{F}$ supported on $\sum_{i=1}^k t_i \leq 1$ there is a corresponding choice of F. In particular, we can show that many of the L_i are simultaneously prime infinitely often, if we can show that $\sup_{\tilde{F}} (\sum_{i=1}^k J_i(\tilde{F})/I(\tilde{F})) \to \infty$ as $k \to \infty$.

[2] $\tilde{F}$ is F differentiated with respect to each coordinate.

A key advantage of this generalization is that we can make use of high dimensional phenomena such as concentration of measure. We concentrate on functions $\tilde{F}$ the form

$$\tilde{F}(t_1,\dots,t_k)=\begin{cases}\prod_{i=1}^k G(t_i), & \sum_{i=1}^k t_i<1,\\ 0, & \text{otherwise},\end{cases}$$

and make a probabilistic interpretation of the integrals $J_i(\tilde{F})$ and $I(\tilde{F})$. Let $Z_1,\dots,Z_k$ be i.i.d. random variables on $[0,\infty]$ with probability density function G^2, expectation $\mu=\int_0^\infty tG(t)^2dt$ and variance $\sigma^2=\int_0^\infty (t-\mu)^2G(t)^2dt$. Then

$$I(\tilde{F})=\mathbb{P}\Big(\sum_{i=1}^k Z_i<1\Big),\qquad J_\ell(\tilde{F})\ge\Big(\int_0^{1/2}G(t)dt\Big)^2\mathbb{P}\Big(\sum_{i=1}^k Z_i<\frac{1}{2}\Big).$$

The random variable $\sum_{i=1}^k Z_i$ has mean $k\mu$ and variance $k\sigma^2$, and so it becomes concentrated on $k\mu$ when k is large provided $\sigma^2/\mu\to 0$ as $k\to\infty$. In particular, if $\mu<1/3k$ and $\sigma^2k\to 0$, then $\mathbb{P}(\sum_{i=1}^k Z_i<1/2)$ approaches 1 as $k\to\infty$. Therefore, to show that $\sum_{\ell=1}^k J_\ell(\tilde{F})/I(\tilde{F})\to\infty$ as $k\to\infty$, it suffices to find a function G satisfying

$$\int_0^\infty tG(t)^2<\frac{1}{3k},\qquad \int_0^\infty G(t)^2dt=1,$$

$$k\int_0^\infty t^2G(t)^2dt\to 0\quad\text{and}\quad k\Big(\int_0^\infty G(t)dt\Big)^2\to\infty\quad\text{as}\quad k\to\infty.$$

We find that choosing

$$G(t)\approx\begin{cases}\frac{\sqrt{k\log k}}{1+tk\log k}, & t<k^{-3/4},\\ 0, & \text{otherwise},\end{cases}\tag{3-3}$$

gives a function G satisfying these constraints. (This choice can be found via the calculus of variations, and further calculations show that this choice is essentially optimal.) Putting this all together, we find that for some constant $c>0$

$$\mathbb{E}\,\#\{i:\ L_i(n)\text{ prime}\}\ge(c\log k+o(1))\frac{\log R}{\log X}.$$

In particular, taking $R=X^{1/4-o(1)}$ (as allowed by the Bombieri-Vinogradov theorem) and letting k be sufficiently large, we find that there are infinitely many integers n such that $(c\log k)/4+o(1)$ of the $L_i(n)$ are simultaneously prime. Performing these calculations carefully allows one to take $c\approx 1$ when k is large.

Morally, the effect of such a choice of function $\tilde{F}$ is to make 'typical' divisors $(d_1, \dots, d_k)$ occurring in (3-1) to have $\prod_{i=1}^k d_i$ smaller, but for it to be more common that some of the components of $(d_1, \dots, d_k)$ are unusually large when compared with (2-1) or (2-3). This correspondingly causes the random integer n chosen with probability $w(n)$ to be such that the $L_i(n)$ are more likely to have slightly smaller prime factors, but it is also more likely that some of the $L_i(n)$ are prime.

4 Consequences for small gaps between primes

The above argument shows that there is a constant $c > 0$ such that for any set $\{L_1, \dots, L_k\}$ of integral linear functions satisfying the hypotheses of Conjecture 3, at least $c \log k$ of the linear functions L_i are simultaneously prime infinitely often. To show that there are primes close together, we simply take the linear functions to be of the form $L_i(n) = n + h_i$ for some integers $h_1 \le \cdots \le h_k$ chosen to make $\prod_{i=1}^k L_i(n)$ have no fixed prime divisor, and so that $h_k - h_1$ is small.

In general, a good choice of the h_i is to take h_i to be the i^{th} prime after the integer k. With this choice, $\prod_{i=1}^k L_i(n)$ has no fixed prime divisor and $h_k - h_i \approx k \log k$, so we can find intervals of length $k \log k$ containing $c \log k$ primes infinitely often. By working out the best possible implied constants, the argument we have sketched allows us to show that there are m primes in an interval of length $O(m^3 e^{4m})$ infinitely often. By incorporating refinements of the work of Zhang on primes in arithmetic progressions by the Polymath 8a project Castryck et al. [2014], and using some bounds from Harman's sieve Harman [2007], this can be improved slightly to $O(e^{3.815m})$ by work of R. C. Baker and Irving [2017].

If we are only interested in just how small a *single* gap can be, then we can improve the analysis and get an explicit bound on the size of the gap by adopting a numerical analysis perspective. The key issue is to find the smallest value of k such that for all large X

$$\mathbb{E}\,\#\{1 \le i \le k : L_i(n) \text{ prime}\} > 1,$$

since this immediately implies that two of the linear functions are simultaneously prime. Recalling that we can choose $R = x^{1/4-\epsilon}$ for any $\epsilon > 0$, using (3-2) we reduce the problem to finding a value of k as small as possible, such that we can find a function $\tilde{F} : [0, \infty)^k \to \mathbb{R}$ with

$$\frac{\sum_{i=1}^k J_i(\tilde{F})}{I(\tilde{F})} > 4.$$

We fix some basis functions $g_1, \dots, g_r : [0, \infty)^k \to \mathbb{R}$ which are supported on $(t_1, \dots, t_k)$ satisfying $\sum_{i=1}^k t_i \le 1$, and restrict our attention to functions $\tilde{F}$ in the linear span of the g_i; that is functions $\tilde{F}$ of the form

$$\tilde{F}(t_1,\dots,t_k)=\sum_{i=1}^{r} f_i g_i(t_1,\dots,t_r),$$

for some coefficients $\mathbf{f}=(f_1,\dots f_r)\in\mathbb{R}^r$ which we think of as variables we will optimize over. For such a choice, we find that $\sum_{i=1}^k J_i(\tilde{F})$ and $I(\tilde{F})$ are both quadratic forms in the variables $f_1,\dots,f_r$, and the coefficients of these quadratic forms are explicit integrals in terms of $g_1,\dots,g_r$. If we choose a suitably nice basis $g_1,\dots,g_r$, then these integrals are explicitly computable, and so we obtain explicit $r\times r$ real symmetric matrices M_1 and M_2 such that

$$\frac{\sum_{i=1}^k J_i(\tilde{F})}{I(\tilde{F})}=\frac{\mathbf{f}^T M_1\mathbf{f}}{\mathbf{f}^T M_2\mathbf{f}}.$$

We then find that the choice of coefficients $\mathbf{f}$ which maximizes this ratio is the eigenvector of $M_2^{-1}M_1$ corresponding to the largest eigenvalue, and the value of the ratio is given by this largest eigenvalue. Thus the existence of a good function $\tilde{F}$ can be reduced to checking whether the largest eigenvalue of a finite matrix is larger than 4, which can be performed numerically by a computer.

If we choose the g_i to be symmetric polynomials of low degree, then this provides a nice basis since the corresponding integrals have a closed form solution, and allows one to make arbitrarily accurate numerical approximations to the optimal function $\tilde{F}$ with enough computation. For the problem at hand, these numerical calculations are large but feasible. This approach ultimately allows one to show that if $k=54$ there is a function $\tilde{F}$ such that $\sum_{i=1}^{54} J_i(\tilde{F})/I(\tilde{F})>4$.

To turn this into small gaps between primes we need to choose the shifts h_i in our linear functions $L_i(n)=n+h_i$ so that $\prod_{i=1}^{54} L_i(n)$ has no fixed prime divisor, and the h_i are in as short an interval as possible. This is a feasible exhaustive numerical optimization problem, with an optimal choice of the $\{h_1,\dots,h_{54}\}$ given by [3]

$$\begin{aligned}\{&0,2,6,12,20,26,30,32,42,56,60,62,72,74,84,86,90,96,\\&104,110,114,116,120,126,132,134,140,144,152,156,\\&162,170,174,176,182,186,194,200,204,210,216,222,\\&224,230,236,240,242,246,252,254,260,264,266,270\}.\end{aligned}$$

Putting this together, we find

$$\liminf_n(p_{n+1}-p_n)\le 270.$$

[3] Such computations were first performed by Engelsma - see http://www.opertech.com/primes/k-tuples.html

This result is not quite the current record - in Polymath [2014] we make some further technical refinements to the sieve, which corresponds to modifying the expressions $J_i(\tilde{F})$ and $I(\tilde{F})$ slightly. This ultimately allows us to improve $k = 54$ to $k = 50$ and correspondingly improve from gaps of size at most 270 to gaps of at most 246, giving Theorem 2. The main ideas are the same as above.

5 Large gaps between primes

It turns out that because Theorem 1 gives strong partial information about the joint distribution of prime solutions to linear equations, which lie at the heart of many basic estimates about primes, it can be used to make progress on the existence of *large* gaps between primes, although the connection is less direct than with small gaps.

The first major breakthrough on large gaps between primes was due to Westzynthius [1931], who showed that there were gaps which could be arbitrarily large compared with the average gap. During the 1930s this was refined with ideas due to Erdős [1940] and Rankin [1936], giving

$$\sup_{p_n \le X} (p_{n+1} - p_n) \ge c' \frac{\log X \cdot \log\log X \cdot \log\log\log\log X}{(\log\log\log X)^2}, \tag{5-1}$$

for some constant $c' > 0$. Subsequent improvements over the next 75 years Schönhage [1963], Rankin [1962/1963], and Maier and Pomerance [1990] were only in improving the value of the constant c', the strongest being $c' = 2e^\gamma + o(1)$, due to Pintz [2014]. All of these approaches are based on a variant of the following lemma, which reduces the problem of constructing large gaps between primes to a combinatorial covering problem.

Lemma 5. *If one can choose residue classes $a_p \pmod p$ for $p \le x$ such that every element of $\{1, \dots, y\}$ is congruent to $a_p \pmod p$ for some $p \le x$, then there is a prime $p_n \ll e^x$ such that $p_{n+1} - p_n \ge y$.*

This lemma (which is a simple consequence of the Chinese Remainder Theorem), can be thought of as a natural generalization of the argument that $n! + 2, \dots, n! + n$ are n consecutive composite integers, and so explicitly demonstrates a prime gap of size at least n. (This roughly corresponds to choosing $a_p = 1$ for all primes p and taking $y = x$.)

The key idea in the Erdős–Rankin construction was to choose $a_p = 0$ for ‘medium sized’ primes, and choose a_p differently for small and large primes. Specifically, a version of their argument follows the following strategy to choose the a_p in turn, for some parameter $2 < z < x^{1/2}$:

1. Choose $a_p = 0$ for ‘medium primes’ $p \in [z, x/3]$.

2. Choose $a_p = 1$ for 'small primes' $p < z$.

3. Choose a_p greedily for 'large primes' $p \in (x/3, x]$.

By 'choosing greedily' we mean that we pick a residue class $a_q \pmod q$ which contains the largest number of integers in $\{1, \dots, y\}$ which are not congruent to $a_p \pmod p$ for some previously chosen a_p. There must be a residue class containing at least one uncovered element if we have not already covered all elements.

By choosing z appropriately[4], this allows one to cover $\{1, \dots, y\}$ by residue classes $a_p \pmod p$ for $p \le 7y(\log\log y)^2/(\log y \cdot \log\log\log y)$, which ultimately results in the bound (5-1). The key feature making this construction work is that choosing $a_p = 0$ for a very large number of 'medium primes' is much more efficient that a typical choice. This is because integers in $\{1, \dots, y\}$ with no prime factors bigger than z_1 are much less common than integers avoiding a random residue class for each prime bigger than z_1.

It was a well-known challenge of Erdős as to whether one could improve upon (5-1) by an arbitrarily large constant, and this was verified independently by Ford, Green, Konyagin, and Tao [2016] and the author Maynard [2016b]. Ultimately the approach of Ford-Green-Konyagin-Tao relied on the work of Green-Tao and Green-Tao-Ziegler on linear equations in primes Green and Tao [2010], Green and Tao [2012], and Green, Tao, and Ziegler [2012], whereas the work of the author relied on versions of Theorem 1. So far this second approach has proved more flexible for gaining quantitative improvements over (5-1), the strongest known results being due to a collaboration between all these authors Ford, Green, Konyagin, Maynard, and Tao [2018].

We focus here on the approach based around Theorem 1, first thinking about obtaining an arbitrarily large constant improvement over (5-1). We follow the same overall strategy as Erdős–Rankin, but improve the analysis for the large primes. By choosing the residue classes in a more sophisticated manner, we are able to remove *many* uncovered elements on average, rather than just 1 element, and this is the key feature which allows us to improve on (5-1).

Using the same choice of a_p as Erdős–Rankin for $p \le x/3$, we see that the elements of $\{1, \dots, y\}$ which are not covered by $a_p \pmod p$ for $p \le x/3$ are integers $n < y$ where n has no prime factors in $[z, x/3]$ and $n - 1$ has no prime factors less than z. Let us call the set of such integers $\mathcal{S}$. This is a set which is very similar to the primes, since most elements have a very large prime factor, and it is not clear that there are *any* possible a_p which might cover more than one additional element. Indeed, a typical residue class $a_p \pmod p$ for $p > x/3$ will contain *no* elements of $\mathcal{S}$. The problem of showing the existence of unusual residue classes containing many elements of $\mathcal{S}$ leads us to the following toy problem.

[4] $z = \exp(\log x \cdot \log\log\log x \,/\, 2\log\log x)$ gives a suitable choice.

Problem 1. *Given a prime modulus q, can we find a residue class $a_q \pmod q$ which contains many primes all less than $q(\log q)^{1/2}$?*

This toy problem can be answered in the positive by a variant of Theorem 1. If we choose our linear functions to be of the form $L_i(n) = n + h_i q$ for suitable constants h_i, then the existence of a residue class containing many small primes is implied by many of the L_i being simultaneously prime at n for some $n \le q$. The underlying sieve methodology is flexible enough to handle the fact that now the linear functions depend on q, and so can solve the toy problem. This correspondingly shows that for each large prime p, there are some residue classes $a_p \pmod p$ containing many elements of $\mathcal{S}$.[5]

To turn this into an actual covering, we need the residue classes for *different* large primes to be approximately 'independent' from one another. To do this we use the probabilistic method, by choosing a residue class at random for each large prime $p \in (x/3, x/2]$, and showing that with high probability this results in approximately independent behavior. Specifically, we choose a_p randomly with

$$\mathbb{P}(a_p = a \pmod p) \propto \sum_{\substack{n \equiv a \pmod p \\ L_1(n),\dots,L_k(n) \in \mathcal{S}}} w_{\mathcal{L}_p}(n),$$

where $w_{L_p}(n)$ is the normalized sieve weight introduced in Section 3 for the functions $L_1, \dots, L_k$ with $L_i(n) = n + h_i p$. We make these choices independently for all $p \in (x/3, x/2]$, so

$$\mathbb{P}\,(n \text{ not covered by large primes}) = \prod_{p \in [x/3, x/2]} \Big(1 - \sum_{m \equiv n \pmod p} w_{\mathcal{L}_p}(m)\Big)$$
$$\le \exp\Big(-\mathbb{E}\,\#\{p \in [x/3, x/2] : n \equiv a_p \pmod p\}\Big).$$

In particular, if the expected number of times any $n \in \mathcal{S}$ is congruent to $a_p \pmod p$ for some $p \in (x/3, x/2]$ is at least t, then the expected number of elements of $\mathcal{S}$ which are not covered by $a_p \pmod p$ for $p \le x/2$ is at most $e^{-t}\#\mathcal{S}$. If t is large, we can then greedily choose residue classes $a_p \pmod p$ for $p \in (x/2, x]$ to cover these few remaining elements.

Thus our new strategy for choosing the a_p is:

1. Choose $a_p = 0$ for 'medium primes' $p \in [z, x/3]$.

2. Choose $a_p = 1$ for 'small primes' $p < z$.

[5] The work of Green-Tao on linear equations in primes allows one to show for *most* large primes q there are k primes less than $q(\log q)^{1/2}$ for any fixed k, which is sufficient to improve the estimates for large primes.

3. Choose a_p randomly according to the sieve weights $w_{\mathcal{L}_p}$ independently for 'large primes' $p \in (x/3, x/2]$.

4. Choose a_p greedily for 'very large primes' $p \in (x/2, x]$.

This gives an arbitrarily large constant improvement over (5-1) provided we show that we can take t arbitrarily large. Calculations similar to those of Section 3 allow us to take t to be of size $\log k$ when we consider k linear functions, and so letting k be large enough we succeed in showing that the constant in (5-1) can indeed be taken to be arbitrarily large.

To get a quantitative improvement over (5-1) we run the essentially the same argument, but we need a version of Theorem 1 which has uniformity with respect to the number k of linear functions we consider as well as uniformity with respect to the coefficients of the linear functions. Such a version of Theorem 1 was established in Maynard [2016a]. With some technical modifications, this would ultimately yield a bound

$$\sup_{p_n \le X} (p_{n+1} - p_n) \ge c'' \frac{\log X \cdot \log\log X}{\log\log\log X}$$

for some constant $c'' > 0$. This is not quite as good as Theorem 3, because one can improve the quantitative argument further by being more careful about the manner in which we choose the a_p for different large primes. If instead of choosing residue classes independently at random we use ideas based on the 'semi-random' or 'Rödl nibble' method from combinatorics, we are able to establish a hypergraph covering lemma which allows our covering by residue classes to have almost no overlaps. After working through the technical details, this ultimately gives an additional improvement of a factor $\log\log\log\log X$, and hence gives Theorem 3.

6 Limitations

Both Theorem 1 and Theorem 3 appear to be the qualitative limit of what these methods can give, and require an entirely new approach to do better. Theorem 2 depends on the quantitative aspects of Theorem 1, and can potentially be improved slightly. New ideas are likely needed to significantly improve upon Theorem 2, however.

Optimal weights in high-dimensional sieves are poorly understood, and we do not know of general barriers beyond the parity phenomenon. In the context of Theorem 1 the parity phenomenon means that we cannot hope to prove $k/2$ of our linear functions are simultaneously prime based on a sieve argument. In particular, significant new ideas are required to attack the Twin Prime Conjecture.

Although in principle this leaves open the possibility of having rather more than $\log k$ of the linear functions being simultaneously prime, since the Selberg sieve weights seem to perform best in high dimensional sieving situations, we expect that it is unlikely to be possible to much do better than (3-2) based on weights formed by short divisor sums, even if we cannot prove a direct obstruction. Heuristic arguments show that over fairly general classes of potential Selberg sieve weights, we do not expect to do better than the choice given by (3-1). Given the choice (3-1), it is possible to show that a choice of smooth function similar to (3-3) is essentially best possible.

For the question of explicit small gaps between primes, there is some potential for further progress. Stronger results about primes in arithmetic progressions allow us to take R in (3-2) larger, which should reduce the critical value of k, and hence the size of the gap. The current record of 246 in Theorem 2 does not make use of the new equidistribution estimates of Zhang or its refinements (but these would likely only lead to small improvements). If we assume optimistic conjectures on the distribution of primes then we can do significantly better. Under the Elliott-Halberstam conjecture one can show gaps of size 12 Maynard [2015], and a generalization of the Elliott-Halberstam conjecture to numbers with several prime factors allows us to reach the absolute limit of these methods. Specifically, we have the following.

Theorem 6 (Polymath [2014]). *Assume the 'Generalized Elliott-Halberstam Conjecture' (see Polymath [ibid.]). Then we have*

$$\liminf_{n}(p_{n+1}-p_n)\leq 6.$$

The parity phenomenon makes it impossible for a first moment method of this type to prove a result less than 6, and so Theorem 6 is the strongest result of this type we can hope to prove along these lines.

All proofs showing the existence of large gaps between primes rely on some variant of Lemma 5, which allows one to construct a sequence of consecutive composite integers $n_1,\dots,n_1+y$ all with a prime factor of size $O(\log n_1)$. This places a severe limitation on how large the gaps we produce can be, since we expect that a large gap between primes will involve many composites n whose smallest prime factor is much larger than $\log n$. Specifically, Maier and Pomerance [1990] conjectured that the largest string of consecutive integers less than X all containing such a small prime factor should be of length

$$\log X\cdot(\log\log X)^{2+o(1)}.$$

Therefore we do not expect to be able to produce gaps larger than this without a new approach. The 'semi-random' method used in Ford, Green, Konyagin, Maynard, and Tao [2018] to show the existence of a good choice residue classes for large primes is essentially as good as one can hope for, so any quantitative progress based on the same overall method would likely require an improvement to Problem 1, showing the existence of more than $\log\log q$ primes less than $q(\log q)^{1/2}$ in some residue class modulo q. A uniform version of Conjecture 3 suggests that there should be residue classes containing roughly $(\log q)^{1/2}/\log\log q$ such primes, but we do not know how to prove this.

7 Other applications and further reading

For a more thorough survey of the details of these ideas on small gaps between primes, as well as the ideas behind the breakthrough of Zhang, we refer the reader to the excellent survey articles of Granville [2015] and Kowalski [2015]. For a more details of the original work of Goldston, Pintz and Yıldırım we refer the reader to survey by Soundararajan [2007].

One useful feature of the argument of Section 3 is that the full strength of the Bombieri-Vinogradov theorem was not required to prove bounded gaps between primes. Provided we can estimate primes in arithmetic progressions with modulus of size x^ϵ on average, we would obtain a version of Theorem 1 with $c\epsilon \log k$ of the linear functions are prime. This allows one to show the existence of bounded gaps between primes in many subsets of the primes where one has this type of weaker arithmetic information. A general statement of this type was established in Maynard [2016a]. The fact that one can restrict the entire argument to an arithmetic progression also allows one to get some control on the joint distribution of various arithmetic functions. There have been many recent works making use of these flexibilities in the setup of the sieve method, including Thorner [2014], Castillo, Hall, Lemke Oliver, Pollack, and Thompson [2015], Banks, Freiberg, and Turnage-Butterbaugh [2015], Freiberg [2016], Pollack [2014], H. Li and Pan [2015], R. C. Baker and Pollack [2016], Matomäki and Shao [2017], R. C. Baker and Zhao [2016a], Chua, Park, and Smith [2015], Vatwani [2017], Troupe [2016], Pintz [2015, 2017], Huang and Wu [2017], R. C. Baker and Zhao [2016b], Banks, Freiberg, and Maynard [2016], R. Baker and Freiberg [2016], Kaptan [2016], Parshall [2016], and Pollack and Thompson [2015].

New results on long gaps between primes have also found further applications to other situations R. Baker and Freiberg [2016], Maier and Rassias [2017], and J. Li, Pratt, and Shakan [2017]. It is hopeful that the ideas behind Theorem 1thrm:ManyGaps can find further applications in the future.

THE SUBCONVEXITY PROBLEM FOR L-FUNCTIONS

Ritabrata Munshi

Abstract

Estimating the size of automorphic L-functions on the critical line is a central problem in analytic number theory. An easy consequence of the standard analytic properties of the L-function is the convexity bound, whereas the generalised Riemann Hypothesis predicts a much sharper bound. Breaking the convexity barrier is a hard problem. The moment method has been used to surpass convexity in the case of L-functions of degree one and two. In this talk I will discuss a different method, which has been quite successful to settle certain longstanding open problems in the case of degree three.

At the 1994 International Congress at Zürich, J. B. Friedlander [1995] briefly described the essence of the amplified moment method which he was developing in a series of joint works with Duke and Iwaniec, with the aim of obtaining non-trivial bounds for L-functions. Since then the amplification technique has proved to be very effective in a number of scenarios involving $GL(2)$ L-functions (see J. Friedlander and Iwaniec [1992], Duke, J. B. Friedlander, and Iwaniec [1993, 1994, 1995, 2001, 2002], Kowalski, Michel, and VanderKam [2002], Michel [2004], Harcos and Michel [2006], and Blomer and Harcos [2008]). But there are major hurdles in extending the method far beyond. In the last decade the automorphic period approach has been developed in great detail and generality (over number fields), by Michel, Venkatesh and others (see Bernstein and Reznikov [2010], Michel and Venkatesh [2010], Wu [2014]). This puts the moment method in a proper perspective and gives a satisfactory explanation to the 'mysterious identities between families of L-functions' that already occurs in the study of the moments of the Rankin-Selberg L-functions Harcos and Michel [2006], Michel [2004]. This has been the topic of Michel's address at the 2006 International Congress at Madrid Michel and Venkatesh [2006]. Here I will briefly describe a new approach to tackle subconvexity, which has not only settled some of the longstanding open problems in the field, but has also matched in strength the existing benchmarks. As there are several excellent accounts

MSC2010: primary 11F66; secondary 11M41.
Keywords: L-functions, subconvexity, circle method.

on the subconvexity problem for general automorphic L-functions and on its importance in number theory, equidistribution and beyond (see J. B. Friedlander [1995], Iwaniec and Sarnak [2000], Michel [2007], Michel and Venkatesh [2006], Sarnak [1998]), I will discuss some specific cases which will easily bring out the new features of the method in contrast to the amplified moment method of Friedlander-Iwaniec.

First let us recall the subconvexity problem and the amplification technique with the aid of an example. The Ramanujan Δ-function

$$\Delta(z) = \eta(z)^{24} = \sum_{n=1}^{\infty} \tau(n) e^{2\pi i n z}$$

is a modular form of weight 12 for the full modular group $SL(2,\mathbb{Z})$, and is the prototype for all modular forms. Let χ be a primitive Dirichlet character with modulus M, then the twist $\Delta \otimes \chi$ is a modular form of weight 12 for the congruence group $\Gamma_0(M^2)$ with nebentypus χ^2. It was conjectured by Ramanujan, and later proved by Deligne, that $\tau(n) \ll n^{\frac{11}{2}+\varepsilon}$. Accordingly we define the normalized Fourier coefficients $\lambda_\Delta(n) = \tau(n)/n^{11/2}$, so that the associated Hecke L-function

$$L(s, \Delta \otimes \chi) = \sum_{n=1}^{\infty} \frac{\lambda_\Delta(n)\chi(n)}{n^s}$$

is absolutely convergent for $\mathrm{Re}(s) > 1$ and satisfies the Riemann type functional equation $s \to 1-s$ with center at $s = 1/2$. The multiplicativity of the τ function, again conjectured by Ramanujan and proved shortly thereafter by Mordell (and by Hecke in general), leads to a degree two Euler product representation of this L-function. The basic analytic properties of this type of L-functions - analytic continuation, functional equation - were established by Hecke. This is an example of an automorphic L-function of degree two. In general, understanding the behaviour of automorphic L-functions inside the critical strip $0 \leq \mathrm{Re}(s) \leq 1$, and in particular on the central line $\mathrm{Re}(s) = 1/2$, is the main problem in this field.

There are few results in complex analysis which dictate the behaviour of holomorphic functions inside a domain, once their behaviour is known on the boundary. One such result is the convexity principle of Phragmén-Lindelöf, which when applied to the above L-function, yields the bound

$$L\left(\tfrac{1}{2} + it, \Delta \otimes \chi\right) \ll C^{1/4+\varepsilon}$$

for any $t \in \mathbb{R}$ and any $\varepsilon > 0$, where $C = [M(1+|t|)]^2$. (The notation '$\ll$' here means that there exists a constant $c(\varepsilon)$ depending only on ε such that the absolute value of the left-hand side is smaller than $c(\varepsilon)$ times the right-hand side.) The same bound can be obtained through the approximate functional equation which gives a Dirichlet series approximation to the L-value. It is now understood that the length of this approximation can not be smaller than the square-root of the size of the analytic conductor J. B. Friedlander [1995], Iwaniec and Sarnak [2000], which for the particular example we are considering is given by C. A direct consequence of the approximate functional equation is the bound

$$L(\tfrac{1}{2}+it, \Delta \otimes \chi) \ll C^{\varepsilon} \sup_{N \ll C^{1/2+\varepsilon}} \frac{|S(N)|}{N^{1/2}} + C^{-2018},$$

where $S(N)$ are Dirichlet polynomials of the form

$$S(N) = \sum_{n=1}^{\infty} \lambda_{\Delta}(n)\chi(n)n^{it}\, W\left(\frac{n}{N}\right)$$

with W a smooth bump function. A trivial estimation of this sum recovers the above convexity bound $O(C^{1/4+\varepsilon})$. This is far from what one expects to be the truth. Indeed the Generalized Riemann Hypothesis (GRH) implies the Generalized Lindelöf Hypothesis which predicts a bound with exponent 0 in place of $1/4$. Any bound with exponent $1/4 - \delta$ for some $\delta > 0$ is called a subconvex bound. Such bounds have several striking applications Michel [2007], Sarnak [1995].

In the example we are considering there are two distinct parameters of interest, namely t, which is allowed to take any real value, and M which can take any positive integral value. In other words, there are two types of subfamilies of L-values of interest, viz.

$$\{L(\tfrac{1}{2}+it, \Delta \otimes \chi) : t \in \mathbb{R}\}$$

where the character χ is kept fixed, and

$$\{L(\tfrac{1}{2}+it, \Delta \otimes \chi) : \chi \bmod M \;\; \text{primitive}, M \in \mathbb{N}\}$$

where t is held fixed and the character varies with the modulus tending to infinity. A subconvex bound for the former type of subfamilies is called t-aspect subconvexity and that for the latter type is called M-aspect (or twist aspect). Often, especially in arithmetic applications, the parameter M is of interest, and one is required to the break the convexity barrier in the M-aspect only. One such application is the uniform distribution of rational points on sphere (Linnik's problem) Michel [2007].

The t-aspect subconvexity for $L(s,\Delta)$ (χ principal character) was first established by Good using the spectral theory of Maass forms. Good's approach is via the moment method and is based on getting a strong error term in the asymptotic expansion for the second moment

$$\int_T^{2T} |L(1/2+it,\Delta)|^2 \mathrm{d}t.$$

In Good [1982] he establishes that the above integral is asymptotically

$$TP(\log T) + O((T\log T)^{2/3})$$

where P is a linear polynomial. This strong error term is achieved by studying the more concentrated second moment

$$\int_{T-T/U}^{T+T/U} |L(1/2+it,\Delta)|^2 \mathrm{d}t.$$

where one strives to get U as big as possible. Expanding the absolute value square using the approximate functional equation, and then executing the t-integral one is left with a shifted convolution sum problem which may be tackled by studying the Dirichlet series

$$\sum_{n=1}^{\infty} \frac{\tau(n)\overline{\tau(n+h)}}{(n+h/2)^s}.$$

The automorphic forms enter the picture as the above series can be realised as the Petersson inner product of the form Δ and the h-th Poincare series. The analytic continuation of this L-series beyond the region of absolute convergence was first obtained by Selberg [1965]. But it was Good who first effectively used the spectral interpretation of the above Dirichlet series to obtain estimates for moments of L-function. The estimates obtained by Good give the optimal choice $U=(T\log T)^{1/3}$, and the above asymptotic expansion follows. This in turn yields

$$L(\tfrac{1}{2}+it,\Delta) \ll (1+|t|)^{1/3+\varepsilon},$$

which is the $GL(2)$ analogue of the famous estimate of Hardy-Littlewood-Weyl for the Riemann zeta function $\zeta(1/2+it) \ll (1+|t|)^{1/6+\varepsilon}$. The most straightforward way to prove the Weyl bound for the zeta function is through exponential sums, but a proof based on the moment method, similar in spirit as above, was obtained by Iwaniec [1980].

The twist aspect subconvexity for $L(s,\Delta\otimes\chi)$ is a harder problem. One reason being that there is no simple way to recover a subconvex bound for an individual L-value from an asymptotic for the second moment

$$\sum_{\psi \bmod M} |L(1/2+it, \Delta \otimes \psi)|^2.$$

There is no natural way (while retaining some sort of spectral completeness of the family) to shorten the outer sum so as to obtain a second moment concentrated around χ, the particular character we are interested in. (However this is again possible for the weight/spectral aspect, e.g. Lau, Liu, and Ye [2006], Sarnak [2001].) Of course, one way will be to estimate a higher moment, say the fourth, but this turns out to be a much harder problem. Though one would not need an asymptotic expansion in this case, but even getting an appropriately strong bound is difficult. The amplification technique originated to bypass this problem. The simple idea being to consider the weighted moment

$$\sum_{\psi \bmod M} w(\psi)|L(1/2+it, \Delta \otimes \psi)|^2,$$

where the weights are necessarily non-negative, and $w(\chi)$ is in some sense larger than the average weight. One way to assign such weights (amplifier) is to consider sums of the form

$$w(\psi) = \left|\sum_{\ell \sim L} a(\ell)\psi(\ell)\right|^2,$$

where the coefficients $a(\ell)$ are allowed to depend on χ, Δ and t. In the particular example we are looking at, the choice is rather simple $a(\ell) = \bar{\chi}(\ell)$. Indeed $|\chi(\ell)| = 1$, hence bounded away from 0, if $(\ell, M) = 1$. (But such simple effective lower bounds are not available for Fourier coefficients of modular or Maass forms, and the construction of the amplifier, in the more general setup, has to go through deeper arithmetic structure like Hecke relations.) Using this amplifier Duke, J. B. Friedlander, and Iwaniec [1993] obtained the subconvex bound

$$L(1/2, \Delta \otimes \chi) \ll M^{\frac{1}{2}-\frac{1}{22}+\varepsilon}.$$

This bound has been improved and extended to cover twists of any $GL(2)$ automorphic form. The strongest bound is due to Blomer and Harcos [2008], where they get the exponent $1/2 - 1/8$ pushing to the limit the amplification method and utilising ideas of Bykovskii. This exponent corresponds to the classic result of Burgess $L(1/2, \chi) \ll M^{3/16+\varepsilon}$ for the Dirichlet L-function Burgess [1963]. In the same paper Blomer and Harcos get a hybrid subconvex bound

$$L(\tfrac{1}{2}+it, \Delta \otimes \chi) \ll [M(1+|t|)]^{\frac{1}{2}-\frac{1}{40}+\varepsilon}.$$

A strong hybrid subconvex bound for Dirichlet L-function was obtained by Heath-Brown [1980] extending the work of Burgess [1963].

In general, the basic philosophy of the moment method and the amplification technique can be described as follows. Suppose one seeks to get a bound for $L(\pi_0) = L(1/2, \pi_0)$ where π_0 is an automorphic form. The approximate functional equation reduces the problem to getting cancellation in a sum of the form

$$S_{\pi_0} = \sum_{n \sim C^{1/2}} \lambda_{\pi_0}(n)$$

where λ_{π_0} are the Whittaker-Fourier coefficients and C is the conductor of π_0. As a first step, we need to find a 'spectrally complete family' $\mathfrak{F}$ containing π_0, where all the objects in $\mathfrak{F}$ have 'comparable conductors'. Let

$$\mathfrak{M} = \sum_{\pi \in \mathfrak{F}} |S_\pi|^2,$$

then dropping all terms in the sum except the particular object we are interested in, we conclude the bound $S_{\pi_0} \ll \mathfrak{M}^{1/2}$. Since $\mathfrak{M}$ cannot be smaller than $|\mathfrak{F}|$, the diagonal contribution, for subconvexity we at least need that $|\mathfrak{F}| \ll C^{1/2-\delta}$. So the family cannot be too big. Indeed, larger the family less likely it is, even with amplification, to obtain a non-trivial bound for a particular L-value $L(\pi_0)$, as the individual contribution gets washed out in the large average. Now let us consider the problem of estimating the moment $\mathfrak{M}$. The usual way for the moment method is to open the absolute value and then execute the sum over forms

$$\sum_{\pi \in \mathfrak{F}} \lambda_\pi(n)\overline{\lambda_\pi(m)},$$

using some sort of quasi-orthogonality (e.g. Petersson trace formula). So to get a good estimate we need the family to be big enough - e.g. the off-diagonal contribution in the Petersson trace formula is easily seen to be smaller for larger families, say when the level is bigger. This dichotomy on the size of the family puts a severe restriction on the choice of $\mathfrak{F}$. It is probably 'an accident' that such families exist for L-functions of degree one and two. The amplification technique kicks in when one stumbles upon a family, where $|\mathfrak{F}| = C^{1/2}$. Then one has to manufacture a suitable amplifier A_π, and has to estimate the amplified moment

$$\mathfrak{M}^\sharp = \sum_{\pi \in \mathfrak{F}} |A_\pi|^2 |S_\pi|^2,$$

instead of $\mathfrak{M}$.

I shall now explain a different approach to subconvexity in the context of the above example. We are seeking cancellation in the sum $S(N) = \sum_{n\sim N} \lambda_\Delta(n)\chi(n)n^{it}$, where $N = C^{1/2}$. The basic idea is to separate the oscillation of the Fourier coefficient $\lambda_\Delta(n)$ from that of $\chi(n)n^{it}$. We do this bluntly by introducing a new variable, and rewriting the sum as

$$S(N) = \sum\sum_{\substack{m,n\sim N\\ m=n}} \lambda_\Delta(n)\chi(m)m^{it}.$$

Next we detect the equation $m = n$ using the circle method to arrive at

$$S(N) = \frac{1}{Q^2}\sum_{q\sim Q}\ \sum_{\substack{a \bmod q\\ (a,q)=1}} \Big[\sum_{n\sim N} \lambda_\Delta(n)e_q(an)\Big]\Big[\sum_{m\sim N} \chi(m)m^{it}e_q(-am)\Big]$$

with $Q = N^{1/2} = C^{1/4}$, where we are using the standard shorthand notation $e_q(z) = e^{2\pi i z/q}$. Summation formulas of Poisson and Voronoi, reduces the expression to a bilinear form with Kloosterman fractions

$$\sum\sum_{\substack{m,q\sim Q\\ (m,q)=1}} \chi(q\bar{m})(qm^{-1})^{it}e_q(-M\bar{m})$$

where $\bar{m}$ is the multiplicative inverse of m modulo q. The trivial estimation of this sum yields the convexity bound. A deep result of Duke, Friedlander and Iwaniec gives some cancellation in such sums. But in Munshi [2014] I proceeded in a different direction which paved the way for further developments in the method. Suppose by some means we had reached a similar expression with a factorizable modulus $q = q_1q_2$ with $q_i \sim Q_i$ and $Q_1Q_2 = Q$. Then one could apply the Cauchy inequality to dominate the above expression by

$$Q^{1/2}\sum_{q_2\sim Q_2}\left[\sum_{\substack{m\sim Q\\ (m,q_2)=1}}\Big|\sum_{\substack{q_1\sim Q_1\\ (m,q_1)=1}} \chi(q_1)q_1^{it}e_{q_1q_2}(-M\bar{m})\Big|^2\right]^{1/2},$$

and now it would be possible to get more cancellation by opening the absolute value square and applying the Poisson summation formula on the sum over m. The new input that one would need is the Weil bound for Kloosterman sums. But how does one get this desired structure on the modulus? In Munshi [ibid.] I used Jutila's version of the circle method to achieve this goal, and was able to prove

$$L(\tfrac{1}{2}+it, \Delta\otimes\chi) \ll [M(1+|t|)]^{\frac{1}{2}-\frac{1}{18}+\varepsilon},$$

which was an improvement over the above mentioned result of Blomer-Harcos. There is another interesting way to achieve the same structure - 'congruence-equation trick'. Pick a set of primes $\mathbb{Q}_1$ from the interval $[Q_1, 2Q_1]$. Then for any $q_1 \in \mathbb{Q}_1$ we split the integral equation $m = n$ into a congruence $m \equiv n \bmod q_1$ and a smaller integral equation $(m-n)/q_1 = 0$. The last equation can be detected by a circle method with modulus $Q_2 = \sqrt{N/Q_1}$. Detecting the congruence using additive characters modulo q_1, we arrive at an expression similar to one we got above with $q = q_1 q_2$. Of course the price we pay to get this factorization is the increase in the size of the modulus $q \sim \sqrt{Q_1 N}$. But the structural advantage compensates this loss adequately, and even provides the desired extra saving. (For applications of this trick to Diophantine problems, see Browning and Munshi [2013] and Munshi [2015a].)

Unfortunately, this simple approach does not work for the twisted $GL(3)$ L-functions $L(s, \pi \otimes \chi)$ where π is a Hecke-Maass cusp form for $SL(3, \mathbb{Z})$. Previously Li [2011] and Blomer [2012] had studied the t-aspect and the M-aspect subconvexity problems for these L-functions in the special case where π is a symmetric square lift of a $SL(2, \mathbb{Z})$ Hecke-Maass cusp form. (A p-adic version of Li's result was established in Munshi [2013b] using the ideas of Munshi [2013a].) Their approach is an extension of Conrey and Iwaniec [2000] method where non-negativity of certain L-values plays a crucial role. As such their results could not be extended to cover generic $SL(3, \mathbb{Z})$ forms. In Munshi [2015d] I partially succeeded in the M-aspect. Suppose the character χ factorises as $\chi_1 \chi_2$ where χ_i is primitive modulo M_i with $(M_1, M_2) = 1$, $M_1 < M_2$. We are seeking cancellation in the sum

$$S_3(N) = \sum_{n \sim N} \lambda_\pi(n, 1) \chi(n),$$

where $\lambda_\pi(n, r)$ are the normalised Whittaker-Fourier coefficients of the form π, and $N = M^{3/2}$ - square-root of the size of the conductor. As before we separate the oscillation of the Fourier coefficients from that of the character by introducing a new variable and an equation,

$$S_3(N) = \mathop{\sum\sum}_{\substack{m,n \sim N \\ m=n}} \lambda_\pi(n, 1) \chi(m).$$

Now we use the congruence-equation trick to split the integral equation $m = n$ as $m \equiv n \bmod M_1$ and the integral equation $(m-n)/M_1 = 0$. Here this trick acts as a level lowering mechanism as the modulus M_1 was intrinsic to the problem. The remaining integral equation is detected using the circle method with modulus of smaller size $Q =$

$\sqrt{N/M_1}$. The resulting expression now looks like

$$S_3(N) = \frac{1}{Q^2 M_1} \sum_{q \sim Q} \sum_{\substack{a \bmod qM_1 \\ (a,q)=1}} \Big[\sum_{n \sim N} \lambda_\pi(n,1) e_{qM_1}(an) \Big] \times \Big[\sum_{m \sim N} \chi(m) e_{qM_1}(-am) \Big],$$

and one is again able to win, as long as $\sqrt{M_2} < M_1 < M_2$, by applying summation formulas - Poisson summation and $GL(3)$ Voronoi summation - followed by an application of Cauchy to escape from the trap of involution, and another application of Poisson summation. Here one needs to use Deligne's bound for complete exponential sums.

Though it was clear that this approach would not extend to general characters, the t-aspect subconvexity for $L(s,\pi)$ for π a $SL(3,\mathbb{Z})$ form, became tractable. Indeed the t-aspect is related to twists by highly factorizable characters. In Munshi [2015b] I established the following subconvex bound.

Theorem 1. *Let π be a Hecke-Maass cusp form for $SL(3,\mathbb{Z})$. Then we have*

$$L(\tfrac{1}{2}+it,\pi) \ll (1+|t|)^{\frac{3}{4}-\frac{1}{16}+\varepsilon}.$$

Curiously the exponent matches with Li's bound in Li [2011] for symmetric square lifts, though the two approaches are totally different. The above result is proved using the technique outlined above, but now one have to use the archimedean analogue of the congruence-equation trick. Imagine $M_1 = p^r$ with p a fixed prime and $r \to \infty$, then the congruence condition $m \equiv n \bmod M_1$ corresponds to a condition on the p-adic size of $m-n$. This translates as $|m-n| \ll N/M_1$ in the archimedean situation of t-aspect. In Munshi [2015b] we choose a suitable parameter V and factorise the integral equation $m-n=0$ (of size N) into a distance condition $|m-n| \ll N/V$ and the smaller integral equation $m-n=0$ (of size N/V). The size restriction $|m-n| \ll N/V$ is then detected using an integral involving $(m/n)^{iv}$.

For the twist aspect one needs to introduce higher order harmonics. The usual circle methods and the DFI delta method are based on $GL(1)$ harmonics, or the harmonics of the abelian circle group S^1. These are the trigonometric functions $e(z)$. The delta method gives a Fourier resolution of the delta symbol $\delta : \mathbb{Z} \to \{0,1\}$, $\delta(0)=1$ and $\delta(n)=0$ for $n \neq 0$. A very rough version of this formula looks like

$$\delta(n) \approx \frac{1}{C^2} \sum_{c \sim C} \sum_{\substack{a \bmod c \\ (a,c)=1}} e_c(an).$$

Usually to detect the event $n = 0$ with n varying in the range $[-N, N]$ one takes $C = \sqrt{N}$ so as to minimise the total conductor - the arithmetic modulus c and the amplitude of the oscillation in the weight function (which we have ignored above) - in the circle method formula. In several cases, it turns out that all one needs is a circle method formula with C slightly smaller than $\sqrt{N}$. For example, the subconvexity of $L(s, \Delta \otimes \chi)$ follows quite easily if one has such an elusive circle method.

In the above applications we always needed a souped up version of the usual circle method formula, which we achieved by putting extra structural conditions on the fractions a/c that parametrise the outer sum. In all cases we ended up relating the L-value under focus to an average of products of L-values, e.g.

$$L(1/2 + it, \Delta \otimes \chi) \leftrightsquigarrow \sum_{f \in \mathfrak{F}} L(s_1, \Delta \otimes v_f) L(s_2 + it, \chi \otimes v_f)$$

where $\mathfrak{F}$ is a collection of (Farey) fractions with suitable factorization of denominator, and for $f = (a, c)$, v_f is the additive character $n \to e_c(an)$. Hence at the end we are still computing moments of certain products of L-values (but not sizes of L-values). Since clearly the $GL(1)$ harmonics will not suffice for higher degree L-functions, one looks for expansions of delta involving higher order harmonics. The trace formulas of non-abelian groups are natural sources for such expansions. For example, the Petersson trace formula for modular forms gives

$$\begin{aligned}\delta(m-n) = &\sum_{f \in H_k(q,\psi)} w_f^{-1} \lambda_f(n) \overline{\lambda_f(m)} \\ &- 2\pi i^{-k} \sum_{c=1}^{\infty} \frac{S_\psi(m,n;cq)}{cq} J_{k-1}\left(\frac{4\pi\sqrt{nm}}{cq}\right)\end{aligned}$$

for $m, n > 0$. Here $H_k(q, \psi)$ is an orthogonal Hecke basis for the space of cusp forms of weight k level q and nebentypus ψ, $S_\psi(m, n; c)$ are Kloosterman sums and $J_{k-1}(x)$ is the J-Bessel function. Since the left hand side does not depend on ψ, q or k, one may take suitable averages to jazz up the formula a bit and make it more suitable for application. In Munshi [2015c] and Munshi [2016], where I was considering the arithmetic twist aspect, it was more natural to take averages over q and ψ. One would imagine that when the problem in focus is in the t-aspect or spectral aspect, one would need to take average over k. Taking averages over nebentypus and level, executing the sum over ψ in the second part, and applying the reciprocity relations, we get

$$\delta(m-n) \approx \frac{1}{Q^2} \sum_{q \sim Q} \sum_{\substack{\psi \bmod q \\ \psi(-1)=(-1)^k}} \sum_{f \in H_k(q,\psi)} w_f^{-1} \lambda_f(n) \overline{\lambda_f(m)}$$

$$- \frac{2\pi i^{-k}}{Q} \sum_{q \sim Q} \Big[\frac{1}{N} \sum_{c \sim C} \sum_{\substack{a \bmod c \\ (a,c)=1}} e_c((a+1)\bar{q}m + (\bar{a}+1)\bar{q}n) \Big],$$

with $C = N/Q$. The first part of the formula involves $GL(2)$ harmonics, or Fourier coefficients of modular forms, the second part is like the usual circle method formula, and in fact matches in length to that if we take $Q = \sqrt{N}$. There are however two advantages - first one can take larger Q and thereby make c smaller, and secondly one can take advantage of the extra averaging over q. The cost one pays is of course the introduction of the more complicated $GL(2)$ harmonics in the formula. This version of delta method was introduced in Munshi [2015c] to tackle the M-aspect subconvexity for $L(s, \pi \otimes \chi)$ with π a $SL(3, \mathbb{Z})$ form. In the follow up paper Munshi [2016] a much simplified version of the approach was given. The second version of the proof is more in line with Munshi [2015d] and Munshi [2015b].

Theorem 2. *Let π be a Hecke-Maass cusp form for $SL(3, \mathbb{Z})$ and χ is a primitive character modulo M. Then we have*

$$L(\tfrac{1}{2}, \pi \otimes \chi) \ll M^{\frac{3}{4}-\theta},$$

for some explicitly computable $\theta > 0$.

The reader perhaps has already realised that the above method is robust enough and that these results should generalise to Hecke-Maass cusp forms for any congruence subgroups of $SL(3, \mathbb{Z})$. Also in the last stated theorem we can have a subconvex bound at any point on the critical line with polynomial dependence on t. The work of Blomer [2012] for quadratic twists of symmetric square lifts, in contrast, is only for the central point. There are other trace formulas which can be utilised in the same fashion. For example the Kuznetsov trace formula can be used to give an expansion of the delta involving Fourier coefficients of Maass forms and Einsenstein series. I believe that this would be the key in settling the weight/spectral aspect subconvexity for the symmetric square L-functions or the t-aspect subconvexity for $GL(4)$ L-functions. My recent preprint Munshi [2017b] addresses the level aspect subconvexity for the symmetric square L-function. Let me also mention that a preprint of Blomer and Buttcane [2015] gives a partial result towards settling the spectral aspect subconvexity for $GL(3)$ L-functions. They do not use the above method.

Few recent works have used the above method to get strong bounds for lower degree L-functions. First Aggarwal [2017] and Singh [2017] have independently revisited Good's problem using the method of Munshi [2015b]. Here it is likely that this method is strong enough to yield the Weyl exponent. I have shown that the $GL(2)$ delta method can be used to prove the Burgess exponent both for twists of $GL(2)$ forms and for classical Dirichlet L-functions Munshi [2017a]. New ideas are still required to break the Burgess barrier. However in a joint work with Singh Munshi and Singh [2017], we have shown that the Weyl bound holds in the M-aspect for twists of $GL(2)$ L-functions when the modulus is a suitable prime power, for example if $M = p^3$ for a prime p. This work again uses the congruence-equation trick. In this context, let me mention that Milićević [2016] and Blomer and Milićević [2015] have developed a p-adic version of the Van der Corput method, which yields a sub-Weyl bound for Dirichlet L-functions when the modulus is a suitably high p power, and gives a sub-Burgess bound (which asymptotically decreases to Weyl bound) for twists of $GL(2)$ L-functions by similar characters.

Finally I would like to mention that Holowinsky and Nelson [n.d.] have come up with a much 'abridged version' of the method. This have simplified and shortened the proofs substantially. Their work is pivoted on a crucial observation that there is a 'central identity' which makes the circle method approach to subconvexity work. They have shown that in many cases this central identity can be derived using simpler summation formulas, completely avoiding the circle method. However one drawback that still remains in their work is that it is not clear how to predict this central identity without taking recourse to the circle method approach. This is now an active topic of research. First Holowinsky-Nelson have given a simpler proof for the twists of $GL(3)$ L-functions. Y. Lin [n.d.] have used this approach to give a hybrid bound for $GL(3)$ L-functions, and Aggarwal, Holowinsky, Lin, and Sun [n.d.] have given the non-circle method version of Munshi [2017a]. Apart from the problem of breaking the longstanding Burgess barrier, the following two problems should be the main focus of the circle method approach.

Problem 1: Weight/spectral aspect subconvexity for symmetric square L-functions.

Problem 2: t-aspect subconvexity for $GL(4)$ L-functions.

I hope one of these would be solved before the next International Congress.

ARITHMETIC MODELS FOR SHIMURA VARIETIES

Georgios Pappas

Abstract

We describe recent work on the construction of well-behaved arithmetic models for large classes of Shimura varieties and report on progress in the study of these models.

Introduction

Before the term became standard, certain "Shimura varieties" such as modular curves, Hilbert-Blumenthal varieties, and Siegel modular varieties, were already playing an important role in number theory. Indeed, these are, respectively, quotients of the domains on which modular, Hilbert, and Siegel modular forms, are defined. In a series of groundbreaking works Shimura [1964, 1970], Shimura initiated the arithmetic study of general quotients $\Gamma\backslash H$ of a hermitian symmetric domain H by the action of a discrete congruence arithmetic group Γ of holomorphic automorphisms of H. Such quotients are complex algebraic varieties and Shimura used the theory of moduli and of complex multiplication of abelian varieties to construct canonical models over explicit number fields for many of them.

Deligne reformulated and generalized Shimura's theory and emphasized the group and motivic theoretic source of the constructions (Deligne [1971, 1979] and Deligne, Milne, Ogus, and Shih [1982]). In Deligne's elegant definition, one starts with a pair $(\mathbb{G}, X)$ of a connected reductive algebraic group $\mathbb{G}$ defined over the rational numbers $\mathbb{Q}$ and a $\mathbb{G}(\mathbb{R})$-conjugacy class $X = \{h\}$ of an algebraic group homomorphism $h : \mathbb{S} \to \mathbb{G} \otimes_{\mathbb{Q}} \mathbb{R}$. Here, $\mathbb{S} = \mathrm{Res}_{\mathbb{C}/\mathbb{R}}(\mathbb{G}_{\mathrm{m}})$ is the algebraic torus over $\mathbb{R}$ whose real points are the group $\mathbb{C}^\times$. When the pair $(\mathbb{G}, X)$ satisfies Deligne's conditions (Deligne [1979, (2.1.1.1)-(2.1.1.3)]), we say that $(\mathbb{G}, X)$ is a *Shimura datum*. These conditions imply that each connected component

MSC2010: primary 11G18; secondary 14G35.

X^+ of X is naturally a hermitian symmetric domain. The Shimura varieties $\mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X)$ are then the quotients

$$\mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X) = \mathbb{G}(\mathbb{Q})\backslash X \times (\mathbb{G}(\mathbb{A}_f)/\mathbb{K})$$

for $\mathbb{K}$ an open compact subgroup of the finite adelic points $\mathbb{G}(\mathbb{A}_f)$ of $\mathbb{G}$. Here, $\mathbb{G}(\mathbb{Q})$ acts diagonally on $X \times (\mathbb{G}(\mathbb{A}_f)/\mathbb{K})$, with the action on X given by $\mathbb{G}(\mathbb{Q}) \subset \mathbb{G}(\mathbb{R})$ followed by conjugation, and on $\mathbb{G}(\mathbb{A}_f)/\mathbb{K}$ by $\mathbb{G}(\mathbb{Q}) \subset \mathbb{G}(\mathbb{A}_f)$ followed by left translation. Such a quotient is the disjoint union of a finite number of quotients of the form $\Gamma\backslash X^+$, where Γ are discrete congruence arithmetic groups. Hence, $\mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X)$ has a natural complex analytic structure induced from that on X. In fact, by work of Baily and Borel, there is a quasi-projective complex algebraic structure on $\mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X)$. Following the original work of Shimura and others, the existence of canonical models of $\mathrm{Sh}_K(\mathbb{G}, X)$ over a number field (the "reflex field" $\mathbb{E} = \mathbb{E}(\mathbb{G}, X)$) was shown in all generality by Borovoĭ [1987] and Milne (see Milne [1990] and the references there).

Many of the applications of Shimura varieties in number theory depend on understanding models of them over the ring of integers $\mathcal{O}_{\mathbb{E}}$ of the reflex field, or over localizations and completions of $\mathcal{O}_{\mathbb{E}}$. Indeed, perhaps the main application of Shimura varieties is to Langlands' program to associate Galois representations to automorphic representations. A related goal is to express the Hasse-Weil zeta functions of Shimura varieties as a product of automorphic L-functions.

After some earlier work by Eichler, Shimura, Sato and Ihara, a general plan for realizing this goal was given by Langlands, first for the local factor of the zeta function at a prime of good (*i.e.* smooth) reduction.[1] Langlands suggested expressing the numbers of points over finite fields of an integral model in terms of orbital integrals which appear in versions of the Arthur-Selberg trace formula. This was extended and realized in many cases, mainly by (Kottwitz [1990, 1992], see Langlands and Ramakrishnan [1992]). It is now often referred to as the Langlands-Kottwitz method. Langlands also considered the local factor of the zeta function for an example of a Shimura surface at a prime of bad (non-smooth) reduction Langlands [1979]. This example was treated carefully and the argument was extended to a larger class of Shimura varieties by Rapoport and Zink [1982] and by Rapoport [1990]. At primes of bad reduction, the singularities of the model have to be accounted for; the points need to be weighted by the semi-simple trace of Frobenius on the sheaf of nearby cycles. In fact, the Galois action on the nearby cycles can be used to study the local Langlands correspondence, as in the work of Harris and Taylor [2001]. In relation to this, Scholze recently extended the Langlands-Kottwitz method so that it can be applied, in principle at least, to the general case of bad reduction (Scholze [2013]).

[1] At least for proper Shimura varieties; in our brief report, we will ignore the issues arising from non-properness and the extensive body of work on compactifications.

A starting point of all the above is the existence of a reasonably well-behaved arithmetic model of the Shimura variety. For some time, such models could only be constructed for Shimura varieties of PEL type, *i.e.* those given as moduli spaces of abelian varieties with additional polarization, endomorphism, and level structures, and over primes at which the level subgroup is "parahoric" (*e.g.* Rapoport and Zink [1996]). Recently, due to advances in p-adic Hodge theory and in our understanding of the underlying group theory, the construction has been extended to most Shimura varieties of "abelian type" (at good reduction by Kisin [2010], see also earlier work of Vasiu [1999]; at general parahoric level in Kisin and Pappas [2015]). These Shimura varieties include most cases with $\mathbb{G}$ a classical group.

The construction and properties of these models is the subject of our report. There are, of course, more uses for these in number theory besides in the Langlands program. For example, one could mention showing Gross-Zagier type formulas via intersection theory over the integers, or developments in the theory of p-adic automorphic forms. Here, we view their construction and study as a topic of its own and discuss it independently of applications.

In fact, there are deep relations and analogies between this subject and the study of other spaces of interest in number theory, representation theory, and the geometric Langlands program, such as moduli spaces of bundles, or versions of affine Grassmannians and flag varieties. Increasingly, these connections, especially with the geometric side of Langlands program, are taking center stage. For example, certain p-adically integral models of homogeneous spaces that appear as subschemes of global ("Beilinson-Drinfeld") affine Grassmannians, the so-called "local models", play an important role. These local models also appear in the theory of deformations of Galois representations Kisin [2009]. After first giving some background, we start by discussing local models. We then describe results on arithmetic models of Shimura varieties and their reductions, and finish with an account of the local theory of Rapoport-Zink formal schemes.

Acknowledgments. I would like to thank my collaborators, especially M. Kisin and X. Zhu, for making much of the progress reported on here possible, and M. Rapoport for generously sharing his knowledge over the years.

1 Recollections on p-adic groups

Let G be a connected reductive group over the field of p-adic numbers $\mathbb{Q}_p$ for a prime number p. Let $\bar{\mathbb{Q}}_p$ be an algebraic closure of $\mathbb{Q}_p$. We denote by L the p-adic completion of the maximal unramified extension of $\mathbb{Q}_p$ in $\bar{\mathbb{Q}}_p$ and by $\mathcal{O}_L$ the integers of L. We will also denote by $k = \bar{\mathbb{F}}_p$ the algebraically closed residue field of L and by σ the automorphism of L which lifts the Frobenius $x \mapsto x^p$.

Recall that $g, g' \in G(L)$ are σ-conjugate, if there is $h \in G(L)$ with $g' = h^{-1} g \sigma(h)$. We denote by $B(G)$ the set of σ-conjugacy classes of $G(L)$. Recall the functorial surjective homomorphism $\kappa_G(L) : G(L) \to \pi_1(G)_I$ from Kottwitz [1997]. Here, $\mathrm{Gal}(\bar{L}/L) \simeq I \subset \mathrm{Gal}(\bar{\mathbb{Q}}_p/\mathbb{Q}_p)$ is the inertia subgroup and $\pi_1(G)_I$ the inertia coinvariants of the algebraic fundamental group $\pi_1(G)$ of G over $\bar{\mathbb{Q}}_p$. We denote the kernel of $\kappa_G(L)$ by $G(L)_1$.

Let S be a maximal split torus of G_L. By Steinberg's theorem, G_L is quasi-split and the centralizer of S is a maximal torus T of G_L. Denote by N the normalizer of T. The quotient $\widetilde{W} = \widetilde{W}_{G,S} = N(L)/T(L)_1$ is the *Iwahori-Weyl group* associated to S. It is an extension of the relative Weyl group $W_0 = N(L)/T(L)$ by $\pi_1(T)_I$. Since $\pi_1(T) = X_*(T)$ (the group of cocharacters of T over $\bar{L}$), we obtain an exact sequence $1 \to X_*(T)_I \to \widetilde{W} \to W_0 \to 1$.

Suppose that $\{\mu\}$ is the conjugacy class of a cocharacter $\mu : \mathbb{G}_{\mathrm{m}\bar{\mathbb{Q}}_p} \to G_{\bar{\mathbb{Q}}_p}$. Then $\{\mu\}$ is defined over the *local reflex field* E which is a finite extension of $\mathbb{Q}_p$ contained in $\bar{E} = \bar{\mathbb{Q}}_p$. Denote by $\mathcal{O}_E$ the integers of E and by k_E its residue field. There is a corresponding homogeneous space $G_{\bar{E}}/P_{\mu^{-1}}$ which has a canonical model $X_\mu = X(\{\mu\})$ defined over E. Here, P_ν denotes the parabolic subgroup that corresponds to the cocharacter ν.

A pair $(G, \{\mu\})$ of a connected reductive group G over $\mathbb{Q}_p$, together with a conjugacy class $\{\mu\}$ of a cocharacter μ as above, is a *local Shimura pair*,[2] if μ is *minuscule* (*i.e.*, for any root α of $G_{\bar{\mathbb{Q}}_p}$, $\langle \alpha, \mu \rangle \in \{-1, 0, 1\}$.)

We denote by $\mathcal{B}(G, \mathbb{Q}_p)$ the (extended) Bruhat-Tits building of $G(\mathbb{Q}_p)$ Bruhat and Tits [1972, 1984] and Tits [1979]. The group $G(\mathbb{Q}_p)$ acts on $\mathcal{B}(G, \mathbb{Q}_p)$ on the left. If Ω is a subset of $\mathcal{B}(G, \mathbb{Q}_p)$, we write $G(\mathbb{Q}_p)_\Omega = \{g \in G(\mathbb{Q}_p) \mid g \cdot y = y,\ \text{for all } y \in \Omega\}$ for the pointwise fixer of Ω. Similarly, we have the subgroup $G(L)_\Omega$ of $G(L)$.

By the main result of Bruhat and Tits [1984], if Ω is bounded and contained in an apartment, there is a smooth affine group scheme $\mathcal{G}_\Omega$ over $\mathrm{Spec}\,(\mathbb{Z}_p)$ with generic fiber G and with $\mathcal{G}_\Omega(\mathcal{O}_L) = G(L)_\Omega$, which is uniquely characterized by these properties. By definition, the "connected fixer" $G(\mathbb{Q}_p)^\circ_\Omega$ is $\mathcal{G}^\circ_\Omega(\mathbb{Z}_p)$, where $\mathcal{G}^\circ_\Omega$ is the connected component of $\mathcal{G}_\Omega$. It is a subgroup of finite index in $G(\mathbb{Q}_p)_\Omega$. When $\Omega = \{x\}$ is a point, we simply write $G(\mathbb{Q}_p)_x$ and $G(\mathbb{Q}_p)^\circ_x$. If Ω is an open facet and $x \in \Omega$, then $G(\mathbb{Q}_p)^\circ_\Omega = G(\mathbb{Q}_p)^\circ_x$.

A *parahoric* subgroup of $G(\mathbb{Q}_p)$ is any subgroup which is the connected stabilizer $G(\mathbb{Q}_p)^\circ_x$ of some point x in $\mathcal{B}(G, \mathbb{Q}_p)$ as above. These are open compact subgroups of $G(\mathbb{Q}_p)$. We call $\mathcal{G}^\circ_x$ a "parahoric group scheme".

We now recall some more terms and useful facts (Tits [1979], Haines and Rapoport [2008]): A point $x \in \mathcal{B}(G, \mathbb{Q}_p)$ is *hyperspecial*, when $\mathcal{G}_x$ is reductive; then $\mathcal{G}_x = \mathcal{G}^\circ_x$. Hyperspecial points exist if and only if G is *unramified* over $\mathbb{Q}_p$, *i.e.* if G is quasi-split and splits over an unramified extension of $\mathbb{Q}_p$. When x is a point in an open alcove,

[2] Compare this with the term "local Shimura datum" used in Rapoport and Viehmann [2014]. A local Shimura datum $(G, \{\mu\}, [b])$ also includes the choice of a σ-conjugacy class $[b]$.

then the parahoric $G(\mathbb{Q}_p)^\circ_x$ is called an *Iwahori* subgroup. Iwahori subgroups exist for all G. Each maximal open compact subgroup of $G(\mathbb{Q}_p)$ contains a parahoric subgroup with finite index. If the group $\pi_1(G)_I$ has no torsion, then $G(\mathbb{Q}_p)_x = G(\mathbb{Q}_p)^\circ_x$, for all x. Then, all maximal open compact subgroups are parahoric.

Let $K = G(\mathbb{Q}_p)^\circ_x$ be parahoric and denote by $\tilde{K}$ the corresponding parahoric subgroup $G(L)^\circ_x$ of $G(L)$; we have $\tilde{K} = \mathcal{G}^\circ_x(\mathcal{O}_L)$.

Suppose x lies in the apartment associated to S. A choice of an alcove $C \subset \mathcal{B}(G, L)$ contained in that apartment provides the Iwahori-Weyl group $\widetilde{W} = \widetilde{W}_{G,S}$ with a Bruhat partial order $\leq$. Suppose $x \in C$ and set $\widetilde{W}^{\tilde{K}} = (N(L) \cap \tilde{K})/T(L)_1$, which is a subgroup of $\widetilde{W}$. The inclusion $N(L) \subset G(L)$ induces Haines and Rapoport [ibid.] a bijection

$$\widetilde{W}^{\tilde{K}}\backslash\widetilde{W}/\widetilde{W}^{\tilde{K}} \xrightarrow{\sim} \tilde{K}\backslash G(L)/\tilde{K}.$$

There is also a partial order $\leq$ on these double cosets: Set $[w] = \widetilde{W}^{\tilde{K}} w \widetilde{W}^{\tilde{K}}$. Then $[w_1] \leq [w_2]$ if and only if there are $w_1' \in [w_1]$, $w_2' \in [w_2]$, with $w_1' \leq w_2'$.

We refer the reader to Pappas, Rapoport, and Smithling [2013] for the definition of the $\{\mu\}$*-admissible subset*

$$\mathrm{Adm}_{\tilde{K}}(\{\mu\}) \subset \widetilde{W}^{\tilde{K}}\backslash\widetilde{W}/\widetilde{W}^{\tilde{K}} \simeq \tilde{K}\backslash G(L)/\tilde{K}$$

of Kottwitz and Rapoport. This is a finite set which has the following property: If $[w] \in \mathrm{Adm}_{\tilde{K}}(\{\mu\})$ and $[w'] \leq [w]$, then $[w'] \in \mathrm{Adm}_{\tilde{K}}(\{\mu\})$.

Let us continue with the above set-up. The *affine Deligne-Lusztig set* $X_K(\{\mu\}, b)$ associated to G, $\{\mu\}$, K, and $b \in G(L)$, is the subset of $G(L)/\tilde{K}$ consisting of those cosets $g\tilde{K}$ for which $g^{-1}b\sigma(g) \in \tilde{K}w\tilde{K}$, for some $[w] \in \mathrm{Adm}_{\tilde{K}}(\{\mu\})$.

If b' and b are σ-conjugate $b' = h^{-1}b\sigma(h)$, then $g\tilde{K} \mapsto hg\tilde{K}$ gives a bijection $X_K(\{\mu\}, b) \xrightarrow{\sim} X_K(\{\mu\}, b')$. The group $J_b(\mathbb{Q}_p) = \{j \in G(L) \mid j^{-1}b\sigma(j) = b\}$ acts on $X_K(\{\mu\}, b)$ by $j \cdot g\tilde{K} = jg\tilde{K}$. Set $f = [k_E : \mathbb{F}_p]$. The identity $\Phi_E(g\tilde{K}) = b\sigma(b)\cdots\sigma^{f-1}(b)\sigma^f(g)\tilde{K}$ defines a map $\Phi_E : X_K(\{\mu\}, b) \to X_K(\{\mu\}, b)$.

Our last reminder is of the affine Grassmannian of G. By definition, the *affine Grassmanian* Aff_G of G is the ind-projective ind-scheme over Spec $(\mathbb{Q}_p)$ which represents (*e.g.* Pappas and Rapoport [2008]) the fpqc sheaf associated to the quotient presheaf given by $R \mapsto G(R(\!(t)\!))/G(R[\![t]\!])$.

2 Local models

Let $(G, \{\mu\})$ be a local Shimura pair and K a parahoric subgroup of $G(\mathbb{Q}_p)$. Denote by $\mathcal{G}$ the corresponding parahoric group scheme over Spec $(\mathbb{Z}_p)$ so that $K = \mathcal{G}(\mathbb{Z}_p)$ and set again $\tilde{K} = \mathcal{G}(\mathcal{O}_L)$. A form of the following appears in Rapoport [2005].

Conjecture 2.1. *There exists a projective and flat scheme* $\mathrm{M}_K(G,\{\mu\})$ *over* $\mathrm{Spec}\,(\mathcal{O}_E)$ *which supports an action of* $\mathcal{G}\otimes_{\mathbb{Z}_p}\mathcal{O}_E$ *and is such that:*

(i) The generic fiber $\mathrm{M}_K(G,\{\mu\})\otimes_{\mathcal{O}_E} E$ *is* G_E*-isomorphic to* X_μ*,*

(ii) There is a $\tilde{K}$*-equivariant bijection between* $\mathrm{M}_K(G,\{\mu\})(k)$ *and*

$$\{g\tilde{K}\in G(L)/\tilde{K}\mid \tilde{K}g\tilde{K}\in \mathrm{Adm}_{\tilde{K}}(\{\mu\})\}\subset G(L)/\tilde{K}.$$

The scheme $\mathrm{M}_K(G,\{\mu\})$ is a *local model* associated to $(G,\{\mu\})$ and K.

We now consider the following "tameness" condition:

(T) The group G *splits over a tamely ramified extension of* $\mathbb{Q}_p$ *and* p *does not divide the order of the fundamental group* $\pi_1(G^{\mathrm{der}})$ *of the derived group.*

Under the assumption (T), Conjecture 2.1 is shown in Pappas and Zhu [2013]. The construction of the local models in Pappas and Zhu [ibid.] is as follows.

(I) We first construct a smooth affine group scheme $\underline{\mathcal{G}}$ over $\mathbb{Z}_p[u]$ which, among other properties, satisfies:

1) the restriction of $\underline{\mathcal{G}}$ over $\mathbb{Z}_p[u,u^{-1}]$ is reductive,

2) the base change $\underline{\mathcal{G}}\otimes_{\mathbb{Z}_p[u]}\mathbb{Z}_p$, given by $u\mapsto p$, is isomorphic to the parahoric group scheme $\mathcal{G}$.

For this, we use that $\mathbb{Z}_p[u^{\pm 1}]=\mathbb{Z}_p[u,u^{-1}]\to\mathbb{Q}_p$, given by $u\mapsto p$, identifies the étale fundamental group of $\mathbb{Z}_p[u^{\pm1}]$ with the tame quotient of the Galois group of $\mathbb{Q}_p$; our tameness hypothesis enters this way. We first obtain the restriction $\underline{\mathcal{G}}|_{\mathbb{Z}_p[u^{\pm1}]}$ from its constant Chevalley form $H\otimes_{\mathbb{Z}_p}\mathbb{Z}_p[u^{\pm1}]$ by using, roughly speaking, the "same twist" that gives G from its constant form $H\otimes_{\mathbb{Z}_p}\mathbb{Q}_p$. This is quite straightforward when G is quasi-split and the twist is given using a diagram automorphism; the general case uses explicit Azumaya algebras over $\mathbb{Z}_p[u^{\pm1}]$. The extension $\underline{\mathcal{G}}$ to $\mathbb{Z}_p[u]$ of the reductive group scheme $\underline{\mathcal{G}}|_{\mathbb{Z}_p[u^{\pm1}]}$ is then given by generalizing some of the constructions in Bruhat and Tits [1984] to this two-dimensional set-up.

(II) Consider the functor that sends $\varphi:\mathbb{Z}_p[u]\to R$ to the set of isomorphism classes of pairs $(\mathcal{E},\beta)$, with $\mathcal{E}$ a $\underline{\mathcal{G}}$-torsor over $\mathbb{A}^1_R$ and β a section of $\mathcal{E}$ over $\mathrm{Spec}\,(R[u,(u-\varphi(u))^{-1}])$. We show that this is represented by an ind-projective ind-scheme (the *global* affine Grassmannian, *cf.* Beilinson and Drinfeld [1996]) $\mathrm{Aff}_{\underline{\mathcal{G}},\mathbb{A}^1}\to\mathbb{A}^1=\mathrm{Spec}\,(\mathbb{Z}_p[u])$. Using the construction of $\underline{\mathcal{G}}$ and Beauville and Laszlo [1994], we obtain an equivariant isomorphism

$$\mathrm{Aff}_G\xrightarrow{\sim}\mathrm{Aff}_{\underline{\mathcal{G}},\mathbb{A}^1}\otimes_{\mathbb{Z}_p[u]}\mathbb{Q}_p$$

where the base change is given by $u\mapsto p$. (The above isomorphism is induced by $t\mapsto u-p$, with the notation of Section 1 for Aff_G.)

(III) Since $\mathbb{G}_{\mathrm{m}}=\mathrm{Spec}\,(\mathbb{Q}_p[t,t^{-1}])$, our cocharacter μ defines $\mu(t)\in G(\bar{\mathbb{Q}}_p(\!(t)\!))$. In turn, this gives a $\bar{\mathbb{Q}}_p$-point $[\mu(t)]=\mu(t)G(\bar{\mathbb{Q}}_p[\![t]\!])$ of Aff_G.

Since μ is minuscule and the conjugacy class $\{\mu\}$ is defined over E, the orbit

$$G(\bar{\mathbb{Q}}_p[[t]]) \cdot [\mu(t)] \subset G(\bar{\mathbb{Q}}_p((t)))/G(\bar{\mathbb{Q}}_p[[t]]) = \mathrm{Aff}_G(\bar{\mathbb{Q}}_p),$$

is equal to the set of $\bar{\mathbb{Q}}_p$-points of a *closed* subvariety S_μ of $\mathrm{Aff}_{G,E} := \mathrm{Aff}_G \otimes_{\mathbb{Q}_p} E$. The stabilizer $H_{\mu^{-1}} := G(\bar{\mathbb{Q}}_p[[t]]) \cap \mu(t)G(\bar{\mathbb{Q}}_p[[t]])\mu(t)^{-1}$ of $[\mu(t)]$ is the inverse image of $P_{\mu^{-1}}(\bar{\mathbb{Q}}_p)$ under $G(\bar{\mathbb{Q}}_p[[t]]) \to G(\bar{\mathbb{Q}}_p)$ given by reduction modulo t. This gives a G_E-equivariant isomorphism $X_\mu \xrightarrow{\sim} S_\mu$ which we can use to identify X_μ with $S_\mu \subset \mathrm{Aff}_{G,E}$.

Definition 2.2. *We define* $\mathrm{M}_K(G, \{\mu\})$ *to be the (flat, projective) scheme over* $\mathrm{Spec}\,(\mathcal{O}_E)$ *given by the reduced Zariski closure of the image of*

$$X_\mu \xrightarrow{\sim} S_\mu \subset \mathrm{Aff}_{G,E} \xrightarrow{\sim} \mathrm{Aff}_{\underline{\mathcal{G}},\mathbb{A}^1} \otimes_{\mathbb{Z}_p[u]} E$$

in the ind-scheme $\mathrm{Aff}_{\underline{\mathcal{G}},\mathbb{A}^1} \otimes_{\mathbb{Z}_p[u]} \mathcal{O}_E$.

The next includes the main general facts about the structure of $\mathrm{M}_K(G, \{\mu\})$ and can be extracted from the results of Pappas and Zhu [2013].

Theorem 2.3. *Suppose that* (T) *holds. The scheme* $\mathrm{M}_K(G, \{\mu\})$ *of Definition 2.2 satisfies Conjecture 2.1. In addition:*

a) The scheme $\mathrm{M}_K(G, \{\mu\})$ *is normal.*

b) The geometric special fiber $\mathrm{M}_K(G, \{\mu\}) \otimes_{\mathcal{O}_E} k$ *is reduced and admits a* $\mathcal{G} \otimes_{\mathbb{Z}_p} k$*-orbit stratification by locally closed and smooth strata* $S_{[w]}$*, with* $S_{[w]}(k) \simeq \{g\tilde{K} \in G(L)/\tilde{K} \mid [w] = \tilde{K}g\tilde{K}\}$*, for each* $[w] \in \mathrm{Adm}_{\tilde{K}}(\{\mu\})$.

c) The closure $\overline{S}_{[w]}$ *of each stratum is normal and Cohen-Macaulay and equal to the union* $\bigcup_{[w'] \leq [w]} S_{[w']}$*, where* $\leq$ *is given by the Bruhat order.*

One main ingredient is the proof, by Zhu [2014], of the coherence conjecture of Pappas and Rapoport [2008]. The coherence conjecture is a certain numerical equality in the representation theory of (twisted) Kac-Moody groups. Its statement is, roughly speaking, independent of the characteristic, and so enough to show in the function field case where more tools are available.

Before Pappas and Zhu [2013], there have been various, often ad hoc, constructions of local models obtained by using variants of linked Grassmannians (Rapoport and Zink [1996], Pappas [2000]; see the survey Pappas, Rapoport, and Smithling [2013] and the references within, and Section 3 below for an example).

An extension of the above construction of local models, to the case G is the restriction of scalars of a tame group from a wild extension, is given in Levin [2016]. One would expect that a completely general construction of the local model $\mathrm{M}_K(G, \{\mu\})$ can be given by using a hypothetical version of the affine Grassmannian in which $R \mapsto \mathcal{G}(R[[u]])$ is replaced by the functor $R \mapsto \mathcal{G}(W(R))$. Here $W(R)$ is the ring of p-typical Witt vectors of

R. (See Section 5 for a related construction when $\mathcal{G}$ is reductive.) Such Witt affine Grassmannians are defined in characteristic p by Zhu [2017] (but only "after perfection") and further studied by Bhatt and Scholze [2017]; other variations have been used by Scholze.

3 Global theory: Arithmetic models

Let $(\mathbb{G}, \{h\})$ be a Shimura datum as in the introduction. Define $\mu_h : \mathbb{G}_{m\mathbb{C}} \to \mathbb{G}_{\mathbb{C}}$ by $\mu_h(z) = h_{\mathbb{C}}(z, 1)$. The $G(\mathbb{C})$-conjugacy class $\{\mu_h\}$ is defined over the reflex field $\mathbb{E} \subset \bar{\mathbb{Q}} \subset \mathbb{C}$. Write $\mathbb{Z}_s$ for the maximal subtorus of the center $Z(\mathbb{G})$ which is $\mathbb{R}$-split but which has no $\mathbb{Q}$-split subtorus and set $\mathbb{G}^c = \mathbb{G}/\mathbb{Z}_s$.

Consider a $\mathbb{Q}$-vector space $\mathbb{V}$ with a perfect alternating bilinear pairing $\psi : \mathbb{V}\times\mathbb{V} \to \mathbb{Q}$. Set $\dim_{\mathbb{Q}}(\mathbb{V}) = 2g$. Let $\mathbb{G} = \mathrm{GSp}(\mathbb{V}, \psi)$ be the group of symplectic similitudes and $X = S^{\pm}$ the Siegel double space. This is the set of homomorphisms $h : \mathbb{S} \to \mathbb{G}_{\mathbb{R}}$ such that: (1) The $\mathbb{C}^{\times}$-action given by $h(\mathbb{R}) : \mathbb{C}^* \to \mathbb{G}(\mathbb{R})$ gives on $\mathbb{V}_{\mathbb{R}}$ a Hodge structure of type $\{(-1, 0), (0, -1)\}$: $\mathbb{V}_{\mathbb{C}} = \mathbb{V}^{-1.0} \oplus \mathbb{V}^{0,-1}$, and, (2) the form $(x, y) \mapsto \psi(x, h(i)y)$ on $\mathbb{V}_{\mathbb{R}}$ is positive (or negative) definite. The pairs $(\mathrm{GSp}(\mathbb{V}, \psi), S^{\pm})$ give the most important examples of Shimura data. By Riemann's theorem, if $\mathbb{V}_{\mathbb{Z}}$ is a $\mathbb{Z}$-lattice in $\mathbb{V}$, and $h \in S^{\pm}$, the quotient torus $\mathbb{V}^{-1,0}/\mathbb{V}_{\mathbb{Z}}$ is a complex abelian variety of dimension g. This leads to an interpretation of the Shimura varieties $\mathrm{Sh}_{\mathbb{K}}(\mathrm{GSp}(\mathbb{V}, \psi), S^{\pm})$ as moduli spaces of (polarized) abelian varieties of dimension g with level structure.

A Shimura datum $(\mathbb{G}, X)$ with $X = \{h\}$ is of *Hodge type*, when there is a symplectic space $(\mathbb{V}, \psi)$ over $\mathbb{Q}$ and a closed embedding $\rho : \mathbb{G} \hookrightarrow \mathrm{GSp}(\mathbb{V}, \psi)$ such that the composition $\rho \circ h$ lies in the Siegel double space $S^{\pm}$. Then, we also have $\mathbb{G} = \mathbb{G}^c$. In this case, the Shimura varieties $\mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X)$ parametrize abelian varieties together with (absolute) Hodge cycles (see below). A special class of Shimura data of Hodge type are those of *PEL type* Kottwitz [1992, §5], Rapoport and Zink [1996, Ch. 6]. For those, the corresponding Shimura varieties $\mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X)$ are (essentially) moduli schemes of abelian varieties together with polarization, endomorphisms and level structure.

A Shimura datum $(\mathbb{G}, X)$ is of *abelian type* if there is a datum of Hodge type $(\mathbb{G}_1, X_1)$ and a central isogeny $\mathbb{G}_1^{\mathrm{der}} \to \mathbb{G}^{\mathrm{der}}$ between derived groups which induces an isomorphism $(\mathbb{G}_1^{\mathrm{ad}}, X_1^{\mathrm{ad}}) \xrightarrow{\sim} (\mathbb{G}^{\mathrm{ad}}, X^{\mathrm{ad}})$. Here, the superscript $^{\mathrm{ad}}$ denotes passing to the adjoint group: If $X = \{h\}$, then $X^{\mathrm{ad}} = \{h^{\mathrm{ad}}\}$ with h^{ad} the composition of $h : \mathbb{S} \to \mathbb{G}_{\mathbb{R}}$ with $\mathbb{G}_{\mathbb{R}} \to \mathbb{G}_{\mathbb{R}}^{\mathrm{ad}}$. Roughly speaking, most Shimura data $(\mathbb{G}, X)$ with $\mathbb{G}$ a classical group are of abelian type.

Fix a prime number p and a prime $\mathfrak{p}$ of the reflex field $\mathbb{E}$ above p which is obtained from an embedding $\bar{\mathbb{Q}} \hookrightarrow \bar{\mathbb{Q}}_p$. Let E be the completion of $\mathbb{E}$ at $\mathfrak{p}$ and set $G = \mathbb{G}_{\mathbb{Q}_p}$. Then $\{\mu_h\}$ gives a conjugacy class $\{\mu\}$ of G defined over the local reflex field E and $(G, \{\mu\})$ is a local Shimura pair.

Fix a *parahoric* subgroup $K = K_p \subset \mathbb{G}(\mathbb{Q}_p) = G(\mathbb{Q}_p)$. For any open compact subgroup $K^p \subset \mathbb{G}(\mathbb{A}_f^p)$ we can consider the Shimura variety $\mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X)$ over $\mathbb{E}$, where $\mathbb{K} = K_p K^p \subset \mathbb{G}(\mathbb{A}_f)$.

We now assume that a local model $\mathrm{M}_K(G, \{\mu\})$ as in Conjecture 2.1 is given for $(G, \{\mu\})$ and parahoric K.

Conjecture 3.1. *There is a scheme $\mathcal{S}_{K_p}(\mathbb{G}, X)$ over* $\mathrm{Spec}\,(\mathcal{O}_E)$ *which supports a right action of $\mathbb{G}(\mathbb{A}_f^p)$ and has the following properties:*

a) Any sufficiently small open compact subgroup $K^p \subset \mathbb{G}(\mathbb{A}_f^p)$ acts freely on $\mathcal{S}_{K_p}(\mathbb{G}, X)$, and the quotient $\mathcal{S}_{\mathbb{K}}(\mathbb{G}, X) := \mathcal{S}_{K_p}(\mathbb{G}, X)/K^p$ is a scheme of finite type over $\mathcal{O}_E$ which extends $\mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X) \otimes_{\mathbb{E}} E$. We have $\mathcal{S}_{K_p}(\mathbb{G}, X) = \varprojlim_{K^p} \mathcal{S}_{K_p K^p}(\mathbb{G}, X)$ where the limit is over all such $K^p \subset \mathbb{G}(\mathbb{A}_f^p)$.

b) For any discrete valuation ring $R \supset \mathcal{O}_E$ of mixed characteristic $(0, p)$, the map $\mathcal{S}_{K_p}(\mathbb{G}, X)(R) \to \mathcal{S}_{K_p}(\mathbb{G}, X)(R[1/p])$ is a bijection.

c) There is a smooth morphism of stacks over $\mathrm{Spec}\,(\mathcal{O}_E)$

$$\lambda : \mathcal{S}_{K_p}(\mathbb{G}, X) \to [(\mathcal{G}^c \otimes_{\mathbb{Z}_p} \mathcal{O}_E)\backslash \mathrm{M}_K(G, \{\mu\})]$$

which is invariant for the $\mathbb{G}(\mathbb{A}_f^p)$-action on the source and is such that the base change λ_E is given by the canonical principal $\mathbb{G}_E^c$-bundle over $\mathrm{Sh}_{K_p}(\mathbb{G}, X) \otimes_{\mathbb{E}} E$ (Milne [1990, III, §3]). Here, we set $\mathcal{G}^c = \mathcal{G}/\mathcal{Z}_s$, where $\mathcal{Z}_s$ is the Zariski closure of the central torus $Z_s \subset G$ in $\mathcal{G}$.

It is important to record that the existence of the smooth λ as in (c) implies:

(c') For each closed point $x \in \mathcal{S}_{K_p}(\mathbb{G}, X)$, there is a closed point $y \in \mathrm{M}_K(G, \{\mu\})$ and étale neighborhoods $U_x \to \mathcal{S}_{K_p}(\mathbb{G}, X)$ of x and $V_y \to \mathrm{M}_K(G, \{\mu\})$ of y, which are isomorphic over $\mathcal{O}_E$.

The significance of (c') is that the singularities of $\mathrm{M}_K(G, \{\mu\})$ control the singularities of $\mathcal{S}_{K_p}(\mathbb{G}, X)$, and so, by (a), also of the integral models $\mathcal{S}_{\mathbb{K}}(\mathbb{G}, X)$ for $\mathbb{K} = K_p K^p$, with K^p sufficiently small. In what follows, we will often assume that K^p is sufficiently small without explicitly saying so.

The "extension property" (b) ensures that the special fiber of $\mathcal{S}_{K_p}(\mathbb{G}, X)$ is sufficiently large, in particular, it cannot be empty. Unfortunately, it is not clear that properties (a)-(c) uniquely characterize the schemes $\mathcal{S}_{K_p}(\mathbb{G}, X)$. We will return to this question later.

Before we give some general results we discuss the illustrative example of the Siegel Shimura datum $(\mathrm{GSp}(\mathbb{V}, \psi), S^{\pm})$ as in Section 3.

Fix a prime p. Set $V = \mathbb{V}_{\mathbb{Q}_p}$ and denote the induced form on V also by ψ. For a $\mathbb{Z}_p$-lattice Λ in V, its dual is $\Lambda^\vee = \{x \in V \mid \psi(x, y) \in \mathbb{Z}_p\,,\text{for all } y \in \Lambda\}$. Now choose a chain of lattices $\{\Lambda_i\}_{i \in \mathbb{Z}}$ in V with the following properties: $\Lambda_i \subset \Lambda_{i+1}$ and $\Lambda_{i-m} = p\Lambda_i$, for all i and a fixed "period" $m > 0$, and $\Lambda_i^\vee = \Lambda_{-i+a}$, for all i and (fixed) $a = 0$ or 1. The chain $\{\Lambda_i\}_{i\in\mathbb{Z}}$ gives rise to a point in the building of $G = \mathrm{GSp}(V, \psi)$ over $\mathbb{Q}_p$. The corresponding parahoric K is the subgroup of all $g \in \mathrm{GSp}(V, \psi)$ such that $g\Lambda_i = \Lambda_i$, for all i. Every parahoric subgroup of $G(\mathbb{Q}_p)$ is obtained from such a lattice chain.

In this case, schemes $\mathcal{S}_K(\mathrm{GSp}(\mathbb{V}, \psi), S^\pm)$ that satisfy the conjecture are given by moduli spaces as we will now explain. Recall that the category $AV_{(p)}$ of abelian schemes up to prime-to-p isogeny has objects abelian schemes and morphisms given by tensoring the Hom groups by $\mathbb{Z}_{(p)}$. We consider the functor which associates to a $\mathbb{Z}_p$-algebra R the set of isomorphism classes of m-tuples $\{(A_i, \alpha_i, \tilde{\nu}, \eta)\}_{i\in\mathbb{Z}/m\mathbb{Z}}$ where (see Rapoport and Zink [1996, Ch. 6] for details):

1) A_i are up to prime-to-p isogeny projective abelian schemes over R,

2) $\alpha_i : A_i \to A_{i+1}$ are isogenies of height $\log_p([\Lambda_{i+1} : \Lambda_i])$ in $AV_{(p)}$ such that the compositions $\alpha_{r+m-1}\cdots\alpha_{r+1}\alpha_r = p$, for all $0 \le r < m$,

3) $\tilde{\nu}$ is a set of isomorphisms $\{\nu_i : A_i \xrightarrow{\sim} A^\vee_{-i+a}\}_{i\in\mathbb{Z}/m\mathbb{Z}}$ in $AV_{(p)}$ which are compatible with α_i, and is a $\mathbb{Z}_{(p)}^\times$-homogeneous polarization,

4) η is a prime-to-p level structure of type K^p on $\{(A_i, \alpha_i, \tilde{\nu})\}_i$.

When $K^p \subset \mathbb{G}(\mathbb{A}_f^p)$ is sufficiently small, this functor is represented by a scheme $\mathcal{S}_{KK^p}(\mathrm{GSp}(\mathbb{V}, \psi), S^\pm)$ over $\mathbb{Z}_p$. The limit over K^p is easily seen to satisfy (a) while (b) follows from the Néron-Ogg-Shafarevich criterion for good reduction of abelian varieties. Next, we discuss (c).

For a $\mathbb{Z}_p$-algebra R, set $\Lambda_{i,R} := \Lambda_i \otimes_{\mathbb{Z}_p} R$ and denote by $a_{i,R} : \Lambda_{i,R} \to \Lambda_{i+1,R}$ the map induced by the inclusion $\Lambda_i \to \Lambda_{i+1}$ and by $(\ ,\ )_i : \Lambda_{i,R} \times \Lambda_{-i+a,R} \to R$ the perfect R-bilinear pairing induced by ψ since $\Lambda_i^\vee = \Lambda_{-i+a}$.

A result of Görtz [2003] implies that, in this case, the local model $\mathrm{M}_K(G, \{\mu\})$ of Pappas and Zhu [2013] represents the functor which sends a $\mathbb{Z}_p$-algebra R to the set of sequences $\{\mathfrak{F}_i\}_{i\in\mathbb{Z}}$, where: $\mathfrak{F}_i \subset \Lambda_{i,R}$ is an R-submodule which is Zariski locally a direct summand of $\Lambda_{i,R}$ of rank g, and, for all i, we have: $a_i(\mathfrak{F}_i) \subset \mathfrak{F}_{i+1}$, $(\mathfrak{F}_i, \mathfrak{F}_{-i+a})_i = 0$, and $\mathfrak{F}_{i-m} = p\mathfrak{F}_i \subset p\Lambda_{i,R} = \Lambda_{i-m,R}$.

The morphism λ is defined by first showing that the "crystalline" system of modules, homomorphisms and pairings, obtained by applying the Dieudonné functor to $\{(A_i, \alpha_i, \nu_i)\}$, is locally isomorphic to the corresponding "Betti" system given by the lattice chain $\{\Lambda_i\}$ and ψ. Then, λ sends $\{(A_i, \alpha_i, \tilde{\nu}, \eta)\}$ to $\mathfrak{F}_i$ given by the Hodge filtration of A_i. It is smooth since, by Grothendieck-Messing theory, deformations of an abelian variety are determined by lifts of its Hodge filtration. This argument first appeared in de Jong [1993] and Deligne and Pappas [1994]. It extends to most PEL type cases Rapoport and Zink [1996]. In general, we need a different approach which we explain next.

We now discuss general results. Assume that p is odd and that (T) holds. Assume also that the local models $\mathrm{M}_K(G, \{\mu\})$ are as defined in Pappas and Zhu [2013]. The next result is shown in Kisin and Pappas [2015], following earlier work of Kisin [2010].

Theorem 3.2. *(i) Assume that $(\mathbb{G}, X)$ is of abelian type. Then Conjecture 3.1 with (c) replaced by (c'), is true for $(\mathbb{G}, X)$ and K.*

(ii) Assume that $(\mathbb{G}, X)$ is of Hodge type and that the parahoric subgroup K is equal to the stabilizer of a point in the Bruhat-Tits building of G. Then Conjecture 3.1 is true for $(\mathbb{G}, X)$ and K.

Let us try to explain some ideas in the proofs.

We will first discuss (ii). So, the Shimura datum $(\mathbb{G}, X)$ is of Hodge type and the parahoric subgroup $K \subset G(\mathbb{Q}_p)$ is the stabilizer of a point z in the building $\mathcal{B}(G, \mathbb{Q}_p)$, *i.e.* the stabilizer group scheme is already connected, $\mathcal{G} = \mathcal{G}_z = \mathcal{G}_z^\circ$.

After adjusting the symplectic representation $\rho : \mathbb{G} \hookrightarrow \mathrm{GSp}(\mathbb{V}, \psi)$ which gives the Hodge embedding, we can find a $\mathbb{Z}_p$-lattice $\Lambda \subset V = \mathbb{V}_{\mathbb{Q}_p}$ on which ψ takes $\mathbb{Z}_p$-integral values, such that ρ induces

1) a closed group scheme embedding $\rho_{\mathbb{Z}_p} : \mathcal{G} = \mathcal{G}_z \hookrightarrow \mathrm{GL}(\Lambda)$, and

2) an equivariant closed embedding $\rho_* : \mathrm{M}_K(G, \{\mu\}) \hookrightarrow \mathrm{Gr}(g, \Lambda^\vee) \otimes_{\mathbb{Z}_p} \mathcal{O}_E$.

Here $\mathrm{Gr}(g, \Lambda^\vee)$ is the Grassmannian over $\mathbb{Z}_p$ with R-points given by R-submodules $\mathcal{F} \subset \Lambda_R^\vee$ which are locally direct summands of rank $g = \dim_{\mathbb{Q}}(\mathbb{V})/2$. Finding Λ is subtle and uses that the representation ρ is *minuscule*.

Choose a $\mathbb{Z}$-lattice $\mathbb{V}_{\mathbb{Z}} \subset \mathbb{V}$ such that $\mathbb{V}_{\mathbb{Z}_{(p)}} := \mathbb{V}_{\mathbb{Z}} \otimes_{\mathbb{Z}} \mathbb{Z}_{(p)} = \mathbb{V} \cap \Lambda$. We can now find $\{s_\alpha\}_\alpha \subset \mathbb{V}^{\otimes}_{\mathbb{Z}_{(p)}} \subset \mathbb{V}^{\otimes}$ such that the functor

$$R \mapsto \mathbb{G}_{\mathbb{Z}_{(p)}}(R) = \{g \in \mathrm{GL}(\mathbb{V}_{\mathbb{Z}_{(p)}} \otimes_{\mathbb{Z}_{(p)}} R) \mid g \cdot s_\alpha = s_\alpha, \text{ for all } \alpha\}$$

gives the unique flat group scheme $\mathbb{G}_{\mathbb{Z}_{(p)}}$ over $\mathbb{Z}_{(p)}$ that extends both $\mathbb{G}$ and $\mathcal{G}$. Here, $\mathbb{V}^{\otimes} := \bigoplus_{r,s \geq 0}(V^{\otimes r} \otimes (V^\vee)^{\otimes s})$, similarly for $\mathbb{V}^{\otimes}_{\mathbb{Z}_{(p)}}$.

Now fix $K^p \subset \mathbb{G}(\mathbb{A}_f^p)$ small enough so, in particular, $V_{\hat{\mathbb{Z}}} := V_{\mathbb{Z}} \otimes_{\mathbb{Z}} \hat{\mathbb{Z}}$ is stable by the action of K^p; then $V_{\hat{\mathbb{Z}}}$ is $\mathbb{K} = KK^p$-stable also. We can find $K'^p \subset \mathrm{GSp}(\mathbb{V})(\mathbb{A}_f^p)$ such that ρ gives a closed embedding

$$\iota : \mathrm{Sh}_{KK^p}(\mathbb{G}, X) \hookrightarrow \mathrm{Sh}_{K'_pK'^p}(\mathrm{GSp}(\mathbb{V}), S^\pm) \otimes_{\mathbb{Q}} \mathbb{E},$$

where K'_p is the subgroup of $\mathrm{GSp}(V, \psi)$ that stabilizes the lattice Λ, and such that $\mathbb{V}_{\hat{\mathbb{Z}}}$ is also stable by the action of $\mathbb{K}' = K'_pK'^p$.

We define $\mathcal{S}_{KK^p}(\mathbb{G}, X)$ to be the normalization of the reduced Zariski closure of the image of ι_E in the integral model $\mathcal{S}_{K'_pK'^p}(\mathrm{GSp}(\mathbb{V}), S^\pm) \otimes_{\mathbb{Z}_p} \mathcal{O}_E$ (which is a moduli scheme, as in Section 3) and set $\mathcal{S}_K(\mathbb{G}, X) := \varprojlim_{K^p} \mathcal{S}_{KK^p}(\mathbb{G}, X)$. Checking property

(a) is straightforward and (b) follows from the Néron-Ogg-Shafarevich criterion for good reduction. The hard work is in showing (c).

Since $\mathbb{V}_{\hat{\mathbb{Z}}}$ is stable by the action of $\mathbb{K}'$, which is sufficiently small, we have a universal abelian scheme over $\mathrm{Sh}_{\mathbb{K}'}(\mathrm{GSp}(\mathbb{V}), S^{\pm})$ which we can restrict via ι to obtain an abelian scheme $\mathcal{A}$ over $\mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X)$. By construction, the tensors s_α above give sections $s_{\alpha,\mathrm{B}}$ of the local system of $\mathbb{Q}$-vector spaces over $\mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X)(\mathbb{C})$ with fibers $\mathrm{H}^1_{\mathrm{B}}(\mathcal{A}_v(\mathbb{C}), \mathbb{Q})^{\otimes}$ given using the first Betti (singular) cohomology of the fibers $\mathcal{A}_v(\mathbb{C})$ of the universal abelian variety. These are "Hodge cycles" in the sense that they are of type $(0, 0)$ for the induced Hodge structure on $\mathrm{H}^1_{\mathrm{B}}(\mathcal{A}(\mathbb{C}), \mathbb{Q})^{\otimes}$. We are going to chase these around using various comparison isomorphisms.

Let $\kappa \supset \mathbb{E}$ be a field with an embedding $\sigma : \bar{\kappa} \hookrightarrow \mathbb{C}$ over $\mathbb{E}$ of its algebraic closure. Suppose $x \in \mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X)(\kappa)$ and let $\mathcal{A}_x$ be the corresponding abelian variety over κ. There are comparison isomorphisms $\mathrm{H}^1_{B}(\mathcal{A}_x(\mathbb{C}), \mathbb{Q}) \otimes_{\mathbb{Q}} \mathbb{C} \simeq \mathrm{H}^1_{\mathrm{dR}}(\mathcal{A}_x) \otimes_{\kappa,\sigma} \mathbb{C}$, and $\mathrm{H}^1_{B}(\mathcal{A}_x(\mathbb{C}), \mathbb{Q}) \otimes_{\mathbb{Q}} \mathbb{Q}_l \simeq \mathrm{H}^1_{\mathrm{et}}(\mathcal{A}_x \otimes_\kappa \bar{\kappa}, \mathbb{Q}_l)$, for any prime l. Set $s_{\alpha,B,x}$ be the fiber of $s_{\alpha,B}$ over the complex point $\sigma(x)$ and denote by $s_{\alpha,\mathrm{dR},x}$, $s_{\alpha,\mathrm{et},x}$, the images of $s_{\alpha,B,x}$ under these isomorphisms. The tensors $s_{\alpha,\mathrm{et},x}$ are independent of the embedding σ, are fixed by the action of $\mathrm{Gal}(\bar{\kappa}/\kappa)$, and it follows from Deligne's "Hodge implies absolute Hodge" theorem that $s_{\alpha,\mathrm{dR},x}$ lie in $\mathrm{H}^1_{\mathrm{dR}}(\mathcal{A}_x)^{\otimes}$ and, in fact, in $F^0(\mathrm{H}^1_{\mathrm{dR}}(\mathcal{A}_x)^{\otimes})$ (Kisin [2010]).

For $l = p$, the corresponding $\mathrm{Gal}(\bar{\kappa}/\kappa)$-invariant tensors ("Tate cycles") $s_{\alpha,\mathrm{et},x}$ lie in the lattice $\mathrm{H}^1_{\mathrm{et}}(\mathcal{A}_x \otimes_\kappa \bar{\kappa}, \mathbb{Z}_p)^{\otimes} = T_p(\mathcal{A}_x)^{\otimes}$, where $T_p(\mathcal{A}_x)$ is the p-adic Tate module $\varprojlim_n (\mathcal{A}_x \otimes_\kappa \bar{\kappa})[p^n]$. In order to control the local structure of $\mathcal{S}_{KK^p}(\mathbb{G}, X)$ and eventually relate it to $\mathrm{M}_K(G, \{\mu\})$, we need to employ some form of crystalline deformation theory and so we also have to understand the "crystalline realization" of our tensors. Assume that $\kappa = F$ is a finite extension of E and that the abelian variety $\mathcal{A}_x$ has good reduction. Then we obtain an $\mathcal{O}_F$-valued point $\tilde{x}$ of $\mathcal{S}_{KK^p}(\mathbb{G}, X)$ that extends x and reduces to $\bar{x}$. A key point is to show that the Tate cycles $s_{\alpha,\mathrm{et},x}$ for $l = p$ give, via the étale/crystalline comparison, corresponding "nice" *integral* crystalline cycles $s_{\alpha,\mathrm{cris},\bar{x}} \in \mathbb{D}(\mathcal{A}_{\bar{x}})^{\otimes}$ on the Dieudonné module $\mathbb{D}(\mathcal{A}_{\bar{x}})$ of the abelian variety $\mathcal{A}_{\bar{x}}$ over the residue field of F. For this we need a suitably functorial construction that relates crystalline p-adic Galois representations of $\mathrm{Gal}(\bar{F}/F)$ to Frobenius semilinear objects integrally, and without restriction on the absolute ramification of F. This is provided by the theory of Breuil-Kisin modules Kisin [2009, 2010].

Let F_0 be the maximal unramified extension of $\mathbb{Q}_p$ contained in F. Denote by W_0 the ring of integers of F_0 and by $\varphi : W_0[\![u]\!] \to W_0[\![u]\!]$ the lift of Frobenius with $\varphi(u) = u^p$. Choose a uniformizer π of F which is a root of an Eisenstein polynomial $E(u) \in W_0[u]$. A Breuil-Kisin module $(\mathfrak{M}, \Phi)$ is a finite free $W_0[\![u]\!]$-module $\mathfrak{M}$ with an isomorphism $\Phi : \varphi^*(\mathfrak{M})[1/E(u)] \xrightarrow{\sim} \mathfrak{M}[1/E(u)]$, where $\varphi^*(\mathfrak{M}) := W_0[\![u]\!] \otimes_{\varphi, W_0[\![u]\!]} \mathfrak{M}$. Kisin has constructed a fully faithful tensor functor $T \mapsto \mathfrak{M}(T)$ from the category of $\mathrm{Gal}(\bar{F}/F)$-stable $\mathbb{Z}_p$-lattices in crystalline $\mathbb{Q}_p$-representations to the category of Breuil-Kisin modules.

Now let $T^\vee = \mathrm{Hom}_{\mathbb{Z}_p}(T, \mathbb{Z}_p)$ be the linear dual of the p-adic Tate module $T = T_p(\mathcal{Q}_x)$. Then there are natural isomorphisms Kisin [2009]

$$\varphi^*(\mathfrak{M}(T^\vee)/u\mathfrak{M}(T^\vee)) \simeq \mathbb{D}(\mathcal{Q}_{\bar{x}}), \quad \varphi^*(\mathfrak{M}(T^\vee)) \otimes_{W_0[\![u]\!], u\mapsto\pi} \mathcal{O}_F \simeq \mathrm{H}^1_{\mathrm{dR}}(\mathcal{Q}_{\tilde{x}}).$$

Applying Kisin's functor to the Tate cycles $s_{\alpha,\mathrm{et},x}$ gives Frobenius invariant tensors $\tilde{s}_\alpha \in \mathfrak{M}(T_p(\mathcal{Q}_x)^\vee)^\otimes$. By using the isomorphism above, these give the crystalline cycles $s_{\alpha,\mathrm{cris},\bar{x}} \in \mathbb{D}(\mathcal{Q}_{\bar{x}})^\otimes$. The main result now is:

Theorem 3.3. *There is a $W_0[\![u]\!]$-linear isomorphism*

$$\beta : \Lambda^\vee \otimes_{\mathbb{Z}_p} W_0[\![u]\!] \xrightarrow{\sim} \mathfrak{M}(T_p(\mathcal{Q}_x)^\vee)$$

such that $\beta^\otimes$ takes $s_\alpha \otimes 1$ to $\tilde{s}_\alpha$, for all α.

In addition to the properties of Kisin's functor, the important input in the proof is the statement that all $\mathcal{G}$-torsors over $\mathrm{Spec}\,(W_0[\![u]\!]) - \{(0,0)\}$ are trivial. This uses crucially that $\mathcal{G} = \mathcal{G}_z^\circ$ is parahoric.

Using β and the above, we obtain isomorphisms

$$\beta_{\mathrm{dR}} : \Lambda^\vee \otimes_{\mathbb{Z}_p} \mathcal{O}_F \xrightarrow{\sim} \mathrm{H}^1_{\mathrm{dR}}(\mathcal{Q}_{\tilde{x}}), \quad \beta_{\mathrm{cris}} : \Lambda^\vee \otimes_{\mathbb{Z}_p} W_0 \xrightarrow{\sim} \mathbb{D}(\mathcal{Q}_{\bar{x}}),$$

such that $\beta^\otimes_{\mathrm{dR}}(s_\alpha \otimes 1) = s_{\alpha,\mathrm{dR},\tilde{x}}$, resp. $\beta^\otimes_{\mathrm{cris}}(s_\alpha \otimes 1) = s_{\alpha,\mathrm{cris},\bar{x}}$[3].The inverse image

$$\beta^{-1}_{\mathrm{dR}}(F^0(\mathcal{Q}_{\tilde{x}})) \subset \Lambda^\vee \otimes_{\mathbb{Z}_p} \mathcal{O}_F$$

of the deRham filtration $F^0(\mathcal{Q}_{\tilde{x}}) = \mathrm{H}^0(\mathcal{Q}_{\tilde{x}}, \Omega^1_{\mathcal{Q}_{\tilde{x}}/\mathcal{O}_F}) \subset \mathrm{H}^1_{\mathrm{dR}}(\mathcal{Q}_{\tilde{x}})$ now gives an $\mathcal{O}_F$-point of the Grassmannian $\mathrm{Gr}(g, \Lambda^\vee)$. This is easily seen to factor through ρ_* to the local model $\mathrm{M}_K(G, \{\mu\})$ and defines the image of λ on $\tilde{x} \in \mathcal{S}_{\mathbb{K}}(\mathbb{G}, X)(\mathcal{O}_F)$.

Next, we use β to construct a versal deformation of the abelian scheme $\mathcal{Q}_{\tilde{x}}$ over the completion $S = \widehat{\mathcal{O}}_{\mathrm{M}_K(G,\{\mu\}),\bar{y}}$ of the local ring of $\mathrm{M}_K(G, \{\mu\})$ at $\bar{y} = \lambda(\bar{x})$. This deformation is equipped with Frobenius invariant crystalline tensors that appropriately extend $\tilde{s}_\alpha$. It is constructed using Zink's theory of displays Zink [2002]. In this, (connected) p-divisible groups over a p-adic ring S are described by "displays", which are systems of Frobenius modules over the ring of Witt vectors $W(S)$. In our case, we give a display over $W(S)$ whose Frobenius semilinear maps are, roughly speaking, valued in the

[3] In the case that K is hyperspecial and $F = F_0$, the existence of such an isomorphism β_{cris} was conjectured by Milne and was shown by Kisin [2010] and Vasiu [2013].

group scheme $\mathcal{G}$. Our construction is inspired by the idea that the local model $\mathrm{M}_K(G, \{\mu\})$ should also appear inside a Witt affine Grassmannian (see Section 2 and also Section 5 for a similar construction).

Finally, using a result of Blasius and Wintenberger and parallel transport for the Gauss-Manin connection, we show that there exists a homomorphism $S \to \widehat{\mathcal{O}}_{\mathcal{S}_{\mathbb{K}}(\mathbb{G},X),\bar{x}}$ which matches $\tilde{x}$ and $\tilde{y}$ and then has to be an isomorphism. Property (c') and then (c) follows.

To deal with the case that $(\mathbb{G}, X)$ is of abelian type, we follow Deligne's strategy Deligne [1979] for constructing canonical models for these types. Deligne relates a connected component of the Shimura variety for $(\mathbb{G}, X)$ to one of the Hodge type $(\mathbb{G}_1, X_1)$ (as in the definition of abelian type above). In this, he uses an action of $\mathbb{G}^{\mathrm{ad}}(\mathbb{Q}) \cap \mathbb{G}^{\mathrm{ad}}(\mathbb{R})^+$ on these varieties. The argument extends after giving a moduli interpretation for this action. Then, $\mathcal{S}_K(\mathbb{G}, X)$ is constructed, by first taking a quotient of a connected component of $\mathcal{S}_{K_1}(\mathbb{G}_1, X_1)$ by a finite group action (which is shown to be free), and then "inducing" from that quotient.

The strategy for these proofs is due to Kisin [2010] who showed the results when K is hyperspecial (*i.e.* $\mathcal{G}$ is reductive). Then $\mathrm{M}_K(G, \{\mu\})$ is the natural smooth model of the homogeneous space X_μ and $\mathcal{S}_{\mathbb{K}}(\mathbb{G}, X)$ is smooth over $\mathcal{O}_E$. (The condition on $\pi_1(G^{\mathrm{der}})$ is not needed then. Also, the case $p = 2$ is treated by Kim and Madapusi Pera [2016].) In this important hyperspecial case, the integral models $\mathcal{S}_K(\mathbb{G}, X)$ can be shown to be "canonical", in the sense of Milne: They can be characterized as the unique, up to isomorphism, regular, formally smooth schemes that satisfy (a), (c'), and an extension property stronger than (b) in which Spec (R) is replaced by any regular, formally smooth scheme over $\mathcal{O}_E$ (see Kisin [2010], Vasiu and Zink [2010]). Hence, they are also independent of the various choices made in their construction. It is unclear if schemes satisfying (a), (b) and (c) as in the conjecture, with $\mathrm{M}_K(G, \{\mu\})$ given a priori, are uniquely determined in the general parahoric case. In Kisin and Pappas [2015], we show this in a few cases. Regardless, we conjecture that the schemes $\mathcal{S}_K(\mathbb{G}, X)$ produced by the above results are independent of the choices made in their construction.

In the hyperspecial case, there is also earlier work of Vasiu [1999] who pursued a different approach (see also Moonen [1998]). Vasiu applied directly an integral comparison homomorphism between p-adic étale cohomology and crystalline cohomology due to Faltings, to understand carefully chosen crystalline tensors of low degree that should be enough to control the group.

Let us note here that, in contrast to all the previous theory, there are few results when K is a subgroup smaller than parahoric, even in PEL cases: When K is the pro-p radical of an Iwahori subgroup, combining the above with results of Oort-Tate or Raynaud on p-torsion group schemes, often leads to well-behaved models (Pappas [1995], Haines and Rapoport [2012]). Also, when the deformation theory is controlled by a formal group (or

"$\mathcal{O}$-module") of dimension 1 (as is in the case of modular curves) the notion of Drinfeld level structure can be used to describe integral models for all level subgroups (Katz and Mazur [1985], Harris and Taylor [2001]).

4 Reductions: Singularities and points

Singularities: Kottwitz-Rapoport stratification and nearby cycles. To fix ideas, we assume that the assumptions of Theorem 3.2 (ii) are satisfied so that the result applies. In particular, $(\mathbb{G}, X)$ is of Hodge type. Set $\mathcal{S} := \mathcal{S}_{\mathbb{K}}(\mathbb{G}, X)$, $\mathrm{M} := \mathrm{M}_K(G, \{\mu\})$, $S :=$ Spec $(\mathcal{O}_E)$ and $d := \dim(\mathrm{Sh}_{\mathbb{K}}(\mathbb{G}, X))$.

Since the morphism λ is smooth, Theorem 2.3 implies that special fiber $\mathcal{S} \otimes_{\mathcal{O}_E} k_E$ is reduced, and that we obtain a stratification of $\mathcal{S} \otimes_{\mathcal{O}_E} \bar{\mathbb{F}}_p$ by locally closed smooth strata $\mathcal{S}_{[w]} = \lambda_{\mathbb{K}}^{-1}(S_{[w]})$, for $[w] \in \mathrm{Adm}_{\tilde{K}}(\{\mu\})$. Furthermore:

Theorem 4.1. *For each $[w] \in \mathrm{Adm}_{\tilde{K}}(\{\mu\})$, the Zariski closure $\overline{\mathcal{S}}_{[w]}$ is equal to the union $\bigcup_{[w'] \leq [w]} \mathcal{S}_{[w']}$ and is normal and Cohen-Macaulay.*

Now pick a prime $l \neq p$ and consider the complex of nearby cycles $\mathrm{R}\Psi(\mathcal{S}, \bar{\mathbb{Q}}_l)$ of $\mathcal{S} \to S$ on $\mathcal{S} \otimes_{\mathcal{O}_E} \bar{\mathbb{F}}_p$. This is obtained from the nearby cycles $\mathrm{R}\Psi(\mathrm{M}, \bar{\mathbb{Q}}_l)$ of $\mathrm{M} \to S$ by pulling back along the smooth λ. Set $f = [k_E : \mathbb{F}_p]$ and $q = p^f$. For each $r \geq 1$, the semi-simple trace of Rapoport [1990] defines a function

$$\psi_{\mathbb{K},r} : \mathcal{S}(\mathbb{F}_{q^r}) \to \bar{\mathbb{Q}}_l; \quad \psi_{\mathbb{K},r}(\bar{x}) = \mathrm{Tr}^{\mathrm{ss}}(\mathrm{Frob}_{\bar{x}}, \mathrm{R}\Psi(\mathcal{S}, \bar{\mathbb{Q}}_l)_{\bar{x}}).$$

The smoothness of λ and $\mathcal{G}$, and Lang's lemma, gives that $\psi_{\mathbb{K},r}$ factors through

$$\lambda_{\mathbb{K}}(\mathbb{F}_{q^r}) : \mathcal{S}(\mathbb{F}_{q^r}) \to \mathcal{G}(\mathbb{F}_{q^r}) \backslash \mathrm{M}_K(G, \{\mu\})(\mathbb{F}_{q^r}).$$

Denote by $\mathbb{Q}_{p^n}$ the unramified extension of $\mathbb{Q}_p$ of degree n contained in L; let $\mathbb{Z}_{p^n} \simeq W(\mathbb{F}_{p^n})$ be its integers. Set $K_r = \mathcal{G}(\mathbb{Z}_{q^r})$. If G is quasi-split over $\mathbb{Q}_{q^r}$, then we have a bijection $\mathcal{G}(\mathbb{F}_{q^r}) \backslash \mathrm{M}_K(G, \{\mu\})(\mathbb{F}_{q^r}) \cong K_r \backslash G(\mathbb{Q}_{q^r})/K_r$, and so the map $\lambda_{\mathbb{K}}(\mathbb{F}_{q^r})$ gives $\lambda_{\mathbb{K},r} : \mathcal{S}(\mathbb{F}_{q^r}) \to K_r \backslash G(\mathbb{Q}_{q^r})/K_r$.

By combining results of Pappas and Zhu [2013] on $\mathrm{R}\Psi(\mathrm{M}, \bar{\mathbb{Q}}_l)$ with the above, we obtain:

Theorem 4.2. *a) Suppose that G splits over the finite extension $F/\mathbb{Q}_p$. Then the inertia subgroup $I_{EF} \subset \mathrm{Gal}(\bar{\mathbb{Q}}_p/EF)$ acts unipotently on $\mathrm{R}\Psi(\mathcal{S}, \bar{\mathbb{Q}}_l)$.*

b) Suppose that G is quasi-split over $\mathbb{Q}_{q^r}$. Then the semi-simple trace of Frobenius $\psi_{r,\mathbb{K}} : \mathcal{S}(\mathbb{F}_{q^r}) \to \bar{\mathbb{Q}}_l$ is a composition

$$\mathcal{S}(\mathbb{F}_{q^r}) \xrightarrow{\lambda_{\mathbb{K},r}} K_r \backslash G(\mathbb{Q}_{q^r})/K_r \xrightarrow{z_{\mu,r}} \bar{\mathbb{Q}}_l$$

where $z_{\mu,r}$ is in the center of the Hecke algebra $\bar{\mathbb{Q}}_l[K_r\backslash G(\mathbb{Q}_{q^r})/K_r]$ with multiplication by convolution.

c) Suppose that G is split over $\mathbb{Q}_{q^r}$. Then in (b) above, we can take $z_{\mu,r}$ such that $q^{-d/2}z_{\mu,r}$ is a Bernstein function for μ.

Part (c) has been conjectured by Kottwitz, see Rapoport [2005, (10.3)] and also work of Haines [2014] for more details and an extension of the conjecture. Let us mention that the study of $\mathrm{R}\Psi(\mathrm{M},\bar{\mathbb{Q}}_l)$ in Pappas and Zhu [2013] (as also the proof of Theorem 2.3), uses techniques from the theory of the geometric Langlands correspondence. The "Hecke central" statement was first shown by Gaitsgory for split groups over function fields Gaitsgory [2001], and by Haines and Ngô for unramified unitary and symplectic groups Haines and Ngô [2002]. Gaitsgory's result was, in turn, inspired by Kottwitz's conjecture.

Points modulo p. Under certain assumptions, Langlands and Rapoport gave a conjectural description of the set of $\bar{\mathbb{F}}_p$-points of a model of a Shimura variety together with its actions by Frobenius and Hecke operators Langlands and Rapoport [1987]. The idea, very roughly, is as follows (see also Langlands [1976], Kottwitz [1992]). Since, as suggested by Deligne, most Shimura varieties are supposed to be moduli spaces of certain motives, we should be describing this set via representations of the fundamental groupoid attached to the Tannakian category of motives over $\bar{\mathbb{F}}_p$. A groupoid $\mathfrak{Q}$ which should be this fundamental groupoid (and almost is, assuming the Tate conjecture and other standard conjectures) can be constructed explicitly. Then "$\mathbb{G}$-pseudo-motives" are given by groupoid homomorphisms $\varphi:\mathfrak{Q}\to\mathbb{G}$. The choice of the domain X imposes restrictions, and we should be considering only φ which are "admissible". Then, we also give p and prime-to-p level structures on these φ, as we do for abelian varieties.

The Langlands–Rapoport conjecture was corrected, modified and extended along the way (Reimann [1997] and Kisin [2017]). The conjecture makes better sense when it refers to a specific integral model of the Shimura variety $\mathrm{Sh}_K(\mathbb{G},X)$. When K is hyperspecial, p odd, and $(\mathbb{G},X)$ of abelian type, an extended version of the conjecture was essentially proven (with a caveat, see below) by Kisin [2017], for the canonical integral models constructed in Kisin [2010]. In fact, the conjecture also makes sense when K is parahoric, for the integral models of Kisin and Pappas [2015]. More precisely, let us suppose that the assumptions of Theorem 3.2 are satisfied and that $\mathscr{S}_K(\mathbb{G},X)$ is provided by the construction in the proof.

Conjecture 4.3. *There is a $\langle\Phi_E\rangle\times\mathbb{G}(\mathbb{A}_f^p)$-equivariant bijection*

$$(LR)\qquad \mathscr{S}_K(\mathbb{G},X)(\bar{\mathbb{F}}_p)\xrightarrow{\sim}\bigsqcup_{[\varphi]}\varprojlim_{K^p} I_\varphi(\mathbb{Q})\backslash(X_p(\varphi)\times(X^p(\varphi)/K^p))$$

where Φ_E is the Frobenius over k_E and the rest of the notations and set-up follow Rapoport [2005, §9], Kisin [2017, (3.3)] (taking into account the remark (3.3.9) there).

In particular: The disjoint union is over a set of equivalence classes $[\varphi]$ of admissible $\varphi : \mathfrak{Q} \to \mathbb{G}$, where one uses Kisin's definition of "admissible" for non simply connected derived group. (The classes $[\varphi]$ often correspond to isogeny classes of abelian varieties with additional structures.) We have $I_\varphi = \mathrm{Aut}(\varphi)$, an algebraic group over $\mathbb{Q}$. The set $X^p(\varphi)$ is a right $\mathbb{G}(\mathbb{A}_f^p)$-torsor and the set $X_p(\varphi)$ can be identified with the affine Deligne-Lusztig set $X_K(\{\mu^{-1}\}, b)$ for $b \in G(L)$ obtained from φ. The group $I_\varphi(\mathbb{Q})$ acts on $X^p(\varphi)$ on the left, and there is an injection $I_\varphi(\mathbb{Q}) \to J_b(\mathbb{Q}_p)$ which also produces a left action on $X_p(\varphi) = X_K(\{\mu^{-1}\}, b)$; the quotient is by the diagonal action.

Theorem 4.4. *(Kisin [ibid.]) Assume that K is hyperspecial, p odd, and $(\mathbb{G}, X)$ of abelian type. Then there is a bijection as in (LR) respecting the action of $\langle \Phi_E \rangle \times \mathbb{G}(\mathbb{A}_f^p)$ on both sides, but with the action of $I_\varphi(\mathbb{Q})$ on $X_p(\varphi) \times (X^p(\varphi)/K^p)$ obtained from the natural diagonal action above by conjugating by a (possibly trivial) element $\tau(\varphi) \in I_\varphi^{\mathrm{ad}}(\mathbb{A}_f)$.*

Due to lack of space, we will omit an account of any of the beautiful and subtle arguments in Kisin's proof, or in related earlier work by Kottwitz [1992] and others. We hope that the interested reader will consult the original papers. Let us just mention here that Zhou [2017] has recently made some progress towards the proof of Conjecture 4.3.

5 Local theory: Formal schemes

We now return to the local set-up as in Section 1. Let $(G, \{\mu\})$ be a local Shimura pair and $[b] \in B(G)$ a σ-conjugacy class. Fix a parahoric subgroup $K \subset G(\mathbb{Q}_p)$ and assume that the local model $\mathrm{M}_K(G, \{\mu^{-1}\})$ is defined.

Conjecture 5.1. *There exists a formal scheme $\mathfrak{X}_K(\{\mu\}, b)$ over* $\mathrm{Spf}(\mathcal{O}_E)$ *with $J_b(\mathbb{Q}_p)$-action, which is locally formally of finite type, and is such that:*

a) There is a $\langle \Phi_E \rangle \times J_b(\mathbb{Q}_p)$-equivariant bijection between $\mathfrak{X}_K(\{\mu\}, b)(\bar{\mathbb{F}}_p)$ and the affine Deligne-Lusztig set $X_K(\{\mu\}, b)$.

b) For any $v \in X_K(\{\mu\}, b)$, there is $w \in \mathrm{M}_K(G, \{\mu^{-1}\})(\bar{\mathbb{F}}_p)$ such that the completion of $\mathfrak{X}_K(\{\mu\}, b)$ at the point corresponding to v via (a) is isomorphic to the completion of $\mathrm{M}_K(G, \{\mu^{-1}\})$ at w.

Assuming $\mathfrak{X}_K(\{\mu\}, b)$ exists, we let $\mathcal{X}_K(\{\mu\}, b)$ be its underlying reduced scheme which is locally of finite type over Spec (k_E). (Then $\mathcal{X}_K(\{\mu\}, b)$ could be called an *affine Deligne-Lusztig "variety"*.) Its "perfection" $\mathcal{X}_K(\{\mu\}, b)^{\mathrm{perf}}$, has been constructed by Zhu [2017], using a Witt vector affine flag variety. The rigid fiber $\mathfrak{X}_K(\{\mu\}, b)^{\mathrm{rig}}$ over E would be the *local Shimura variety* for $(G, \{\mu\}, [b])$ and level K whose existence is expected by Rapoport and Viehmann [2014].

Let us take $G = \mathrm{GL}_n$, $\mu_d(z) = \mathrm{diag}(z, \dots, z, 1, \dots, 1)^{-1}$, with d copies of z, and $K = \mathrm{GL}_n(\mathbb{Z}_p)$. For simplicity, set $W = W(\bar{\mathbb{F}}_p)$. The formal schemes $\mathfrak{X}_{\mathrm{GL}_n} :=$

$\mathfrak{X}_K(\{\mu_d\}, b)$ were constructed by Rapoport and Zink [1996]: Fix a p-divisible group H_0 of height n and dimension d over $\bar{\mathbb{F}}_p$ with Frobenius $F = b\cdot\sigma$ on the rational Dieudonné module. Then the formal scheme $\mathfrak{X}_{\mathrm{GL}_n}\hat{\otimes}_{\mathbb{Z}_p} W$ represents (Rapoport and Zink [ibid., Theorem 2.16]) the functor which sends a W-algebra R with p nilpotent on R, to the set of isomorphism classes of pairs (H, τ), where: H is a p-divisible group over R, and $\tau : H_0 \otimes_k R/pR \dashrightarrow H \otimes_R R/pR$ is a quasi-isogeny. The formal scheme $\mathfrak{X}_{\mathrm{GL}_n}$ over $\mathrm{Spf}(\mathbb{Z}_p)$ is obtained from this by descent. This construction of $\mathfrak{X}_K(\{\mu\}, b)$ generalizes to $(G, \{\mu\})$ that are of "EL" or "PEL" type, for many parahoric K; these types are defined similarly to (and often arise from) global Shimura data $(\mathbb{G}, X)$ of PEL type.

The models $\mathcal{S}_{\mathbb{K}}(\mathbb{G}, X)$ of Conjecture 3.1 and the formal schemes $\mathfrak{X}_K(\{\mu\}, b)$ above, should be intertwined via the bijection (LR) as follows:

Suppose that $(\mathbb{G}, X)$ is a Shimura datum which produces the local Shimura pair $(G, \{\mu^{-1}\})$. Take $\bar{x} \in \mathcal{S}_K(\mathbb{G}, X)(\bar{\mathbb{F}}_p)$ with corresponding $b \in G(L)$. Then, there should be a morphism of $\mathrm{Spf}(\mathcal{O}_E)$–formal schemes

$$i_{\bar{x}} : \mathfrak{X}_K(\{\mu\}, b) \times \mathbb{G}(\mathbb{A}_f^p)/K^p \to \widehat{\mathcal{S}}_{\mathbb{K}}(\mathbb{G}, X) := \varprojlim_n \mathcal{S}_{\mathbb{K}}(\mathbb{G}, X) \otimes_{\mathcal{O}_E} \mathcal{O}_E/(p^n),$$

which, on $\bar{\mathbb{F}}_p$-points is given by (LR) and surjects on the "isogeny class" $[\varphi_0]$ of $\bar{x}$, and induces isomorphisms on the formal completions at closed points.

An interesting special case is when the σ-conjugacy class $[b]$ is basic (Kottwitz [1997]). Then the image Z of $i_{\bar{x}}$ should be closed in the special fiber of $\mathcal{S}_{\mathbb{K}}(\mathbb{G}, X)$ and $i_{\bar{x}}$ should be giving a "p-adic uniformization" (*cf.* Rapoport and Zink [1996])

$$(U) \qquad I_{\varphi_0}(\mathbb{Q})\backslash\mathfrak{X}_K(\{\mu\}, b) \times (\mathbb{G}(\mathbb{A}_f^p)/K^p) \xrightarrow{\sim} \widehat{\mathcal{S}}_{\mathbb{K}}(\mathbb{G}, X)_{/Z},$$

of the completion of $\mathcal{S}_{\mathbb{K}}(\mathbb{G}, X)$ along Z.

Assume that $(\mathbb{G}, X)$ is of Hodge type and that the rest of the assumptions of Theorem 3.2 (ii) are also satisfied. Then we can hope to construct $\mathfrak{X}_K(\{\mu\}, b)$ using the model $\mathcal{S}_{\mathbb{K}}(\mathbb{G}, X)$ as follows: First consider the fiber product

$$\begin{array}{ccc} \mathfrak{F} & \to & (\mathfrak{X}_{\mathrm{GSp}} \times 1)\hat{\otimes}_{\mathbb{Z}_p}\mathcal{O}_E \\ \downarrow & & \downarrow i_{\bar{x}} \\ \widehat{\mathcal{S}}_{\mathbb{K}}(\mathbb{G}, X) & \xrightarrow{\iota} & \widehat{\mathcal{S}}_{\mathbb{K}'}(\mathrm{GSp}(\mathbb{V}), S^{\pm})\hat{\otimes}_{\mathbb{Z}_p}\mathcal{O}_E, \end{array}$$

where ι is an appropriate Hodge embedding as in Kisin [2010], or Kisin and Pappas [2015], and $\mathfrak{X}_{\mathrm{GSp}}$ is the Rapoport-Zink formal scheme for the symplectic PEL type. Then, provided we have the set map $X_K(\{\mu\}, b) \to \mathcal{S}_{\mathbb{K}}(\mathbb{G}, X)(\bar{\mathbb{F}}_p)$ sending $1\cdot\tilde{K}$ to $\bar{x}$ (as predicted by the (LR) conjecture), we can define $\mathfrak{X}_K(\{\mu\}, b)$ to be the formal completion of $\mathfrak{F}$ along the (closed) subset given by $X_K(\{\mu\}, b)$. The existence of the "uniformization" morphism $i_{\bar{x}}$ follows immediately. Howard and the author applied this idea to show:

Theorem 5.2. *(Howard and Pappas [2017]) Assume $p \neq 2$, $(\mathbb{G}, X)$ is of Hodge type and K is hyperspecial. Choose a Hodge embedding ρ, a lattice Λ, and tensors $\{s_\alpha\}_\alpha$, as in the proof of Theorem 3.2 (ii). Suppose $\bar{x} \in \mathcal{S}_{\mathbb{K}}(G, X)(\bar{\mathbb{F}}_p)$ and b are as above. Then, $\mathfrak{X}_K(\{\mu\}, b)$ satisfying Conjecture 5.1 can be defined as above, and only depends, up to isomorphism, on $(G, \{\mu\}, b, K)$ and $\rho_{\mathbb{Z}_p} : \mathcal{G} \to \mathrm{GL}(\Lambda)$.*

For basic $[b]$, the uniformization (U) also follows. In the above result, the formal scheme $\mathfrak{X}_K(\{\mu\}, b)\hat{\otimes}_{\mathcal{O}_E} W$ represents a functor on the category of formally finitely generated adic W-algebras (A, I) which are formally smooth over $W/(p^m)$, for some $m \geq 1$ as follows. Set H_0 for the p-divisible group $\mathcal{A}_{\bar{x}}[p^\infty]$. We send (A, I) to the set of isomorphism classes of triples $(H, \tau, \{t_\alpha\}_\alpha)$, where H is a p-divisible group over A, $\tau : H_0 \otimes_k A/(p, I) \dashrightarrow H \otimes_A A/(p, I)$ is a quasi-isogeny, and t_α are (Frobenius invariant) sections of the Dieudonné crystal $\mathbb{D}(H)^\otimes$. We require that the pull-backs $\tau^*(t_\alpha)$ agree in $\mathbb{D}(H_0 \otimes_k A/(p, I))^\otimes[1/p]$ with the constant sections given by $s_{\alpha,\mathrm{crys},\bar{x}}$, and also some more properties listed in Howard and Pappas [ibid., (2.3.3), (2.3.6)]. For K hyperspecial, a different, local, construction of the formal scheme $\mathfrak{X}_K(\{\mu\}, b)$ (still only for "local Hodge types") first appeared in work of Kim [2013].

In some cases, we can also give $\mathfrak{X}_K(\{\mu\}, b)$ directly, by using a group theoretic version of Zink's displays. Assume that K is hyperspecial, so $\mathcal{G}$ is reductive over $\mathbb{Z}_p$. Set $\mathcal{G}_W = \mathcal{G} \otimes_{\mathbb{Z}_p} W$ and pick $\mu : \mathbb{G}_{\mathrm{m}W} \to \mathcal{G}_W$ in our conjugacy class. Set $L^+\mathcal{G}$, resp. $L\mathcal{G}$, for the "positive Witt loop" group scheme, resp. "Witt loop" ind-group scheme, representing $R \mapsto \mathcal{G}(W(R))$, resp. $R \mapsto \mathcal{G}(W(R)[1/p])$. Let $\mathcal{H}_\mu$ be the subgroup scheme of $L^+\mathcal{G}_W$ with R-points given by $g \in \mathcal{G}(W(R))$ whose projection $g_0 \in \mathcal{G}(R)$ lands in the R-points of the parabolic subgroup scheme $\mathcal{P}_\mu \subset \mathcal{G}_W$ associated to μ. We can define a homomorphism $\Phi_{G,\mu} : \mathcal{H}_\mu \to L^+\mathcal{G}_W$ such that $\Phi_{G,\mu}(h) = F \cdot (\mu(p) \cdot h \cdot \mu(p)^{-1})$ in $\mathcal{G}(W(R)[1/p])$, with F given by the Frobenius $W(R) \to W(R)$ (Bueltel and Pappas [2017]). Let R be a p-nilpotent W-algebra. Set

$$\mathfrak{X}'_{\mathcal{G}}(R) = \{(U, g) \in L^+\mathcal{G}(R) \times L\mathcal{G}(R) \mid g^{-1}bF(g) \overset{(*)}{=} U\mu^\sigma(p)\}/\mathcal{H}_\mu(R),$$

where $(*)$ is taken in $L\mathcal{G}(R)$ and the quotient is for the action given by

$$(U, g) \cdot h = (h^{-1}U\Phi_{G,\mu}(h), gh).$$

Denote by $\mathfrak{X}_{\mathcal{G}}$ the étale sheaf associated to $R \mapsto \mathfrak{X}'_{\mathcal{G}}(R)$.

If R is perfect, then F is an isomorphism and $W(R)$ is p-torsion free, so a pair (U, g) with $g^{-1}bF(g) = U\mu^\sigma(p)$ is determined by g. Then

$$\mathfrak{X}'_{\mathcal{G}}(R) = \{g \in L\mathcal{G}(R)/L^+\mathcal{G}(R) \mid g^{-1}bF(g) \in L^+\mathcal{G}(R)\mu^\sigma(p)L^+\mathcal{G}(R)\}.$$

In particular, $\mathfrak{X}_{\mathcal{G}}(\bar{\mathbb{F}}_p) = \mathfrak{X}'_{\mathcal{G}}(\bar{\mathbb{F}}_p) \cong X_K(\{\mu\}, b)$ and the perfection of $\mathfrak{X}_{\mathcal{G}}$ agrees with the space $\mathcal{X}_K(\{\mu\}, b)^{\mathrm{perf}}$ of Zhu [2017]. If $\mathfrak{X}_{\mathcal{G}}$ is representable by a formal scheme, then this satisfies Conjecture 5.1 and gives $\mathfrak{X}_K(\{\mu\}, b)\hat{\otimes}_{\mathcal{O}_E} W$.

Theorem 5.3. *(Bueltel and Pappas [2017]) Let $\rho_{\mathbb{Z}_p} : \mathcal{G} \hookrightarrow \mathrm{GL}_n$ be a closed group scheme embedding. Suppose $\rho_{\mathbb{Z}_p} \circ \mu$ is minuscule and $\rho_{\mathbb{Z}_p}(b)$ has no zero slopes. Then the restriction of $\mathfrak{X}_{\mathcal{G}}$ to Noetherian p-nilpotent W-algebras is represented by a formal scheme which is formally smooth and locally formally of finite type over* $\mathrm{Spf}(W)$.

The proof also gives that, if $\mathfrak{X}_K(\{\mu\}, b)$ is defined as in Theorem 5.2 and $\rho_{\mathbb{Z}_p}(b)$ has no zero slopes, then $\mathfrak{X}_{\mathcal{G}}(R) = \mathfrak{X}_K(\{\mu\}, b)(R)$, for R Noetherian. Hence, then $\mathfrak{X}_K(\{\mu\}, b)$ of Theorem 5.2 is independent of $\rho_{\mathbb{Z}_p}$.

HEURISTICS FOR THE ARITHMETIC OF ELLIPTIC CURVES

Bjorn Poonen

Abstract

This is an introduction to a probabilistic model for the arithmetic of elliptic curves, a model developed in a series of articles of the author with Bhargava, Kane, Lenstra, Park, Rains, Voight, and Wood. We discuss the theoretical evidence for the model, and we make predictions about elliptic curves based on corresponding theorems proved about the model. In particular, the model suggests that all but finitely many elliptic curves over $\mathbb{Q}$ have rank ≤ 21, which would imply that the rank is uniformly bounded.

1 Introduction

Let E be an elliptic curve over $\mathbb{Q}$ (see Silverman [2009] for basic definitions). Let $E(\mathbb{Q})$ be the set of rational points on E. The group law on E gives $E(\mathbb{Q})$ the structure of an abelian group, and Mordell [1922] proved that $E(\mathbb{Q})$ is finitely generated; let $\operatorname{rk} E(\mathbb{Q})$ denote its rank. The present survey article, based primarily on articles Poonen and Rains [2012], Bhargava, Kane, Lenstra, Poonen, and Rains [2015], and Park, Poonen, Voight, and Wood [2016], is concerned with the following question:

Question 1.1. Is $\operatorname{rk} E(\mathbb{Q})$ bounded as E varies over all elliptic curves over $\mathbb{Q}$?

Question 1.1 was implicitly asked by Poincaré [1901, p. 173] in 1901, even before $E(\mathbb{Q})$ was known to be finitely generated! Since then, many authors have put forth guesses, and the folklore expectation has flip-flopped at least once; see Poincaré [1950, p. 495, end of footnote (^{3})], Honda [1960, p. 98], Cassels [1966, p. 257], Tate [1974, p. 194], Mestre [1982], Mestre [1986, II.1.1 and II.1.2], Brumer [1992, Section 1], Ulmer [2002, Conjecture 10.5], and Farmer, Gonek, and Hughes [2007, (5.20)], or see Park, Poonen, Voight, and Wood [2016, Section 3.1] for a summary.

The writing of this article was supported in part by National Science Foundation grant DMS-1601946 and Simons Foundation grants #402472 (to Bjorn Poonen) and #550033.

Keywords: Elliptic curve, rank, Selmer group, Shafarevich–Tate group, abelian variety.

The present survey describes a probabilistic model for the arithmetic of elliptic curves, and presents theorems about the model that suggest that $\operatorname{rk} E(\mathbb{Q}) \le 21$ for all but finitely many elliptic curves E, and hence that $\operatorname{rk} E(\mathbb{Q})$ is bounded. Ours is not the first heuristic for boundedness: there is one by Rubin and Silverberg [2000, Remarks 5.1 and 5.2], for a family of quadratic twists and another by Granville, discussed in Watkins, Donnelly, Elkies, Fisher, Granville, and Rogers [2014, Section 11] and developed further in Watkins [2015]. Interestingly, the latter also suggests a bound of 21.

Modeling ranks directly is challenging because there are few theorems about the distribution of ranks. Also, although there exists extensive computational data that suggests answers to some questions (e.g., Balakrishnan, Ho, Kaplan, Spicer, Stein, and Weigandt [2016]), it seems that far more data would be needed to suggest answers to others. Therefore, instead of modeling ranks in isolation, we model ranks, Selmer groups, and Shafarevich–Tate groups simultaneously, so that we can calibrate and corroborate the model using a diverse collection of known results.

2 The arithmetic of elliptic curves

2.1 Counting elliptic curves by height. Every elliptic curve E over $\mathbb{Q}$ is isomorphic to the projective closure of a unique curve $y^2 = x^3 + Ax + B$ in which A and B are integers with $4A^3 + 27B^2 \neq 0$ (the smoothness condition) such that there is no prime p such that $p^4|A$ and $p^6|B$. Let $\mathscr{E}$ be the set of elliptic curves of this form, so $\mathscr{E}$ contains one curve in each isomorphism class. Define the height of $E \in \mathscr{E}$ by

$$\operatorname{ht} E := \max(|4A^3|, |27B^2|).$$

(This definition is specific to the ground field $\mathbb{Q}$, but it has analogues over other number fields.) Define

$$\mathscr{E}_{\le H} := \{E \in \mathscr{E} : \operatorname{ht} E \le H\}.$$

Ignoring constant factors, we have about $H^{1/3}$ integers A with $|4A^3| \le H$, and $H^{1/2}$ integers B with $|27B^2| \le H$. A positive fraction of such pairs (A, B) satisfy the smoothness condition and divisibility conditions, so one should expect $\#\mathscr{E}_{\le H}$ to be about $H^{1/3}H^{1/2} = H^{5/6}$. In fact, an elementary sieve argument [Brumer 1992, Lemma 4.3] proves the following:

Proposition 2.1. *We have*

$$\#\mathscr{E}_{\le H} = \left(2^{4/3}3^{-3/2}\zeta(10)^{-1} + o(1)\right) H^{5/6}$$

as $H \to \infty$.

Define the density of a subset $S \subseteq \mathscr{E}$ as

$$\lim_{H \to \infty} \frac{\#(S \cap \mathscr{E}_{\leq H})}{\#\mathscr{E}_{\leq H}},$$

if the limit exists. For example, it is a theorem that 100% of elliptic curves E over $\mathbb{Q}$ have no nontrivial rational torsion points; this statement is to be interpreted as saying that the density of the set $S := \{E \in \mathscr{E} : E(\mathbb{Q})_{\text{tors}} = 0\}$ is 1 (even though there do exist E with $E(\mathbb{Q})_{\text{tors}} \neq 0$).

2.2 Elliptic curves over local fields. Our model will be inspired by theorems and conjectures about the arithmetic of elliptic curves over $\mathbb{Q}$. But before studying elliptic curves over $\mathbb{Q}$, we should thoroughly understand elliptic curves over local fields.

Let $\mathbb{Q}_v$ be the completion of $\mathbb{Q}$ at a place v. There is a natural injective homomorphism $\operatorname{inv}\colon \mathrm{H}^2(\mathbb{Q}_v, \mathbb{G}_m) \to \mathbb{Q}/\mathbb{Z}$ that is an isomorphism if v is nonarchimedean.

Let E be an elliptic curve over $\mathbb{Q}_v$. Fix $n \geq 1$. Taking Galois cohomology in the exact sequence

$$0 \longrightarrow E[n] \longrightarrow E \xrightarrow{n} E \longrightarrow 0$$

yields a homomorphism $E(\mathbb{Q}_v)/nE(\mathbb{Q}_v) \to \mathrm{H}^1(\mathbb{Q}_v, E[n])$. Let W_v be its image. If v is a nonarchimedean place not dividing n and E has good reduction, then W_v equals the subgroup of unramified classes in $\mathrm{H}^1(\mathbb{Q}_v, E[n])$ [Poonen and Rains 2012, Proposition 4.13].

The theory of the Heisenberg group [Mumford 1991, pp. 44–46] yields an exact sequence

$$1 \longrightarrow \mathbb{G}_m \longrightarrow \mathfrak{H} \longrightarrow E[n] \longrightarrow 1,$$

which induces a map of sets

$$q_v\colon \mathrm{H}^1(\mathbb{Q}_v, E[n]) \longrightarrow \mathrm{H}^2(\mathbb{Q}_v, \mathbb{G}_m) \overset{\text{inv}}{\hookrightarrow} \mathbb{Q}/\mathbb{Z}.$$

It turns out that q_v is a quadratic form in the sense that $q_v(x+y) - q_v(x) - q_v(y)$ is bi-additive [Zarhin 1974b, §2]. Moreover, $q_v|_{W_v} = 0$ [O'Neil 2002, Proposition 2.3]. In fact, using Tate local duality one can show that W_v is a maximal isotropic subgroup of $\mathrm{H}^1(\mathbb{Q}_v, E[n])$ with respect to q_v [Poonen and Rains 2012, Proposition 4.11].

2.3 Selmer groups and Shafarevich–Tate groups. Now let E be an elliptic curve over $\mathbb{Q}$. Let $\mathbf{A} = \prod_v'(\mathbb{Q}_v, \mathbb{Z}_v)$ be the adèle ring of $\mathbb{Q}$; here v ranges over nontrivial places of $\mathbb{Q}$, Write $E(\mathbf{A})$ for $\prod_v E(\mathbb{Q}_v)/nE(\mathbb{Q}_v)$, and write $\mathrm{H}^1(\mathbf{A}, E[n])$ for the restricted product

$\prod'_v (\mathrm{H}^1(\mathbb{Q}_v, E[n]), W_v)$. We have a commutative diagram

$$\begin{array}{ccc} E(\mathbb{Q})/nE(\mathbb{Q}) & \longrightarrow & \mathrm{H}^1(\mathbb{Q}, E[n]) \\ \downarrow & & \downarrow \beta \\ E(\mathbf{A})/nE(\mathbf{A}) & \xrightarrow{\alpha} & \mathrm{H}^1(\mathbf{A}, E[n]). \end{array}$$

The n-Selmer group is defined by $\mathrm{Sel}_n E := \beta^{-1}(\operatorname{im} \alpha) \subseteq \mathrm{H}^1(\mathbb{Q}, E[n])$. (This is equivalent to the classical definition; we have only replaced $\prod_v \mathrm{H}^1(\mathbb{Q}_v, E[n])$ with a subgroup $\mathrm{H}^1(\mathbf{A}, E[n])$ into which α and β map.) The reason for defining $\mathrm{Sel}_n E$ is that it is a computable finite upper bound for (the image of) $E(\mathbb{Q})/nE(\mathbb{Q})$. On the other hand, the Shafarevich–Tate group is defined by

$$Ш = Ш(E) := \ker \left(\mathrm{H}^1(\mathbb{Q}, E) \to \prod_v \mathrm{H}^1(\mathbb{Q}_v, E) \right).$$

It is a torsion abelian group with an alternating pairing

$$[\ ,\ ] \colon Ш \times Ш \to \mathbb{Q}/\mathbb{Z}$$

defined by Cassels. Conjecturally, Ш is finite; in this case, $[\ ,\ ]$ is nondegenerate and #Ш is a square [Cassels 1962]. The definitions easily yield an exact sequence

$$0 \longrightarrow \frac{E(\mathbb{Q})}{nE(\mathbb{Q})} \longrightarrow \mathrm{Sel}_n E \longrightarrow Ш[n] \longrightarrow 0, \tag{1}$$

so $Ш[n]$ is measuring the difference between $\mathrm{Sel}_n E$ and the group $E(\mathbb{Q})/nE(\mathbb{Q})$ it is trying to approximate.

Each group in (1) decomposes according to the factorization of n into powers of distinct primes, so let us restrict to the case in which $n = p^e$ for some prime p and nonnegative integer e. Taking the direct limit over e yields an exact sequence

$$0 \longrightarrow E(\mathbb{Q}) \otimes \frac{\mathbb{Q}_p}{\mathbb{Z}_p} \longrightarrow \mathrm{Sel}_{p^\infty} E \longrightarrow Ш[p^\infty] \longrightarrow 0$$

of $\mathbb{Z}_p$-modules in which $\mathrm{Sel}_{p^\infty} E := \varinjlim \mathrm{Sel}_{p^e} E$ and $Ш[p^\infty] := \bigcup_{e \geq 0} Ш[p^e]$. Moreover, one can show that if $E(\mathbb{Q})[p] = 0$ (as holds for 100% of curves), then $\mathrm{Sel}_{p^e} E \to (\mathrm{Sel}_{p^\infty} E)[p^e]$ is an isomorphism (cf. Bhargava, Kane, Lenstra, Poonen, and Rains [2015, Proposition 5.9(b)]), so no information about the individual p^e-Selmer groups has been lost in passing to the limit.

2.4 The Selmer group as an intersection of maximal isotropic direct summands. If $\xi = (\xi_v) \in \mathrm{H}^1(\mathbf{A}, E[n])$, then for all but finitely many v we have $\xi_v \in W_v$ and hence $q_v(\xi_v) = 0$, so we may define $Q(\xi) := \sum_v q_v(\xi_v)$. This defines a quadratic form $Q\colon \mathrm{H}^1(\mathbf{A}, E[n]) \to \mathbb{Q}/\mathbb{Z}$.

Theorem 2.2.

(a) *Each of* $\operatorname{im}\alpha$ *and* $\operatorname{im}\beta$ *is a maximal isotropic subgroup of* $\mathrm{H}^1(\mathbf{A}, E[n])$ *with respect to* Q *[Poonen and Rains 2012, Theorem 4.14(a)].*

(b) *If* n *is prime or* $G_{\mathbb{Q}} \to \mathrm{GL}_2(\mathbb{Z}/n\mathbb{Z})$ *is surjective, then* β *is injective. (See Poonen and Rains [ibid., Proposition 3.3(e)] and Bhargava, Kane, Lenstra, Poonen, and Rains [2015, Proposition 6.1].)*

By definition, $\beta(\mathrm{Sel}_n\, E) = (\operatorname{im}\alpha) \cap (\operatorname{im}\beta)$. Thus, under either hypothesis in (b), $\mathrm{Sel}_n\, E$ is isomorphic to an intersection of maximal isotropic subgroups of $\mathrm{H}^1(\mathbf{A}, E[n])$.

Moreover, $\operatorname{im}\alpha$ is a direct summand of $\mathrm{H}^1(\mathbf{A}, E[n])$ [ibid., Corollary 6.8]. It is conjectured that $\operatorname{im}\beta$ is a direct summand as well, at least for asymptotically 100% of elliptic curves over $\mathbb{Q}$ [ibid., Conjecture 6.9], and it could hold for all of them.

2.5 The Birch and Swinnerton-Dyer conjecture. See Wiles [2006] for an introduction to the Birch and Swinnerton-Dyer conjecture more detailed than what we present here, and see Stein and Wuthrich [2013, Section 8] for some more recent advances towards it.

Let $E \in \mathscr{E}$. To E one can associate its L-function $L(E, s)$, a holomorphic function initially defined when $\operatorname{Re} s$ is sufficiently large, but known to extend to a holomorphic function on $\mathbb{C}$ (this is proved using the modularity of E). Just as the Dirichlet analytic class number formula expresses the residue at $s = 1$ of the Dedekind zeta function of a number field k in terms of the arithmetic of k, the Birch and Swinnerton-Dyer conjecture expresses the leading term in the Taylor expansion of $L(E, s)$ around $s = 1$ in terms of the arithmetic of E. We will state it only in the case that $\operatorname{rk} E(\mathbb{Q}) = 0$ since that is all that we will need. In addition to the quantities previously associated to E, we need

- the real period Ω, defined as the integral over $E(\mathbb{R})$ of a certain 1-form; and
- the Tamagawa number c_p for each finite prime p, a p-adic volume analogous to the real period.

Also define

$$Ш_0(E) := \begin{cases} \#Ш(E), & \text{if } \operatorname{rk} E(\mathbb{Q}) = 0; \\ 0, & \text{if } \operatorname{rk} E(\mathbb{Q}) > 0. \end{cases}$$

Conjecture 2.3 (The rank 0 part of the Birch and Swinnerton-Dyer conjecture). *If $E \in \mathscr{E}$, then*

$$L(E,1) = \frac{Ш_0 \, \Omega \, \prod_p c_p}{\#E(\mathbb{Q})_{\text{tors}}^2}. \tag{2}$$

Remark 2.4. In the case where the rank $r := \operatorname{rk} E(\mathbb{Q})$ is greater than 0, Conjecture 2.3 states only that $L(E,1) = 0$, whereas the full Birch and Swinnerton-Dyer conjecture predicts that $\operatorname{ord}_{s=1} L(E,s) = r$ and predicts the leading coefficient in the Taylor expansion of $L(E,s)$ at $s = 1$.

Let $H = \operatorname{ht} E$. Following Lang [1983] (see also Goldfeld and Szpiro [1995], de Weger [1998], Hindry [2007], Watkins [2008], and Hindry and Pacheco [2016]), we estimate the typical size of $Ш_0$ by estimating all the other quantities in (2) as $H \to \infty$; see Park, Poonen, Voight, and Wood [2016, Section 6] for details. The upshot is that if we average over E and ignore factors that are $H^{o(1)}$, then (2) simplifies to $1 \sim Ш_0 \, \Omega$ and we obtain $Ш_0 \sim \Omega^{-1} \sim H^{1/12}$. More precisely:

- $\prod_p c_p = H^{o(1)}$ [de Weger 1998, Theorem 3], [Hindry 2007, Lemma 3.5], [Watkins 2008, pp. 114–115], [Park, Poonen, Voight, and Wood 2016, Lemma 6.2.1];
- $\#E(\mathbb{Q})_{\text{tors}} \le 16$ [Mazur 1977];
- $\Omega = H^{-1/12+o(1)}$ [Hindry 2007, Lemma 3.7], [Park, Poonen, Voight, and Wood 2016, Corollary 6.1.3]; and
- the Riemann hypothesis for $L(E,s)$ implies that $L(E,1) \le H^{o(1)}$ [Iwaniec and Sarnak 2000, p. 713]. In fact, it is reasonable to expect $\operatorname*{Average}_{E \in \mathscr{E}_{\le H}} L(E,1) \asymp 1$. (The symbol $\asymp$ means that the left side is bounded above and below by positive constants times the right side.)

Thus we expect

$$\operatorname*{Average}_{E \in \mathscr{E}_{\le H}} Ш_0(E) = H^{1/12+o(1)} \tag{3}$$

as $H \to \infty$.

3 Modeling elliptic curves over $\mathbb{Q}$

3.1 Modeling the p-Selmer group. According to Theorem 2.2, $\operatorname{Sel}_p E$ is isomorphic to an intersection of maximal isotropic subspaces in an infinite-dimensional quadratic space over $\mathbb{F}_p$. So one might ask whether one could make sense of choosing maximal isotropic subspaces in an infinite-dimensional quadratic space at random, so that one could intersect two of them to obtain a space whose distribution is conjectured to be that of $\operatorname{Sel}_p E$. This can be done by equipping an infinite-dimensional quadratic space with a locally compact topology [Poonen and Rains 2012, Section 2], but the resulting distribution can be obtained more simply by working within a $2n$-dimensional quadratic space and taking the limit as $n \to \infty$. Now every nondegenerate $2n$-dimensional quadratic space with a maximal isotropic subspace is isomorphic to the quadratic space $V_n = (\mathbb{F}_p^{2n}, Q)$, where Q is the quadratic form

$$Q(x_1, \dots, x_n, y_1, \dots, y_n) := x_1 y_1 + \cdots + x_n y_n.$$

Therefore we conjecture that the distribution of $\dim_{\mathbb{F}_p} \operatorname{Sel}_p E$ as E varies over $\mathscr{E}$ equals the limit as $n \to \infty$ of the distribution of the dimension of the intersection of two maximal isotropic subspaces in V_n chosen uniformly at random from the finitely many possibilities. The limit exists and can be computed explicitly; this yields the formula on the right in the following:

Conjecture 3.1 (Poonen and Rains [ibid., Conjecture 1.1]). *For each $s \geq 0$, the density of $\{E \in \mathscr{E} : \dim_{\mathbb{F}_p} \operatorname{Sel}_p E = s\}$ equals*

$$\prod_{j \geq 0} (1 + p^{-j})^{-1} \prod_{j=1}^{s} \frac{p}{p^j - 1}. \tag{4}$$

Remark 3.2. Let E_d be the elliptic curve $dy^2 = x^3 - x$ over $\mathbb{Q}$. Heath-Brown [1993, 1994] proved that the density of integers d such that $\dim_{\mathbb{F}_2} \operatorname{Sel}_2 E_d - 2 = s$ equals

$$\prod_{j \geq 0} (1 + 2^{-j})^{-1} \prod_{j=1}^{s} \frac{2}{2^j - 1},$$

matching (4) for $p = 2$. (The -2 is there to remove the "causal" contribution to $\dim \operatorname{Sel}_2 E_d$ coming from $E_d(\mathbb{Q})[2]$.) As we have explained, this result is a natural consequence of the theory of Section 2.4, but in fact Heath-Brown's result came first and the theory was reverse engineered from it [Poonen and Rains 2012]! Heath-Brown's result was extended by Swinnerton-Dyer [2008] and Kane [2013] to the family of quadratic twists of any $E \in \mathscr{E}$ with $E[2] \subseteq E(\mathbb{Q})$ and no cyclic 4-isogeny.

3.2 Modeling the p^e-Selmer group.

If p is replaced by p^e, then we should replace $\mathbb{F}_p^{2n}$ by $V_n := ((\mathbb{Z}/p^e\mathbb{Z})^{2n}, Q)$. But now there are different types of maximal isotropic subgroups up to isomorphism. For example, if $e = 2$, then $(\mathbb{Z}/p^2\mathbb{Z})^n \times \{0\}^n$ and $(p\mathbb{Z}/p^2\mathbb{Z})^{2n}$

are both maximal isotropic subgroups; of these, only the first is a direct summand of V_n. In what follows, we will use only direct summands, for reasons to be explained at the end of this section.

Conjecture 3.3. *If we intersect two random maximal isotropic direct summands of $V_n := ((\mathbb{Z}/p^e\mathbb{Z})^{2n}, Q)$ and take the limit as $n \to \infty$ of the resulting distribution, we obtain the distribution of* $\operatorname{Sel}_{p^e} E$ *as E varies over $\mathscr{E}$.*

For $m \geq 1$, let $\sigma(m)$ denote the sum of the positive divisors of m. One can prove that the limit as $n \to \infty$ of the average size of the random intersection equals $\sigma(p^e)$, and there is an analogous result for positive integers m not of the form p^e [Bhargava, Kane, Lenstra, Poonen, and Rains 2015, Proposition 5.20]. This suggests the following:

Conjecture 3.4 (Poonen and Rains [2012, Conjecture 1(b)], Bhargava, Kane, Lenstra, Poonen, and Rains [2015, Section 5.7], Bhargava and Shankar [2013a, Conjecture 4])**.** *For each positive integer m,*

$$\operatorname*{Average}_{E \in \mathscr{E}} \# \operatorname{Sel}_m E = \sigma(m).$$

(The average is interpreted as the limit as $H \to \infty$ of the average over $\mathscr{E}_{\leq H}$.)

One could similarly compute the higher moments of the conjectural distribution; see Poonen and Rains [2012, Proposition 2.22(a)] and Bhargava, Kane, Lenstra, Poonen, and Rains [2015, Section 5.5].

There are several reasons why insisting upon direct summands in Conjecture 3.3 seems right:

- Conjecturally, both of the maximal isotropic subgroups arising in the arithmetic of the elliptic curve *are* direct summands: see the last paragraph of Section 2.4.
- Requiring direct summands is essentially the only way to make the model for $\operatorname{Sel}_{p^e} E$ consistent with the model for $\operatorname{Sel}_p E$, given that $\operatorname{Sel}_p E \simeq (\operatorname{Sel}_{p^e} E)[p]$ for 100% of curves [ibid., Remark 6.12].
- It leads to Conjecture 3.4, which has been proved for $m \leq 5$ [Bhargava and Shankar 2015a,b, 2013a,b].

3.3 Modeling the p^∞-Selmer group and the Shafarevich–Tate group. Choosing a maximal isotropic direct summand of $((\mathbb{Z}/p^e\mathbb{Z})^{2n}, Q)$ compatibly for all e is equivalent to choosing a maximal isotropic direct summand of the quadratic $\mathbb{Z}_p$-module $V_n := (\mathbb{Z}_p^{2n}, Q)$. This observation will lead us to a process that models $\operatorname{Sel}_{p^e} E$ for all e simultaneously, or equivalently, that models $\operatorname{Sel}_{p^\infty} E$ directly. To simplify notation, for any

$\mathbb{Z}_p$-module X, let X' denote $X \otimes \frac{\mathbb{Q}_p}{\mathbb{Z}_p}$; if X is a $\mathbb{Z}_p$-submodule of V_n, then X' is a $\mathbb{Z}_p$-submodule of V_n'.

Now choose maximal isotropic direct summands Z and W of V_n with respect to the measure arising from taking the inverse limit over e of the uniform measure on the set of maximal isotropic direct summands of $(\mathbb{Z}/p^e\mathbb{Z})^{2n}$ [Bhargava, Kane, Lenstra, Poonen, and Rains 2015, Sections 2 and 4]; then we conjecture that the limiting distribution of $Z' \cap W'$ as $n \to \infty$ equals the distribution of $\operatorname{Sel}_{p^\infty} E$ as E varies over $\mathscr{E}$. Again, the point is that this limiting distribution is compatible with the previously conjectured distribution for $\operatorname{Sel}_{p^e} E$ for each nonnegative integer e, and the conjecture for $\operatorname{Sel}_{p^e} E$ was based on *theorems* about Selmer groups of elliptic curves (see Section 2.4).

Even better, using the same ingredients, we can model $\operatorname{rk} E(\mathbb{Q})$ and $Ш[p^\infty]$ at the same time:

Conjecture 3.5 (Bhargava, Kane, Lenstra, Poonen, and Rains [ibid., Conjecture 1.3])**.** *If we choose maximal isotropic direct summands Z and W of $(\mathbb{Z}_p^{2n}, Q)$ at random as above, and we define*

$$R := (Z \cap W)', \qquad S := Z' \cap W', \qquad T := S/R,$$

then the limit as $n \to \infty$ of the distribution of the exact sequence

$$0 \longrightarrow R \longrightarrow S \longrightarrow T \longrightarrow 0$$

equals the distribution of the sequence

$$0 \longrightarrow E(\mathbb{Q}) \otimes \frac{\mathbb{Q}_p}{\mathbb{Z}_p} \longrightarrow \operatorname{Sel}_{p^\infty} E \longrightarrow Ш[p^\infty] \longrightarrow 0$$

as E varies over $\mathscr{E}$.

There are several pieces of indirect evidence for the rank and Ш predictions of Conjecture 3.5:

- Each of R and $E(\mathbb{Q}) \otimes \frac{\mathbb{Q}_p}{\mathbb{Z}_p}$ is isomorphic to $(\mathbb{Q}_p/\mathbb{Z}_p)^r$ for some nonnegative integer r, called the $\mathbb{Z}_p$-corank of the module.
- The $\mathbb{Z}_p$-corank of R is 0 or 1, with probability $1/2$ each [ibid., Proposition 5.6]. Likewise, a variant of a conjecture of Goldfeld (see Goldfeld [1979, Conjecture B] and Katz and Sarnak [1999a,b]) predicts that $\operatorname{rk} E(\mathbb{Q})$ (which equals the $\mathbb{Z}_p$-corank of $E(\mathbb{Q}) \otimes \frac{\mathbb{Q}_p}{\mathbb{Z}_p}$) is 0, 1, ≥ 2 with densities $1/2$, $1/2$, 0, respectively.
- The group T is finite and carries a nondegenerate alternating pairing with values in $\mathbb{Q}_p/\mathbb{Z}_p$, just as $Ш[p^\infty]$ conjecturally does (the p-part of the Cassels pairing). In particular, $\#T$ is a square.

- [Smith 2017] has proved a result analogous to Conjecture 3.5 for the family of quadratic twists of any $E \in \mathscr{E}$ with $E[2] \subseteq E(\mathbb{Q})$ and no cyclic 4-isogeny.

Further evidence is that there are in fact *three* distributions that have been conjectured to be the distribution of $Ш[p^\infty]$ as E varies over rank r elliptic curves, and these three distributions coincide [Bhargava, Kane, Lenstra, Poonen, and Rains 2015, Theorems 1.6(c) and 1.10(b)]. This is so even in the cases with $r \geq 2$, which conjecturally occur with density 0. For a fixed nonnegative integer r, the three distributions are as follows:

1. A distribution defined by Delaunay [2001, 2007] and Delaunay and Jouhet [2014], who adapted the Cohen–Lenstra heuristics for class groups [Cohen and Lenstra 1984].

2. The limit as $n \to \infty$ of the distribution of $T := (Z' \cap W')/(Z \cap W)'$ when (Z, W) is sampled from the set of pairs of maximal isotropic direct summands of $(\mathbb{Z}_p^{2n}, Q)$ satisfying $\operatorname{rk}_{\mathbb{Z}_p}(Z \cap W) = r$. (This set of pairs is the set of $\mathbb{Z}_p$-points of a scheme of finite type, so it carries a natural measure [Bhargava, Kane, Lenstra, Poonen, and Rains 2015, Sections 2 and 4].)

3. The limit as $n \to \infty$ through integers of the same parity as r of the distribution of $(\operatorname{coker} A)_{\text{tors}}$ when A is sampled from the space of matrices in $\mathrm{M}_n(\mathbb{Z}_p)$ satisfying $A^T = -A$ and $\operatorname{rk}_{\mathbb{Z}_p}(\ker A) = r$; here $\ker A$ and $\operatorname{coker} A$ are defined by viewing A as a $\mathbb{Z}_p$-linear homomorphism $\mathbb{Z}_p^n \to \mathbb{Z}_p^n$.

The last of these is inspired by the theorem of Friedman and Washington [1989] that for each odd prime p, the limit as $n \to \infty$ of the distribution coker A for $A \in \mathrm{M}_n(\mathbb{Z}_p)$ chosen at random with respect to Haar measure equals the distribution conjectured by Cohen and Lenstra to be the distribution of the p-primary part of the class group of a varying imaginary quadratic field.

3.4 Modeling the rank of an elliptic curve. In the previous section, we saw in the third construction that conditioning on $\operatorname{rk}_{\mathbb{Z}_p}(\ker A) = r$ yields the conjectural distribution of $Ш[p^\infty]$ for rank r curves. The simplest possible explanation for this would be that sampling A at random from $\mathrm{M}_n(\mathbb{Z}_p)_{\text{alt}} := \{A \in \mathrm{M}_n(\mathbb{Z}_p) : A^T = -A\}$ *without* conditioning on $\operatorname{rk}_{\mathbb{Z}_p}(\ker A)$ caused $\operatorname{rk}_{\mathbb{Z}_p}(\ker A)$ to be distributed like the rank of an elliptic curve.

What is the distribution of $\operatorname{rk}_{\mathbb{Z}_p}(\ker A)$? If n is even, then the locus in $\mathrm{M}_n(\mathbb{Z}_p)_{\text{alt}}$ defined by $\det A = 0$ is the set of $\mathbb{Z}_p$-points of a hypersurface, which has Haar measure 0, so $\operatorname{rk}_{\mathbb{Z}_p}(\ker A) = 0$ with probability 1. If n is odd, however, then $\operatorname{rk}_{\mathbb{Z}_p}(\ker A)$ cannot be 0, because $n - \operatorname{rk}_{\mathbb{Z}_p}(\ker A)$ is the rank of A, which is even for an alternating matrix. For n odd, it turns out that $\operatorname{rk}_{\mathbb{Z}_p}(\ker A) = 1$ with probability 1. If we imagine that n was chosen large and with random parity, then the result is that $\operatorname{rk}_{\mathbb{Z}_p}(\ker A)$ is 0 or 1, with probability 1/2 each. This result agrees with the variant of Goldfeld's conjecture mentioned above.

This model cannot, however, distinguish the relative frequencies of curves of various ranks ≥ 2, because in the model the event $\operatorname{rk}_{\mathbb{Z}_p}(\ker A) \geq 2$ occurs with probability 0.

Therefore we propose a refined model in which instead of sampling A from $\mathrm{M}_n(\mathbb{Z}_p)_{\mathrm{alt}}$, we sample A from the set $\mathrm{M}_n(\mathbb{Z})_{\mathrm{alt},\leq X}$ of matrices in $\mathrm{M}_n(\mathbb{Z})_{\mathrm{alt}}$ with entries bounded by a number X *depending on the height H of the elliptic curve being modeled*, tending to ∞ as $H \to \infty$. This way, for elliptic curves of a given height H, the model predicts a potentially positive but diminishing probability of each rank ≥ 2 (the probability that an integer point in a box lies on a certain subvariety), and we can quantify the rate at which this probability tends to 0 as $H \to \infty$ in order to count curves of height up to H having each given rank. In fact, we let n grow with H as well.

Here, more precisely, is the refined model. To model an elliptic curve E of height H, using functions $\eta(H)$ and $X(H)$ to be specified later, we do the following:

1. Choose n to be an integer of size about $\eta(H)$ of random parity (e.g., we could choose n uniformly at random from $\{\lceil \eta(H) \rceil, \lceil \eta(H) \rceil + 1\}$).

2. Choose $A_E \in \mathrm{M}_n(\mathbb{Z})_{\mathrm{alt},\leq X(H)}$ uniformly at random, independently for each E.

3. Define random variables $\text{Ш}'_E := (\operatorname{coker} A)_{\mathrm{tors}}$ and $\operatorname{rk}'_E := \operatorname{rk}_{\mathbb{Z}}(\ker A)$.

Think of $\text{Ш}'_E$ as the "pseudo-Shafarevich–Tate group" of E and rk'_E as the "pseudo-rank" of E; their behavior is intended to model the actual Ш and rank.

To complete the description of the model, we must specify the functions $\eta(H)$ and $X(H)$. We do this by asking "How large is Ш_0 on average?", both in the model and in reality. Recall from (3) that we expect

(5) $$\operatorname*{Average}_{E \in \mathscr{E}_{\leq H}} \text{Ш}_0(E) = H^{1/12+o(1)}.$$

Define

$$\text{Ш}'_{E,0} := \begin{cases} \#\text{Ш}'_E, & \text{if } \operatorname{rk}'_E = 0; \\ 0, & \text{if } \operatorname{rk}'_E > 0. \end{cases}$$

Using that the determinant of an $n \times n$ matrix is given by a polynomial of degree n in the entries, we can prove that

(6) $$\operatorname*{Average}_{E \in \mathscr{E}_{\leq H}} \text{Ш}'_{E,0} = X(H)^{\eta(H)(1+o(1))},$$

assuming that $\eta(H)$ does not grow too quickly with H. Comparing (5) and (6) suggests choosing $\eta(H)$ and $X(H)$ so that $X(H)^{\eta(H)} = H^{1/12+o(1)}$. We assume this from now on. It turns out that we will not need to know any more about $\eta(H)$ and $X(H)$ than this.

3.5 Consequences of the model. To see what distribution of ranks is predicted by the refined model, we must calculate the distribution of ranks of alternating matrices whose entries are integers with bounded absolute value; the relevant result, whose proof is adapted from Eskin and Katznelson [1995], is the following:

Theorem 3.6 (cf. Park, Poonen, Voight, and Wood [2016, Theorem 9.1.1]). *If $1 \le r \le n$ and $n - r$ is even, and $A \in \mathrm{M}_n(\mathbb{Z})_{\mathrm{alt}, \le X}$ is chosen uniformly at random, then*

$$\mathrm{Prob}(\mathrm{rk}(\ker A) \ge r) \asymp_n (X^n)^{-(r-1)/2}.$$

(The subscript n on the symbol $\asymp$ means that the implied constants depend on n.)

Theorem 3.6 implies that for fixed $r \ge 1$ and $E \in \mathscr{E}$ of height H,

$$\mathrm{Prob}(\mathrm{rk}'_E \ge r) = (X(H)^{\eta(H)})^{-(r-1)/2+o(1)} = H^{-(r-1)/24+o(1)}. \tag{7}$$

Using this, and the fact $\#\mathscr{E}_{\le H} \asymp H^{5/6} = H^{20/24}$ (Proposition 2.1), we can now sum (7) over $E \in \mathscr{E}_{\le H}$ to prove the following theorem about our model:

Theorem 3.7 (Park, Poonen, Voight, and Wood [ibid., Theorem 7.3.3]). *The following hold with probability* 1*:*

$$\begin{aligned}
\#\{E \in \mathscr{E}_{\le H} : \mathrm{rk}'_E = 0\} &= H^{20/24+o(1)} \\
\#\{E \in \mathscr{E}_{\le H} : \mathrm{rk}'_E = 1\} &= H^{20/24+o(1)} \\
\#\{E \in \mathscr{E}_{\le H} : \mathrm{rk}'_E \ge 2\} &= H^{19/24+o(1)} \\
\#\{E \in \mathscr{E}_{\le H} : \mathrm{rk}'_E \ge 3\} &= H^{18/24+o(1)} \\
&\vdots \\
\#\{E \in \mathscr{E}_{\le H} : \mathrm{rk}'_E \ge 20\} &= H^{1/24+o(1)} \\
\#\{E \in \mathscr{E}_{\le H} : \mathrm{rk}'_E \ge 21\} &\le H^{o(1)}, \\
\#\{E \in \mathscr{E} : \mathrm{rk}'_E > 21\} &\text{ is finite.}
\end{aligned}$$

This suggests the conjecture that the same statements hold for the *actual* ranks of elliptic curves over $\mathbb{Q}$. In particular, we conjecture that $\mathrm{rk}\, E(\mathbb{Q})$ is uniformly bounded, bounded by the maximum of the ranks of the conjecturally finitely many elliptic curves of rank > 21.

Remark 3.8. Elkies [2006] has found infinitely many elliptic curves over $\mathbb{Q}$ of rank ≥ 19, and one of rank ≥ 28; these have remained the records since 2006.

4 Generalizations

4.1 Elliptic curves over global fields. What about elliptic curves over other global fields K? Let $\mathscr{E}_K$ be a set of representatives for the isomorphism classes of elliptic curves over K. Let $B_K := \limsup_{E \in \mathscr{E}_K} \operatorname{rk} E(K)$. For example, the conjecture suggested by Theorem 3.7 predicts that $20 \le B_{\mathbb{Q}} \le 21$.

Theorem 4.1 (Tèĭt and Šafarevič [1967], Ulmer [2002]). *If K is a global function field, then $B_K = \infty$.*

Even for number fields, B_K can be arbitrarily large (but maybe still always finite):

Theorem 4.2 (Park, Poonen, Voight, and Wood [2016, Theorem 12.4.2]). *There exist number fields K of arbitrarily high degree such that $B_K \ge [K : \mathbb{Q}]$.*

Examples of number fields K for which B_K is large include fields in anticyclotomic towers and certain multiquadratic fields; see Park, Poonen, Voight, and Wood [ibid., Section 12.4].

A naive adaptation of our heuristic (see Park, Poonen, Voight, and Wood [ibid., Sections 12.2 and 12.3]) would suggest $20 \le B_K \le 21$ for every global field K, but Theorems 4.1 and 4.2 contradict this conclusion. Our rationalization of this is that the elliptic curves of high rank in Theorems 4.1 and 4.2 are special in that they are definable over a proper subfield of K, and these special curves exhibit arithmetic phenomena that our model does not take into account. To exclude these curves, let $\mathscr{E}_K^\circ$ be the set of $E \in \mathscr{E}_K$ such that E is not a base change of a curve from a proper subfield, and let $B_K^\circ := \limsup_{E \in \mathscr{E}_K^\circ} \operatorname{rk} E(K)$. It is possible that $B_K^\circ < \infty$ for every global field K.

Remark 4.3. On the other hand, it is not true that $B_K^\circ \le 21$ for all number fields, as we now explain. Shioda [1992] proved that $y^2 = x^3 + t^{360} + 1$ has rank 68 over $\mathbb{C}(t)$. In fact, it has rank 68 also over $K(t)$ for a suitable number field K. For this K, specialization yields infinitely many elliptic curves in $\mathscr{E}_K^\circ$ of rank ≥ 68. Thus $B_K^\circ \ge 68$. See Park, Poonen, Voight, and Wood [2016, Remark 12.3.1] for details.

4.2 Abelian varieties.

Question 4.4. For abelian varieties A over number fields K, is there a bound on $\operatorname{rk} A(K)$ depending only on $\dim A$ and $[K : \mathbb{Q}]$?

By restriction of scalars, we can reduce to the case $K = \mathbb{Q}$ at the expense of increasing the dimension. By "Zarhin's trick" that $A^4 \times (A^\vee)^4$ is principally polarized [Zarhin 1974a], we can reduce to the case that A is principally polarized, again at the expense of increasing the dimension. For fixed $g \geq 0$, one can write down a family of projective varieties including all g-dimensional principally polarized abelian varieties over $\mathbb{Q}$, probably with each isomorphism class represented infinitely many times. We can assume that each abelian variety A is defined by a system of homogeneous polynomials with integer coefficients, in which the number of variables, the number of polynomials, and their degrees are bounded in terms of g. Define the height of A to be the maximum of the absolute values of the coefficients. Then the number of g-dimensional principally polarized abelian varieties over $\mathbb{Q}$ of height $\leq H$ is bounded by a polynomial in H. If there is a model involving a pseudo-rank rk'_A whose probability of exceeding r gets divided by at least a fixed fractional power of H each time r is incremented by 1, as we had for elliptic curves, then the pseudo-ranks are bounded with probability 1. This might suggest a positive answer to Question 4.4, though the evidence is much flimsier than in the case of elliptic curves.

Acknowledgments. I thank Nicolas Billerey, Serge Cantat, Andrew Granville, Eric Rains, Michael Stoll, and John Voight for comments.

POTENTIAL AUTOMORPHY OF $\widehat{G}$-LOCAL SYSTEMS

Jack Thorne

Abstract

Vincent Lafforgue has recently made a spectacular breakthrough in the setting of the global Langlands correspondence for global fields of positive characteristic, by constructing the 'automorphic–to–Galois' direction of the correspondence for an arbitrary reductive group G. We discuss a result that starts with Lafforgue's work and proceeds in the opposite ('Galois–to–automorphic') direction.

1 Introduction

Let $\mathbb{F}_q$ be a finite field, and let G be a split reductive group over $\mathbb{F}_q$. Let X be a smooth projective connected curve over $\mathbb{F}_q$, and let K be its function field. Let $\mathbb{A}_K$ denote the ring of adèles of K. Automorphic forms on G are locally constant functions $f : G(\mathbb{A}_K) \to \overline{\mathbb{Q}}$ which are invariant under left translation by the discrete group $G(K) \subset G(\mathbb{A}_K)$.[1] The space of automorphic forms is a representation of $G(\mathbb{A}_K)$, and its irreducible constituents are called automorphic representations.

Let $\ell \nmid q$ be a prime. According to the Langlands conjectures, any automorphic representation π of $G(\mathbb{A}_K)$ should give rise to a continuous representation $\rho(\pi) : \pi_1^{\text{ét}}(U) \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ (for some open subscheme $U \subset X$). This should be compatible with the (known) unramified local Langlands correspondence, which describes the pullback of $\rho(\pi)$ to $\pi_1^{\text{ét}}(\mathbb{F}_{q_v})$ for every closed point $v : \operatorname{Spec} \mathbb{F}_{q_v} \hookrightarrow U$ in terms of the components π_v of a factorization $\pi = \otimes'_v \pi_v$ into representations of the local groups $G(K_v)$.

Vincent Lafforgue has given an amazing construction of the representation $\rho(\pi)$, which crystallizes and removes many of the ambiguities in this picture in a beautiful way. We give a brief description of this work below.

Our main goal in this article is to describe a work due to Gebhard Böckle, Michael Harris, Chandrashekhar Khare, and myself, where we establish a partial converse to this

MSC2010: 11F80.

[1] This is not the full definition. In the rest of this article we consider only cuspidal automorphic forms, which are defined precisely below.

result Böckle, Harris, Khare, and J. A. Thorne [n.d.]. We restrict to representations $\rho : \pi_1^{\text{ét}}(X) \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ of Zariski dense image, and show that any such representation is *potentially automorphic*, in the sense that there exists a Galois cover $Y \to X$ such that the pullback of ρ to $\pi_1^{\text{ét}}(Y)$ is contained in the image of Lafforgue's construction. We will guide the reader through the context surrounding this result, and discuss some interesting open questions that are suggested by our methods.

2 Review of the case $G = \mathrm{GL}_n$

We begin by describing what is known about the Langlands conjectures in the setting of the general linear group $G = \mathrm{GL}_n$. In this case very complete results were obtained by L. Lafforgue [2002]. As in the introduction, we write $\mathbb{F}_q$ for the finite field with q elements, and let X be a smooth, projective, connected curve over $\mathbb{F}_q$. The Langlands correspondence predicts a relation between representations of the absolute Galois group of K and automorphic representations of the group $\mathrm{GL}_n(\mathbb{A}_K)$. We now describe each of these in turn.

Let K^s be a fixed separable closure of K. We write $\Gamma_K = \mathrm{Gal}(K^s/K)$ for the absolute Galois group of K, relative to K^s. It is a profinite group. If $S \subset X$ is a finite set of closed points, then we write $K_S \subset K^s$ for the maximal extension of K which is unramified outside S, and $\Gamma_{K,S} = \mathrm{Gal}(K_S/K)$ for its Galois group. This group has a geometric interpretation: if we set $U = X - S$, and write $\overline{\eta}$ for the geometric generic point of U corresponding to K^s, then there is a canonical identification $\Gamma_{K,S} \cong \pi_1^{\text{ét}}(U, \overline{\eta})$ of the Galois group with the étale fundamental group of the open curve U.

Fix a prime $\ell \nmid q$ and a continuous character $\omega : \Gamma_K \to \overline{\mathbb{Q}}_\ell^\times$ of finite order. If $n \geq 1$ is an integer, then we write $\mathrm{Gal}_{n,\omega}$ for the set of conjugacy classes of continuous representations $\rho : \Gamma_K \to \mathrm{GL}_n(\overline{\mathbb{Q}}_\ell)$ with the following properties:

1. ρ factors through a quotient $\Gamma_K \to \Gamma_{K,S}$, for some finite subscheme $S \subset X$.

2. $\det \rho = \omega$.

3. ρ is irreducible.

To describe automorphic representations, we need to introduce adèles. If $v \in X$ is a closed point, then the local ring $\mathcal{O}_{X,v}$ is a discrete valuation ring, and determines a valuation $\mathrm{ord}_v : K^\times \to \mathbb{Z}$ which we call a place of K. The completion K_v of K with respect to this valuation is a local field, which can be identified with the field of Laurent series $\mathbb{F}_{q_v}((t_v))$, where $\mathbb{F}_{q_v}$ is the residue field of $\mathcal{O}_{X,v}$ and $t_v \in \mathcal{O}_{X,v}$ is a uniformizing parameter. We write $\mathcal{O}_{K_v} \subset K_v$ for the valuation ring.

The adèle ring $\mathbb{A}_K$ is the restricted direct product of the rings K_v, with respect to their open compact subrings $\mathcal{O}_{K_v}$. It is a locally compact topological ring. Taking adèle points of GL_n, we obtain the group $\mathrm{GL}_n(\mathbb{A}_K)$, which is a locally compact topological group, and which can itself be identified with the restricted direct product of the groups $\mathrm{GL}_n(K_v)$ with respect to their open compact subgroups $\mathrm{GL}_n(\mathcal{O}_{K_v})$.

If $n = 1$, then $\mathrm{GL}_1(\mathbb{A}_K) = \mathbb{A}_K^\times$ and class field theory gives a continuous map

$$\mathrm{Art}_K : K^\times \backslash \mathbb{A}_K^\times \to \Gamma_K^{\mathrm{ab}},$$

which is injective with dense image. We write $\mathcal{A}_{n,\omega}$ for the $\overline{\mathbb{Q}}_\ell$-vector space of functions $f : \mathrm{GL}_n(\mathbb{A}_K) \to \overline{\mathbb{Q}}_\ell$ satisfying the following conditions:

1. f is invariant under left translation by the discrete subgroup $\mathrm{GL}_n(K) \subset \mathrm{GL}_n(\mathbb{A}_K)$.
2. For any $z \in \mathbb{A}_K^\times$, $g \in \mathrm{GL}_n(\mathbb{A}_K)$, $f(gz) = \omega(\mathrm{Art}_K(z))f(g)$.
3. f is smooth, i.e. there exists an open compact subgroup $U \subset \mathrm{GL}_n(\mathbb{A}_K)$ such that for all $u \in U$, $g \in \mathrm{GL}_n(\mathbb{A}_K)$, $f(gu) = f(g)$.

Then the group $\mathrm{GL}_n(\mathbb{A}_K)$ acts on $\mathcal{A}_{n,\omega}$ by right translation. We write $\mathcal{A}_{n,\omega,\mathrm{cusp}} \subset \mathcal{A}_{n,\omega}$ for the subspace of cuspidal functions, i.e. those satisfying the following additional condition:

4. For each proper parabolic subgroup $P \subset \mathrm{GL}_n$, of unipotent radical N, we have

$$\int_{n \in N(K)\backslash N(\mathbb{A}_K)} f(ng)\, dn = 0$$

   for all $g \in \mathrm{GL}_n(\mathbb{A}_K)$. (Note that the quotient $N(K)\backslash N(\mathbb{A}_K)$ is compact, so the integral, taken with respect to a quotient Haar measure on $N(\mathbb{A}_K)$, is well-defined.)

With this definition, $\mathcal{A}_{n,\omega,\mathrm{cusp}} \subset \mathcal{A}_{n,\omega}$ is an $\overline{\mathbb{Q}}_\ell[\mathrm{GL}_n(\mathbb{A}_K)]$-submodule. The following theorem describes the basic structure of this representation of $\mathrm{GL}_n(\mathbb{A}_K)$.

Theorem 2.1. *1. $\mathcal{A}_{n,\omega,cusp}$ is a semisimple admissible $\overline{\mathbb{Q}}_\ell[\mathrm{GL}_n(\mathbb{A}_K)]$-module. Each irreducible constituent $\pi \subset \mathcal{A}_{n,\omega,cusp}$ appears with multiplicity 1.*

2. If $\pi \subset \mathcal{A}_{n,\omega,cusp}$ is an irreducible submodule, then there is a decomposition $\pi = \otimes'_v \pi_v$ of π as a restricted tensor product of irreducible admissible representations π_v of the groups $\mathrm{GL}_n(K_v)$ (where v runs over the set of all places of K).

If π is an irreducible constituent of $\mathcal{A}_{n,\omega,\mathrm{cusp}}$, then we call π a cuspidal automorphic representation of $\mathrm{GL}_n(\mathbb{A}_K)$. We write $\mathrm{Aut}_{n,\omega}$ for the set of isomorphism classes of cuspidal automorphic representations of $\mathrm{GL}_n(\mathbb{A}_K)$.

We can now state Langlands reciprocity for GL_n.

Theorem 2.2. *There is a bijection $\mathrm{Gal}_{n,\omega} \leftrightarrow \mathrm{Aut}_{n,\omega}$.*

In order for this theorem to have content, we need to describe how to characterize the bijection whose existence it asserts. The most basic characterization uses restriction to unramified places. Let v be a place of K. If $\rho \in \mathrm{Gal}_{n,\omega}$, then we can consider its restriction $\rho_v = \rho|_{W_{K_v}}$ to the Weil group $W_{K_v} \subset \Gamma_{K_v}$.[2] If $\pi \in \mathrm{Aut}_{n,\omega}$, then we can consider the factor π_v, which is an irreducible admissible representation of the group $\mathrm{GL}_n(K_v)$.

Definition 2.3. *1. A continuous homomorphism $\rho_v : W_{K_v} \to \mathrm{GL}_n(\overline{\mathbb{Q}}_\ell)$ is said to be unramified if it factors through the unramified quotient $W_{K_v} \to \mathbb{Z}$.*

2. An irreducible admissible representation of the group $\mathrm{GL}_n(K_v)$ is said to be unramified if the subspace $\pi_v^{\mathrm{GL}_n(\mathcal{O}_{K_v})}$ of $\mathrm{GL}_n(\mathcal{O}_{K_v})$-invariant vectors is non-zero.

These two kinds of unramified objects are related by the *unramified local Langlands correspondence*, which can be phrased as follows:

Theorem 2.4. *Let v be a place of K. There is a canonical[3] bijection $\pi_v \mapsto t(\pi_v)$ between the following two sets:*

1. The set of isomorphism classes of unramified irreducible admissible representations π_v of $\mathrm{GL}_n(K_v)$ over $\overline{\mathbb{Q}}_\ell$.

2. The set of semisimple conjugacy classes t in $\mathrm{GL}_n(\overline{\mathbb{Q}}_\ell)$.

Proof (sketch). The proof, which is valid for any reductive group G over $\mathbb{F}_q$, goes via the Satake isomorphism. If G is split then this is an isomorphism

$$\mathcal{H}(G(K_v), G(\mathcal{O}_{K_v})) \otimes_{\mathbb{Z}} \mathbb{Z}[q_v^{\pm\frac{1}{2}}] \to \mathbb{Z}[\widehat{G}]^{\widehat{G}} \otimes \mathbb{Z}[q_v^{\pm\frac{1}{2}}],$$

$$T_{v,f} \mapsto f$$

where $\mathcal{H}$ is the Hecke algebra of $G(\mathcal{O}_{K_v})$-biinvariant functions $f : G(K_v) \to \mathbb{Z}$ of compact support, and $\mathbb{Z}[\widehat{G}]^{\widehat{G}}$ is the algebra of conjugation-invariant functions on the dual group $\widehat{G}$ (which is GL_n if $G = \mathrm{GL}_n$). If π_v is an irreducible admissible representation of $G(K_v)$ over $\overline{\mathbb{Q}}_l$ and $\pi_v^{G(\mathcal{O}_{K_v})} \neq 0$, then $\pi_v^{G(\mathcal{O}_{K_v})}$ is a simple $\mathcal{H} \otimes_{\mathbb{Z}} \overline{\mathbb{Q}}_l$-module, which therefore determines a homomorphism $\mathbb{Z}[\widehat{G}]^{\widehat{G}} \to \overline{\mathbb{Q}}_\ell$. The geometric invariant theory of the adjoint quotient of the reductive group $\widehat{G}$ implies that giving such a homomorphism is equivalent to giving a conjugacy class of semisimple elements in $\widehat{G}(\overline{\mathbb{Q}}_\ell)$. □

[2]Here $\Gamma_{K_v} = \mathrm{Gal}(K_v^s/K_v)$ is the absolute Galois group of K_v, with respect to a fixed choice of separable closure. An embedding $K^s \to K_v^s$ extending the map $K \to K_v$ determines an embedding $\Gamma_{K_v} \to \Gamma_K$. The Weil group $W_{K_v} \subset \Gamma_{K_v}$ is the subgroup of elements which act on the residue field by an integral power of the (geometric) Frobenius element Frob_v; see for example Tate [1979] for a detailed discussion.

[3]As the proof shows, we need to fix as well a choice of a square root of q in $\overline{\mathbb{Q}}_\ell$.

Let S be a finite set of places of K. We write $\mathrm{Gal}_{n,\omega,S} \subset \mathrm{Gal}_{n,\omega}$ for the set of ρ such that for each place $v \notin S$ of K, $\rho|_{W_{K_v}}$ is unramified (we say that 'ρ is unramified outside S'). We write $\mathrm{Aut}_{n,\omega,S} \subset \mathrm{Aut}_{n,\omega}$ for the set of $\pi = \otimes'_v \pi_v$ such that for each place $v \notin S$ of K, π_v is unramified (we say that 'π is unramified outside S'). We can now state a more precise version of Theorem 2.2:

Theorem 2.5. *Let S be a finite set of places of K. Then there is a bijection $\pi \mapsto \rho(\pi) : \mathrm{Aut}_{n,\omega,S} \to \mathrm{Gal}_{n,\omega,S}$ with the following property: for each place $v \notin S$, $\rho(\pi)(\mathrm{Frob}_v)^{ss} \in t(\pi_v)$*[4].

This defining property uniquely characterizes the bijection, if it exists. Indeed, the isomorphism class of any representation $\pi \in \mathrm{Aut}_{n,\omega,S}$ is uniquely determined by the representations π_v $(v \notin S)$: this is the strong multiplicity one theorem. Similarly, any representation $\rho \in \mathrm{Gal}_{n,\omega,S}$ is uniquely determined by the conjugacy classes of the elements $\rho(\mathrm{Frob}_v)^{\mathrm{ss}}$ $(v \notin S)$: the irreducible representation ρ is uniquely determined up to isomorphism by its character $\mathrm{tr}\,\rho$. This continuous function $\mathrm{tr}\,\rho : \Gamma_{K,S} \to \overline{\mathbb{Q}}_\ell$ is determined by its values at a dense set of elements, and the Chebotarev density theorem implies that the Frobenius elements Frob_v $(v \notin S)$ form such a set.

L. Lafforgue proved Theorem 2.5 using an induction on n. If the theorem is known for $n' < n$, then the 'principe de récurrence de Deligne' (see L. Lafforgue [2002, Appendice B]) reduces the problem to constructing, for any $\pi \in \mathrm{Aut}_{n,\omega,S}$, the corresponding Galois representation $\rho(\pi) \in \mathrm{Gal}_{n,\omega,S}$, as well as proving that certain L– and ϵ–factors are matched up under the correspondence. The three main ingredients that make this possible are Grothendieck's theory of L-functions of Galois representations, Laumon's product formula for the ϵ–factors of Galois representations, and Piatetski-Shapiro's converse theorem, which can be used to show that an irreducible admissible representation of $\mathrm{GL}_n(\mathbb{A}_K)$ with sufficiently well-behaved associated L-functions is in fact cuspidal automorphic. We note that in carrying this out Lafforgue actually obtains a much more precise result than Theorem 2.5, in particular re-proving the local Langlands correspondence for GL_n and showing that the global correspondence is compatible with the local one.

One would like to generalise Theorem 2.5 to an arbitrary reductive group G over $\mathbb{F}_q$. However, there are a number (!) of difficulties. To begin with, it is not even clear what the correct statement should be: it is easy to write down the naive analogues of the sets $\mathrm{Aut}_{n,\omega}$ and $\mathrm{Gal}_{n,\omega}$, but we will see some reasons why they cannot be related by a simple bijection. Moreover, no converse theorem is known for a general group G, which means there is no apparent way of proving that a given admissible representation of $G(\mathbb{A}_K)$ is in fact cuspidal automorphic. This is the motivation behind proving a result like our main theorem.

[4]Here and elsewhere, we write x^{ss} for the semisimple part in the Jordan decomposition $x = x^{\mathrm{ss}}x^{\mathrm{u}}$ of an element x of a linear algebraic group.

3 Pseudocharacters

Let us now pass to the case of a general reductive group G over $\mathbb{F}_q$. In order to simplify the discussion here, we will assume that G is split. In this case one can associate to G its dual group $\widehat{G}$, a split reductive group over $\mathbb{Z}$, which is characterized by the property that its root datum is dual to that of G (see e.g. Borel [1979]). If $G = \mathrm{GL}_n$, then $\widehat{G} = \mathrm{GL}_n$, so our discussion will include n-dimensional linear representations as a special case.

We will describe the results of Vincent Lafforgue's construction in the next section. First, we make a detour to describe the notion of $\widehat{G}$-pseudocharacter, which was introduced for the first time in V. Lafforgue [n.d.]. This is a generalization of the notion of the pseudocharacter of an n-dimensional representation (to which it reduces in the case $G = \mathrm{GL}_n$).

Let Γ be a group, and let Ω be an algebraically closed field of characteristic 0. We recall that to any representation $\rho : \Gamma \to \mathrm{GL}_n(\Omega)$, we can associate the character $\operatorname{tr} \rho : \Gamma \to \Omega$; it clearly depends only on ρ up to conjugacy and up to semisimplification. We have the following theorem, the second part of which was proved by Taylor using results of Taylor [1991] and Procesi [1976].

Theorem 3.1. *1. Let $\rho, \rho' : \Gamma \to \mathrm{GL}_n(\Omega)$ be semisimple representations. Then they are isomorphic if and only if* $\operatorname{tr} \rho = \operatorname{tr} \rho'$.

2. Let $t : \Gamma \to \Omega$ be a function satisfying the following conditions:

(a) $t(1) = n$.

(b) For all $\gamma_1, \gamma_2 \in \Gamma$, $t(\gamma_1\gamma_2) = t(\gamma_2\gamma_1)$.

(c) For all $\gamma_1, \dots, \gamma_{n+1} \in \Gamma$, $\sum_{\sigma \in S_{n+1}} t_\sigma(\gamma_1, \dots, \gamma_{n+1}) = 0$, where if σ has cycle decomposition

$$\sigma = (a_1 \dots a_{k_1})(b_1 \dots b_{k_2}) \dots$$

then we set

$$t_\sigma(\gamma_1, \dots, \gamma_{n+1}) = t(\gamma_{a_1} \dots \gamma_{a_{k_1}}) t(\gamma_{b_1} \dots \gamma_{b_{k_2}}) \dots .$$

Then there exists a representation $\rho : \Gamma \to \mathrm{GL}_n(\Omega)$ such that $\operatorname{tr} \rho = t$.

We can call a function $t : \Gamma \to \Omega$ satisfying the condition of Theorem 3.1 a pseudocharacter of dimension n. Then the theorem says that sets of conjugacy classes of semisimple representations $\rho : \Gamma \to \mathrm{GL}_n(\Omega)$ and of pseudocharacters of dimension n are in canonical bijection.

Here is Lafforgue's definition of a $\widehat{G}$-pseudocharacter. Let A be a ring.

Definition 3.2. *Let* $\mathbf{t} = (t_n)_{n \geq 1}$ *be a collection of algebra maps* $t_n : \mathbb{Z}[\widehat{G}^n]^{\widehat{G}} \to \mathrm{Fun}(\Gamma^n, A)$ *satisfying the following conditions:*

1. *For each* $n, m \geq 1$ *and for each* $\zeta : \{1, \dots, m\} \to \{1, \dots, n\}$, $f \in \mathbb{Z}[\widehat{G}^m]^{\widehat{G}}$, *and* $\gamma = (\gamma_1, \dots, \gamma_n) \in \Gamma^n$, *we have*
$$t_n(f^\zeta)(\gamma_1, \dots, \gamma_n) = t_m(f)(\gamma_{\zeta(1)}, \dots, \gamma_{\zeta(m)}),$$
where $f^\zeta(g_1, \dots, g_n) = f(g_{\zeta(1)}, \dots, g_{\zeta(m)})$.

2. *For each* $n \geq 1$, $\gamma = (\gamma_1, \dots, \gamma_{n+1}) \in \Gamma^{n+1}$, *and* $f \in \mathbb{Z}[\widehat{G}^n]^{\widehat{G}}$, *we have*
$$t_{n+1}(\hat{f})(\gamma_1, \dots, \gamma_{n+1}) = t_n(f)(\gamma_1, \dots, \gamma_{n-1}, \gamma_n\gamma_{n+1}),$$
where $\hat{f}(g_1, \dots, g_{n+1}) = f(g_1, \dots, g_{n-1}, g_n g_{n+1})$.

Then $\mathbf{t}$ *is called a* $\widehat{G}$*-pseudocharacter of* Γ *over* A.

Note that $\widehat{G}$ acts on $\widehat{G}^n$ by diagonal conjugation. The subring $\mathbb{Z}[\widehat{G}^n]^{\widehat{G}} \subset \mathbb{Z}[\widehat{G}^n]$ is the ring of functions invariant under this action. We observe that if $\rho : \Gamma \to \widehat{G}(A)$ is a homomorphism, then we can define a $\widehat{G}$-pseudocharacter $\operatorname{tr} \rho = (t_n)_{n \geq 1}$ of Γ over A by the formula
$$t_n(f)(\gamma_1, \dots, \gamma_n) = f(\rho(\gamma_1), \dots, \rho(\gamma_n)).$$
It is clear that this depends only on the $\widehat{G}(A)$-conjugacy class of ρ.

Theorem 3.3. *Let* Γ *be a group, and let* Ω *be an algebraically closed field.*

1. *Let* $\rho, \rho' : \Gamma \to \widehat{G}(\Omega)$ *be* $\widehat{G}$*-completely reducible representations.*[5] *Then* ρ, ρ' *are* $\widehat{G}(\Omega)$*-conjugate if and only if* $\operatorname{tr} \rho = \operatorname{tr} \rho'$.

2. *Let* $\mathbf{t}$ *be a* $\widehat{G}$*-pseudocharacter. Then there exists a representation* $\rho : \Gamma \to \widehat{G}(\Omega)$ *such that* $\mathbf{t} = \operatorname{tr} \rho$.

The proof of Theorem 3.3 is based on Richardson's results about the geometric invariant theory of the action of $\widehat{G}$ on $\widehat{G}^n$ by diagonal conjugation Richardson [1988].

In the case where Γ is profinite, we want to impose continuity conditions on its $\widehat{G}$-pseudocharacters. Fortunately, $\widehat{G}$-pseudocharacters are well-behaved from this point of view.

[5] A representation ρ is said to be $\widehat{G}$-irreducible if its image is contained in no proper parabolic subgroup of $\widehat{G}_\Omega$, and $\widehat{G}$-completely reducible if for any parabolic subgroup $P \subset \widehat{G}_\Omega$ containing the image, there exists a Levi subgroup $L \subset P$ such that $\rho(\Gamma) \subset L(\Omega)$. See e.g. Serre [2005].

Definition 3.4. *Let A be a topological ring, and let Γ be a profinite group. We say that a $\widehat{G}$-pseudocharacter $\mathbf{t}$ of Γ over A is continuous if each map $t_n : \mathbb{Z}[\widehat{G}^n]^{\widehat{G}} \to \mathrm{Fun}(\Gamma^n, A)$ takes values in the subset of continuous functions $\mathrm{Fun}_{\mathrm{cts}}(\Gamma^n, A)$.*

Proposition 3.5. *Let ℓ be a prime, and let Γ be a profinite group. Let $\Omega = \overline{\mathbb{Q}}_\ell$ (with its ℓ-adic topology) or $\overline{\mathbb{F}}_\ell$ (with the discrete topology). Let $\rho : \Gamma \to \widehat{G}(\Omega)$ be a $\widehat{G}$-completely reducible representation. Then ρ is continuous if and only if $\operatorname{tr} \rho$ is continuous.*

Finally, we note that $\widehat{G}$-pseudocharacters are well-behaved from the point of view of reduction modulo ℓ. We will need this in our discussion of the deformation theory of pseudocharacters later on.

Proposition 3.6. *Let ℓ be a prime, and let Γ be a profinite group. Then:*

1. *Let $\mathbf{t}$ be a continuous $\widehat{G}$-pseudocharacter of Γ over $\overline{\mathbb{Q}}_\ell$. Then $\mathbf{t}$ takes values in $\overline{\mathbb{Z}}_\ell$ and $\bar{\mathbf{t}}$, its reduction modulo ℓ, is a continuous $\widehat{G}$-pseudocharacter over $\overline{\mathbb{F}}_\ell$.*

2. *Let $\rho : \Gamma \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ be a continuous representation. After replacing ρ by a $\widehat{G}(\overline{\mathbb{Q}}_\ell)$-conjugate, we can assume that ρ takes values in $\widehat{G}(\overline{\mathbb{Z}}_\ell)$. Let $\overline{\rho} : \Gamma \to \widehat{G}(\overline{\mathbb{F}}_\ell)$ denote the semisimplification of the reduction of ρ modulo ℓ. Then $\overline{\rho}$ depends only on ρ up to $\widehat{G}(\overline{\mathbb{Q}}_\ell)$-conjugacy, and $\operatorname{tr} \overline{\rho} = \overline{\operatorname{tr} \rho}$.*

We now come back to our original case of interest, namely pseudocharacters of the group $\Gamma = \Gamma_{K,S}$. We can define a compatible family of pseudocharacters of $\Gamma_{K,S}$ of dimension n to consist of the data of a number field E and, for each prime-to-q place λ of E, a pseudocharacter $t_\lambda : \Gamma_{K,S} \to E_\lambda$ of dimension n. These should satisfy the following property:

- For each place $v \notin S$ of K, the number $t_\lambda(\mathrm{Frob}_v)$ lies in $E \subset E_\lambda$ and is independent of the choice of λ.

Thus, for example, Deligne [1980, Conjecture I.2.10] asks that every pseudocharacter $t_\ell : \Gamma_{K,S} \to \overline{\mathbb{Q}}_\ell$ satisfying certain conditions should be a member of a compatible family. This leads us to our first question:

Question 3.7. *Is it possible to define a notion of 'compatible family of $\widehat{G}$-pseudocharacters', generalizing the above notion for GL_n?*

If we are willing to consider instead compatible families of representations, then Drinfeld [n.d.] gives a satisfying (positive) answer to Question 3.7 using the results of L. Lafforgue [2002]. The question remains, however, of whether we can phrase this for pseudocharacters in elementary terms and, in particular, whether it is possible to make sense of compatible families when K is instead a global field of characteristic 0 (i.e. a number field).

Here is one case it is easy to make sense of the notion of compatible family:

Proposition 3.8. *Let $\ell \nmid q$ be a prime, and let $\rho : \Gamma_{K,S} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ be a continuous representation of Zariski dense image. Assume that $\widehat{G}$ is semisimple. Then we can find a number field E and an embedding $E \hookrightarrow \overline{\mathbb{Q}}_\ell$, inducing the place λ_0 of E, with the following properties:*

- *For each place $v \notin S$ of K and for each $f \in \mathbb{Z}[\widehat{G}]^{\widehat{G}}$, $f(\rho(\mathrm{Frob}_v)) \in E$. In other words, the conjugacy class of $\rho(\mathrm{Frob}_v)^{ss}$ is defined over E.*
- *For each prime-to-q place λ of E, there exists a continuous homomorphism $\rho_\lambda : \Gamma_{K,S} \to \widehat{G}(E_\lambda)$ of Zariski dense image such that for each place $v \notin S$ of K and for each $f \in \mathbb{Z}[\widehat{G}]^{\widehat{G}}$, $f(\rho_\lambda(\mathrm{Frob}_v))$ lies in E and equals $f(\rho(\mathrm{Frob}_v))$. In other words, $\rho_\lambda(\mathrm{Frob}_v)^{ss}$ lies in the same geometric conjugacy class as $\rho(\mathrm{Frob}_v)^{ss}$.*

Furthermore, for any prime-to-q place λ of E and for any continuous homomorphism $\rho'_\lambda : \Gamma_{K,S} \to \widehat{G}(\overline{E}_\lambda)$ such that for each place $v \notin S$ of K and for each $f \in \mathbb{Z}[\widehat{G}]^{\widehat{G}}$, $f(\rho'_\lambda(\mathrm{Frob}_v))$ lies in E and equals $f(\rho(\mathrm{Frob}_v))$, ρ'_λ is $\widehat{G}(\overline{E}_\lambda)$-conjugate to ρ_λ. In particular, ρ and ρ_{λ_0} are $\widehat{G}(\overline{\mathbb{Q}}_\ell)$-conjugate.

The proof makes use of the proof of the global Langlands correspondence for GL_n by L. Lafforgue [ibid.], together with Chin's application of this work to the analysis of compatible families Chin [2004]; see Böckle, Harris, Khare, and J. A. Thorne [n.d., §6].

4 The work of V. Lafforgue

Having introduced the notion of $\widehat{G}$-pseudocharacter, we can now describe the basic shape of Vincent Lafforgue's results in V. Lafforgue [n.d.]. We recall that G is a split reductive group over $\mathbb{F}_q$. In order to simplify statements, we are now going to impose the further assumption that G has finite centre (i.e. is semisimple).[6] We write $\mathfrak{A}_G$ for the $\overline{\mathbb{Q}}_\ell$-vector space of functions $f : G(\mathbb{A}_K) \to \overline{\mathbb{Q}}_\ell$ satisfying the following conditions:

1. f is invariant under left translation by the discrete subgroup $G(K) \subset G(\mathbb{A}_K)$.
2. f is smooth.

[6] By contrast, the paper V. Lafforgue [n.d.] does not impose any restriction on G; see in particular §12 of *op. cit.*

Then the group $G(\mathbb{A}_K)$ acts on $\mathcal{A}_G$ by right translation. We write $\mathcal{A}_{G,\text{cusp}} \subset \mathcal{A}_G$ for the subspace of cuspidal functions, i.e. those satisfying the following condition:

3. For any proper parabolic subgroup $P \subset G$ of unipotent radical N, we have
$$\int_{n \in N(K)\backslash N(\mathbb{A}_K)} f(ng)\, dn = 0$$
for all $g \in G(\mathbb{A}_K)$.

With this definition, $\mathcal{A}_{G,\text{cusp}}$ is a semisimple admissible $\overline{\mathbb{Q}}_\ell[G(\mathbb{A}_K)]$-module. In general, understanding the constituents of this space is much more complicated than for the group GL_n. For example:

- Multiplicity one does not hold: there can exist representations π of $G(\mathbb{A}_K)$ which appear in $\mathcal{A}_{G,\text{cusp}}$ with multiplicity greater than 1.
- Strong multiplicity one does not hold: there can exist representation π, π' of $G(\mathbb{A}_K)$ which have positive multiplicity in $\mathcal{A}_{G,\text{cusp}}$, such that $\pi_v \cong \pi'_v$ for all but finitely many places v of K, but such that $\pi \not\cong \pi'$.

These phenomena are reflected in what happens on the Galois side. For example:

- There can exist everywhere unramified homomorphisms $\rho, \rho' : \Gamma_K \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ such that $\rho(\mathrm{Frob}_v)$ and $\rho'(\mathrm{Frob}_v)$ are conjugate for every v, but such that ρ, ρ' are not conjugate.
- There can exist homomorphisms $\rho, \rho' : \Gamma_K \to \widehat{G}$ and a place v_0 of K such that for all $v \neq v_0$, ρ and ρ' are unramified at v and $\rho(\mathrm{Frob}_v)$, $\rho'(\mathrm{Frob}_v)$ are $\widehat{G}(\overline{\mathbb{Q}}_\ell)$-conjugate; but $\rho|_{\Gamma_{K_{v_0}}} \not\cong \rho'|_{\Gamma_{K_{v_0}}}$. (Another reason for the failure of strong multiplicity one, not related to this Galois–theoretic phenomenon, is the existence of non-trivial L-packets.)

We refer the reader to Wang [2012] for a survey of how the relation between these phenomena can be understood in terms of Arthur's conjectural decomposition of the space of automorphic forms in terms of A-parameters Arthur [1989].

Lafforgue's construction, quite remarkably, gives a decomposition of the space $\mathcal{A}_{G,\text{cusp}}$ of cusp forms on G which is quite close in appearance to that predicted by Arthur. He defines for each $n \geq 1$, function $f \in \mathbb{Z}[\widehat{G}^n]^{\widehat{G}}$, and tuple of elements $\gamma = (\gamma_1, \dots, \gamma_n) \in \Gamma_K^n$, an operator $S_{n,f,\gamma} \in \mathrm{End}_{\overline{\mathbb{Q}}_\ell}(\mathcal{A}_{G,\text{cusp}})$. He calls these 'excursion operators', and proves the following two theorems:

Theorem 4.1. *1. The operators $S_{n,f,\gamma}$ commute with each other and with the action of $G(\mathbb{A}_K)$.*

2. *Let* $\mathcal{B} \subset \mathrm{End}_{\overline{\mathbb{Q}}_\ell}(\mathcal{A}_{G,cusp})$ *denote the* $\overline{\mathbb{Q}}_\ell$*-subalgebra generated by the operators* $S_{n,f,\gamma}$ *for all possible choices of* n, f, *and* γ. *Then the system of maps* $\mathbf{t} = (t_n)_{n \geq 1}$ *given by*

$$t_n : \mathbb{Z}[\widehat{G}^n]^{\widehat{G}} \to \mathrm{Fun}(\Gamma_K^n, \mathcal{B}),$$
$$f \mapsto (\gamma \mapsto S_{n,f,\gamma})$$

is a $\widehat{G}$*-pseudocharacter of* Γ_K *valued in* $\mathcal{B}$.

Theorem 4.2. *Let* S *be a finite set of places of* K, *and let* $U \subset G(\mathbb{A}_K)$ *be an open compact subgroup such that for each place* $v \notin S$ *of* K, $U_v = G(\mathcal{O}_{K_v})$. *Let* $\mathcal{B}_U$ *denote the quotient of* $\mathcal{B}$ *which acts faithfully on* $\mathcal{A}_{G,cusp,U}$. *Then:*

1. *The pushforward of* $\mathbf{t}$ *along* $\mathcal{B} \to \mathcal{B}_U$ *is pulled back from a* $\widehat{G}$*-pseudocharacter* $\mathbf{t}_U$ *of* $\Gamma_{K,S}$ *valued in* $\mathcal{B}_U$.

2. *If* $v \notin S$, *then the image of* S_{1,f,Frob_v} *in* $\mathcal{B}_U$ *equals the unramified Hecke operator* $T_{v,f}$ *(defined as in the proof of Theorem 2.4, via the Satake isomorphism).*

Since the algebra $\mathcal{B}_U$ contains the unramified Hecke operators, it can be viewed as an enlargement of the usual Hecke algebra.

Corollary 4.3. *Let* π *be a cuspidal automorphic representation of* $G(\mathbb{A}_K)$, *and let* $V_\pi \subset \mathcal{A}_{G,cusp}$ *be the* π*-isotypic component. Let* $\mathcal{B}_\pi$ *denote the quotient of* $\mathcal{B}$ *which acts faithfully on* V_π. *Then* $\mathcal{B}_\pi$ *is a finite-dimensional* $\overline{\mathbb{Q}}_\ell$*-algebra and for each maximal ideal* $\mathfrak{p}$, *one can associate a continuous representation* $\sigma_{\pi,\mathfrak{p}} : \Gamma_K \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ *with the following properties:*

1. $\mathrm{tr}\,\sigma_{\pi,\mathfrak{p}} = \mathbf{t}_\pi$ *mod* $\mathfrak{p}$.

2. *Let* S *be a finite set of places of* K *such that* $\pi_v^{G(\mathcal{O}_{K_v})} \neq 0$ *if* $v \notin S$. *Then* $\sigma_{\pi,\mathfrak{p}}$ *is unramified outside* S *and if* $v \notin S$, *then* $\sigma_{\pi,\mathfrak{p}}(\mathrm{Frob}_v)^{ss} \in t(\pi_v)$.

3. *If* $\mathfrak{p} \neq \mathfrak{p}'$, *then* $\sigma_{\pi,\mathfrak{p}} \not\cong \sigma_{\pi,\mathfrak{p}'}$.

Proof. Since V_π has finite length as a $\overline{\mathbb{Q}}_\ell[G(\mathbb{A}_K)]$-module and $\mathcal{B}_\pi$ is contained inside $\mathrm{End}_{\overline{\mathbb{Q}}_\ell[G(\mathbb{A}_K)]}(V_\pi)$, $\mathcal{B}_\pi$ is a finite-dimensional $\overline{\mathbb{Q}}_\ell$-algebra. Since $\mathcal{B}_\pi$ is a quotient of $\mathcal{B}$, it carries a $\widehat{G}$-pseudocharacter $\mathbf{t}_\pi$. Each maximal ideal $\mathfrak{p} \subset \mathcal{B}_\pi$ has residue field $\overline{\mathbb{Q}}_\ell$, and the pushforward of $\mathbf{t}_\pi$ along the map $\mathcal{B}_\pi \to \mathcal{B}_\pi/\mathfrak{p} \cong \overline{\mathbb{Q}}_\ell$ therefore corresponds, by Theorem 3.3, to a continuous $\widehat{G}$-completely reducible representation $\sigma_{\pi,\mathfrak{p}} : \Gamma_{K,S} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ satisfying the following property: for all $n \geq 1$, $f \in \mathbb{Z}[\widehat{G}^n]^{\widehat{G}}$, $\gamma = (\gamma_1, \ldots, \gamma_n) \in \Gamma_{K,S}^n$, we have

$$f(\sigma_{\pi,\mathfrak{p}}(\gamma_1), \ldots, \sigma_{\pi,\mathfrak{p}}(\gamma_n)) = S_{n,f,\gamma} \bmod \mathfrak{p}.$$

From this identity it is apparent that $\sigma_{\pi,\mathfrak{p}}$ determines $\mathfrak{p}$. Specializing to $n = 1$ and $\gamma = \mathrm{Frob}_v$ for some $v \notin S$, this identity reduces to the formula

$$f(\sigma_{\pi,\mathfrak{p}}(\mathrm{Frob}_v)) = T_{v,f} \bmod \mathfrak{p},$$

or equivalently that $\sigma_{\pi,\mathfrak{p}}(\mathrm{Frob}_v)^{\mathrm{ss}}$ is in the conjugacy class $t(\pi_v)$. □

Question 4.4. *The space V_π can be defined over $\overline{\mathbb{Q}}$. Is there a sense in which its decomposition $V_\pi = \oplus V_{\pi,\mathfrak{p}}$ is independent of ℓ?*

Presumably a positive answer to this question must be tied up with a positive answer to Question 3.7.

We can now define what it means for a Galois representation to be cuspidal automorphic, in the sense of the algebra $\mathfrak{B}$.

Definition 4.5. *We say that a representation $\rho : \Gamma_K \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ is cuspidal automorphic if there exists a cuspidal automorphic representation π of $G(\mathbb{A}_K)$ and a maximal ideal $\mathfrak{p} \subset \mathfrak{B}_\pi$ such that $\rho \cong \sigma_{\pi,\mathfrak{p}}$.*

Note that this definition depends in an essential way on Lafforgue's excursion operators!

We are now in a position to state the main theorem of Böckle, Harris, Khare, and J. A. Thorne [n.d.]:

Theorem 4.6. *Let $\rho : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ be a continuous representation of Zariski dense image. Then ρ is* potentially cuspidal automorphic*: there exists a finite Galois extension L/K such that $\rho|_{\Gamma_{L,\varnothing}}$ is cuspidal automorphic in the sense of Definition 4.5.*

Corollary 4.7. *Let $\rho : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ be a continuous representation of Zariski dense image. Then there exists a finite Galois extension L/K and an everywhere unramified cuspidal automorphic representation π of $G(\mathbb{A}_L)$ such that for each place w of L, $\rho|_{W_{L_w}}$ and π_w are related under the unramified local Langlands correspondence for $G(L_w)$.*

(In fact, Proposition 3.8 implies that the theorem and its corollary are equivalent.) In the remainder of this article we will sketch the proof of Theorem 4.6.

5 An automorphy lifting theorem for G

How can one show that a Galois representation $\rho : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ is automorphic, in the sense of Definition 4.5? For a general group G, we no longer know how to construct automorphic forms using converse theorems.

We pursue a different path which is inspired by the proofs of existing potential automorphy results for Galois representations $\Gamma_E \to \mathrm{GL}_n$, where E is a number field. These are in turn based on automorphy lifting theorems, which are provable instances of the following general principle:

Principle 5.1. *Let $\rho, \rho' : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ be continuous representations and let $\overline{\rho}$, $\overline{\rho}' : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{F}}_\ell)$ denote their reductions modulo ℓ. Suppose that $\overline{\rho}$, $\overline{\rho}'$ are $\widehat{G}(\overline{\mathbb{F}}_\ell)$-conjugate and $\widehat{G}$-irreducible. Suppose that ρ is cuspidal automorphic. Then ρ' is also cuspidal automorphic.*

The first theorem of this type was stated by Wiles on his way to proving Fermat's Last Theorem Wiles [1995]. Our proof of an analogous result is inspired by Diamond's elaboration of the Taylor–Wiles method Diamond [1997], which gives a way to construct an isomorphism $R \cong \mathbb{T}$, where R is a Galois deformation ring and $\mathbb{T}$ is a Hecke algebra acting on cuspidal automorphic forms. By contrast, we prove an '$R = \mathfrak{B}$' theorem, where $\mathfrak{B}$ is a suitable ring of Lafforgue's excursion operators.

We describe these objects in order to be able to state a precise result. We will stick to the everywhere unramified case. We first consider the Galois side. Let $k \subset \overline{\mathbb{F}}_l$ be a finite subfield, and let $\overline{\rho} : \Gamma_{K,\varnothing} \to \widehat{G}(k)$ be a continuous homomorphism. Let Art_k denote the category of Artinian local $W(k)$-algebras A, equipped with an isomorphism $A/\mathfrak{m}_A \cong k$. We define $\mathrm{Lift}_{\overline{\rho}} : \mathrm{Art}_k \to \mathrm{Sets}$ to be the functor of liftings of $\overline{\rho}$, i.e. of homomorphisms $\rho_A : \Gamma_{K,\varnothing} \to \widehat{G}(A)$ such that $\rho_A \bmod \mathfrak{m}_A = \overline{\rho}$.

For any $A \in \mathrm{Art}_k$, the group $\ker(\widehat{G}(A) \to \widehat{G}(k))$ acts on $\mathrm{Lift}_{\overline{\rho}}(A)$ by conjugation, and we write $\mathrm{Def}_{\overline{\rho}} : \mathrm{Art}_k \to \mathrm{Sets}$ for the quotient functor (given by the formula $\mathrm{Def}_{\overline{\rho}}(A) = \mathrm{Lift}_{\overline{\rho}}(A)/\ker(\widehat{G}(A) \to \widehat{G}(k))$). The following lemma is basic.

Lemma 5.2. *Suppose that $\overline{\rho}$ is absolutely $\widehat{G}$-irreducible, and that ℓ does not divide the order of the Weyl group of $\widehat{G}$. Then the functor $\mathrm{Def}_{\overline{\rho}}$ is pro-represented by a complete Noetherian local $W(k)$-algebra $R_{\overline{\rho}}$ with residue field k.*

In order to be able to relate the deformation ring $R_{\overline{\rho}}$ to automorphic forms, we need to introduce integral structures. We therefore write $\mathcal{C}_{G,k}$ for the set of functions $f : G(\mathbb{A}_K) \to W(k)$ satisfying the following conditions:

1. f is invariant under left translation by $G(K)$.

2. f is smooth.

We write $\mathcal{C}_{G,k,\mathrm{cusp}}$ for the intersection $\mathcal{C}_{G,k} \cap \mathcal{A}_{G,\mathrm{cusp}}$ (taken inside $\mathcal{A}_G$). Let $U = \prod_v G(\mathcal{O}_{K_v})$.

Proposition 5.3. *Suppose that $f \in \mathbb{Z}[\widehat{G}^n]^{\widehat{G}}$. Then each operator $S_{n,f,\gamma} \in \mathfrak{B}_U \subset \mathrm{End}_{\overline{\mathbb{Q}}_\ell}(\mathcal{A}^U_{G,cusp})$ leaves invariant the submodule $\mathcal{C}^U_{G,k,cusp}$.*

We write $\mathbb{B}(U, W(k))$ for the $W(k)$-subalgebra of $\mathrm{End}_{W(k)}(\mathcal{C}^U_{G,k,\mathrm{cusp}})$ generated by the operators $S_{n,f,\gamma}$ for $f \in \mathbb{Z}[\widehat{G}^n]^{\widehat{G}}$. Then $\mathbb{B}(U, W(k))$ is a finite flat $W(k)$-algebra and there is a $\widehat{G}$-pseudocharacter $\mathbf{t}_{U,W(k)}$ of $\Gamma_{K,\varnothing}$ valued in $\mathbb{B}(U, W(k))$.

Let $\mathfrak{m}$ be a maximal ideal of $\mathbb{B}(U, W(k))$. Its residue field is a finite extension of the finite field k. After possibly enlarging k, we can assume that the following conditions hold:

- The residue field of $\mathfrak{m}$ equals k.
- There exists a continuous representation $\overline{\rho}_{\mathfrak{m}} : \Gamma_{K,\varnothing} \to \widehat{G}(k)$ such that $\mathrm{tr}\, \overline{\rho}_{\mathfrak{m}} = \mathbf{t}_{U,W(k)} \bmod \mathfrak{m}$.

Then the ring $\mathbb{B}(U, W(k))_{\mathfrak{m}}$ (localization at the maximal ideal $\mathfrak{m}$) is a finite flat local $W(k)$-algebra of residue field k, and it comes equipped with a pseudocharacter $\mathbf{t}_{U,W(k),\mathfrak{m}}$. A natural question to ask is: under what conditions does this pseudocharacter arise from a representation $\rho_{\mathfrak{m}} : \Gamma_{K,\varnothing} \to \widehat{G}(\mathbb{B}(U, W(k))_{\mathfrak{m}})$ lifting $\overline{\rho}_{\mathfrak{m}}$? In other words, under what conditions does the analogue of Theorem 3.3 hold when we no longer restrict to field-valued $\widehat{G}$-pseudocharacters?

Proposition 5.4. *Suppose that $\overline{\rho}_{\mathfrak{m}}$ is absolutely $\widehat{G}$-irreducible, and that its centralizer $\mathrm{Cent}(\widehat{G}^{ad}_k, \overline{\rho}_{\mathfrak{m}})$ is scheme-theoretically trivial.*[7] *Suppose that ℓ does not divide the order of the Weyl group of $\widehat{G}$. Then there is a unique conjugacy class of liftings $[\rho_{\mathfrak{m}}] \in \mathrm{Def}_{\overline{\rho}_{\mathfrak{m}}}(\mathbb{B}(U, W(k))_{\mathfrak{m}})$ such that $\mathrm{tr}\, \rho_{\mathfrak{m}} = \mathbf{t}_{U,W(k),\mathfrak{m}}$.*

Under the assumptions of Proposition 5.4, we see the ring $R_{\overline{\rho}_{\mathfrak{m}}}$ is defined, and that its universal property determines a canonical map $R_{\overline{\rho}_{\mathfrak{m}}} \to \mathbb{B}(U, W(k))_{\mathfrak{m}}$. The localized space $(\mathcal{C}^U_{G,k,\mathrm{cusp}})_{\mathfrak{m}}$ of automorphic forms then becomes a module for the deformation ring $R_{\overline{\rho}_{\mathfrak{m}}}$.

We are now in a position to state a provable instance of Principle 5.1.

Theorem 5.5. *Let $\mathfrak{m} \subset \mathbb{B}(U, W(k))$ be a maximal ideal of residue field k, and suppose that there exists a continuous, absolutely $\widehat{G}$-irreducible representation $\overline{\rho}_{\mathfrak{m}} : \Gamma_{K,\varnothing} \to \widehat{G}(k)$ such that $\mathrm{tr}\, \overline{\rho}_{\mathfrak{m}} = \mathbf{t}_{U,W(k)} \bmod \mathfrak{m}$. Suppose further that the following conditions are satisfied:*

1. *$\ell > \#W$, where W is the Weyl group of the split reductive group $\widehat{G}$.*
2. *The centralizer $\mathrm{Cent}(\widehat{G}^{ad}_k, \overline{\rho}_{\mathfrak{m}})$ is scheme-theoretically trivial.*
3. *The representation $\overline{\rho}_{\mathfrak{m}}$ is absolutely strongly $\widehat{G}$-irreducible.*

[7] Here and elsewhere, $\widehat{G}^{\mathrm{ad}}_k$ denotes the adjoint group of $\widehat{G}_k$, i.e. the quotient of $\widehat{G}_k$ by its centre.

4. *The subgroup $\overline{\rho}_{\mathfrak{m}}(\Gamma_{K(\zeta_\ell)}) \subset \widehat{G}(k)$ is $\widehat{G}$-abundant.*

Then $(\mathcal{C}^U_{G,k,cusp})_{\mathfrak{m}}$ is a finite free $R_{\overline{\rho}_{\mathfrak{m}}}$-module.

Corollary 5.6. *With the assumptions of the theorem, let $\rho : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ be a continuous homomorphism such that $\overline{\rho} \cong \overline{\rho}_{\mathfrak{m}}$. Then ρ is cuspidal automorphic.*

Proof. The theorem implies that the map $R_{\overline{\rho}_{\mathfrak{m}}} \to \mathcal{B}(U, W(k))_{\mathfrak{m}}$ that we have constructed is an isomorphism. Any representation ρ as in the statement of the corollary determines a homomorphism $R_{\overline{\rho}_{\mathfrak{m}}} \to \overline{\mathbb{Q}}_\ell$. (To show this, we first need to prove that a conjugate of ρ takes values in $\widehat{G}(\mathcal{O})$, where $\mathcal{O}$ is a complete Noetherian local $W(k)$-subalgebra of $\overline{\mathbb{Q}}_\ell$ of residue field k.) This in turn determines a homomorphism $\mathcal{B}(U, W(k))_{\mathfrak{m}} \to \overline{\mathbb{Q}}_\ell$, hence a maximal ideal $\mathfrak{p} \subset \mathcal{B}_U$ with the property that for each $n \geq 1$, $f \in \mathbb{Z}[\widehat{G}^n]^{\widehat{G}}$ and $\gamma = (\gamma_1, \dots, \gamma_n) \in \Gamma^n_{K,\varnothing}$,

$$f(\rho(\gamma_1), \dots, \rho(\gamma_n)) = S_{n,f,\gamma} \bmod \mathfrak{p}.$$

This is exactly what it means for ρ be cuspidal automorphic. □

There are two adjectives in the theorem that have yet to be defined: 'strongly $\widehat{G}$-irreducible' and '$\widehat{G}$-abundant'. We remedy this now:

Definition 5.7. *Let Ω be an algebraically closed field, and let Γ be a group. We say that a homomorphism $\sigma : \Gamma \to \widehat{G}(\Omega)$ is strongly $\widehat{G}$-irreducible if for any other homomorphism $\sigma' : \Gamma \to \widehat{G}(\Omega)$ such that for all $\gamma \in \Gamma$, $\sigma(\gamma)^{ss}$ and $\sigma'(\gamma)^{ss}$ are $\widehat{G}(\Omega)$-conjugate, σ' is $\widehat{G}$-irreducible.*

Thus a strongly $\widehat{G}$-irreducible representation is $\widehat{G}$-irreducible. We do not know an example of a representation which is $\widehat{G}$-irreducible but not strongly $\widehat{G}$-irreducible.

Definition 5.8. *Let k be a finite field, and let $H \subset \widehat{G}(k)$ be a subgroup. We say that H is $\widehat{G}$-abundant if the following conditions are satisfied:*

1. *The cohomology groups $H^0(H, \widehat{\mathfrak{g}}_k)$, $H^0(H, \widehat{\mathfrak{g}}_k^\vee)$, $H^1(H, \widehat{\mathfrak{g}}_k^\vee)$ and $H^1(H, k)$ all vanish. (Here $\widehat{\mathfrak{g}}_k$ denotes the Lie algebra of $\widehat{G}_k$, and $\widehat{\mathfrak{g}}_k^\vee$ its dual.)*

2. *For each regular semisimple element $h \in H$, the torus $\mathrm{Cent}(\widehat{G}_k, h)^\circ$ is split.*

3. *For each simple $k[H]$-submodule $W \subset \widehat{\mathfrak{g}}_k^\vee$, there exists a regular semisimple element $h \in H$ such that $W^h \neq 0$ and $\mathrm{Cent}(\widehat{G}_k, h)$ is connected.*

The roles of these two definitions are as follows: the strong irreducibility of $\overline{\rho}_{\mathfrak{m}}$ allows us to cut down $\mathcal{C}^U_{G,k}$ to its finite rank $W(k)$-submodule $\mathcal{C}^U_{G,k,\mathrm{cusp}}$ using only Hecke operators (and not excursion operators). The $\widehat{G}$-abundance of $\overline{\rho}_{\mathfrak{m}}(\Gamma_{K(\zeta_\ell)})$ is used in the construction of sets of Taylor–Wiles places, which are the main input in the proof of Theorem 5.5.

If ℓ is sufficiently large, then the group $\widehat{G}(\mathbb{F}_\ell)$ is both strongly $\widehat{G}$-irreducible (inside $\widehat{G}(\overline{\mathbb{F}}_\ell)$) and $\widehat{G}$-abundant (inside $\widehat{G}(k)$, for a sufficiently large finite extension $k/\mathbb{F}_\ell$). However, it is not clear how many other families of examples there are! This motivates the following question:

Question 5.9. *Can one prove an analogue of Theorem 5.5 with weaker hypotheses? For example, can one replace conditions 3. and 4. with the single requirement that $\overline{\rho}_{\mathfrak{m}}$ is absolutely $\widehat{G}$-irreducible and ℓ is sufficiently large, relative to $\widehat{G}$?*

To weaken the '$\widehat{G}$-abundant' condition is analogous to weakening the 'bigness' condition which appeared in the first automorphy lifting theorems for unitary groups proved in Clozel, Harris, and Taylor [2008]. It seems like an interesting problem to try, in a way analogous to J. Thorne [2012], to replace this condition with the $\widehat{G}$-irreducibility of the residual representation $\overline{\rho}_{\mathfrak{m}}$.

6 Coxeter parameters

In order to apply a result like Theorem 5.5, we need to have a good supply of representations $\overline{\rho} : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{F}}_\ell)$ which we know to be residually automorphic (in the sense of arising from a maximal ideal of the excursion algebra $\mathcal{B}(U, W(k))$ acting on cuspidal automorphic forms).

Famously, Wiles used the Langlands–Tunnell theorem to prove the residual automorphy of odd surjective homomorphisms $\overline{\rho} : \Gamma_{\mathbb{Q}} \to \mathrm{GL}_2(\mathbb{F}_3)$, in order to be able to use his automorphy lifting theorems to prove the modularity of elliptic curves. Many recent applications of automorphy lifting theorems (e.g. to potential automorphy of n-dimensional Galois representations over number fields, or to the construction of lifts of residual representations with prescribed properties, as in Barnet-Lamb, Gee, Geraghty, and Taylor [2014]) have relied upon the automorphy of n-dimensional Galois representations which are induced from a character of the Galois group of a cyclic extension of numbers fields of degree n. The automorphy of such representations was proved by Arthur–Clozel, using a comparison of twisted trace formulae Arthur and Clozel [1989].

We obtain residually automorphic Galois representations from a different source, namely the geometric Langlands program. We first describe the class of representations that we use. We fix a split maximal torus $\widehat{T} \subset \widehat{G}$, and write $W = W(\widehat{G}, \widehat{T})$ for the Weyl group of $\widehat{G}$. We assume in this section that $\widehat{G}$ is simple and simply connected.

Definition 6.1. *An element $w \in W$ is called a Coxeter element if it is conjugate to an element of the form $s_1 \dots s_r$, where $R = \{\alpha_1, \dots, \alpha_r\} \subset \Phi(\widehat{G}, \widehat{T})$ is any choice of ordered root basis and $s_1, \dots, s_r \in W$ are the corresponding simple reflections.*

It is a fact that the Coxeter elements form a single conjugacy class in W, and therefore have a common order h, which is called the Coxeter number of $\widehat{G}$. They were defined and studied by Coxeter in the setting of reflection groups. Kostant applied them to the study of reductive groups Kostant [1959], and his results form the foundation of our understanding of the following definition:

Definition 6.2. *Let Γ be a group, and let Ω be an algebraically closed field. We call a homomorphism $\phi : \Gamma \to \widehat{G}(\Omega)$ a Coxeter homomorphism if it satisfies the following conditions:*

1. *There exists a maximal torus $T \subset \widehat{G}_\Omega$ such that $\phi(\Gamma) \subset N(\widehat{G}_\Omega, T)$, and the image of $\phi(\Gamma)$ in $W \cong N(\widehat{G}_\Omega, T)/T$ is generated by a Coxeter element w. We write ϕ^{ad} for the composite of ϕ with projection $\widehat{G}(\Omega) \to \widehat{G}^{ad}(\Omega)$, and T^{ad} for the image of T in $\widehat{G}^{ad}_\Omega$.*

2. *There exists a prime $t \equiv 1 \bmod h$ not dividing char Ω or $\#W$ and a primitive h^{th}-root of unity $q \in \mathbb{F}_t^\times$ such that $\phi^{ad}(\Gamma) \cap T^{ad}(\Omega)$ is cyclic of order t, and conjugation by w acts on the image by the map $v \mapsto v^q$.*[8]

We recall that if $\widehat{G} = \mathrm{SL}_n$, then $W = S_n$ and the Coxeter elements are the n-cycles. In this case the Coxeter homomorphisms appear among those homomorphisms $\Gamma \to \mathrm{SL}_n(\Omega)$ which are induced from a character of an index n subgroup. However, the above definition is valid for any simply connected simple $\widehat{G}$ and has very good properties:

Proposition 6.3. *Let $\phi : \Gamma \to \widehat{G}(\Omega)$ be a Coxeter homomorphism. Then:*

1. *ϕ is $\widehat{G}$-irreducible.*

2. *If $\phi' : \Gamma \to \widehat{G}(\Omega)$ is another homomorphism such that for all $\gamma \in \Gamma$, $\phi(\gamma)^{ss}$ and $\phi(\gamma')^{ss}$ are $\widehat{G}(\Omega)$-conjugate, then ϕ and ϕ' are themselves $\widehat{G}(\Omega)$-conjugate. In particular, ϕ is even strongly $\widehat{G}$-irreducible.*

3. *The image $\phi(\Gamma)$ is an $\widehat{G}$-abundant subgroup of $\widehat{G}(\Omega)$.*

[8]As the notation suggests, in applications we will take q to be the image in $\mathbb{F}_t$ of the cardinality of the field of scalars in K.

Now suppose that $\phi : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ is a Coxeter parameter. Then there exists a degree h cyclic extension K'/K such that $\phi(\Gamma_{K'})$ is contained in a torus of $\widehat{G}$; the homomorphism $\phi|_{\Gamma_{K'}}$ is therefore associated to Eisenstein series on $G(\mathbb{A}_{K'})$. One can ask whether it is possible to use this to obtain a cuspidal automorphic representation of $G(\mathbb{A}_K)$ (or better, a maximal ideal of the excursion algebra $\mathcal{B}_U$) to which ϕ corresponds. One case in which the answer is affirmative is as follows:

Theorem 6.4. *Let $\phi : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ be a Coxeter parameter such that $\phi(\Gamma_{K\cdot\overline{\mathbb{F}}_q}) \subset \widehat{T}(\overline{\mathbb{Q}}_\ell)$. Then ϕ is cuspidal automorphic, in the sense of Definition 4.5.*

Proof (sketch). Braverman–Gaitsgory construct Braverman and Gaitsgory [2002] the geometric analogue of Eisenstein series for the group G: in other words, a Hecke eigensheaf on $\mathrm{Bun}_{G,\overline{\mathbb{F}}_q}$ with 'eigenvalue' $\phi|_{\Gamma_{K\cdot\overline{\mathbb{F}}_q}}$. This Hecke eigensheaf is equipped with a Weil descent datum, which allows us to associate to it an actual spherical automorphic form $f : G(K)\backslash G(\mathbb{A}_K) \to \overline{\mathbb{Q}}_\ell$ whose Hecke eigenvalues agree with those determined by ϕ, under the Satake isomorphism. Using geometric techniques (see Gaitsgory's appendix to Böckle, Harris, Khare, and J. A. Thorne [n.d.]), one can further show that this automorphic form is in fact cuspidal. The existence of a maximal ideal in the excursion algebra $\mathcal{B}_U$ corresponding to ϕ then follows from the existence of f and the good properties of Coxeter parameters (in particular, the second part of Proposition 6.3). $\square$

To illustrate the method, here is the result we obtain on combining Theorem 6.4 with our automorphy lifting Theorem 5.5:

Theorem 6.5. *Let $\ell > \#W$ be a prime, and let $\rho : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ be a continuous homomorphism such that $\overline{\rho}$ is a Coxeter parameter and $\overline{\rho}(\Gamma_{K\cdot\overline{\mathbb{F}}_q})$ is contained in a conjugate of $\widehat{T}(\overline{\mathbb{F}}_\ell)$. Then ρ is cuspidal automorphic, in the sense of Definition 4.5.*

Here is a question motivated by a potential strengthening of Theorem 6.5:

Question 6.6. *Let $\phi : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ be a Coxeter parameter such that $\phi(\Gamma_{K\cdot\overline{\mathbb{F}}_q}) \subset \widehat{T}(\overline{\mathbb{Q}}_\ell)$, and let π be the everywhere unramified cuspidal automorphic representation of $G(\mathbb{A}_K)$ whose existence is asserted by Theorem 6.4. Can one show that π appears with multiplicity 1 in the space $\mathcal{Q}_{G,cusp}$?*

Taking into account the freeness assertion in Theorem 5.5, we see that a positive answer to Question 6.6 would have interesting consequences for the multiplicity of cuspidal automorphic representations.

7 Potential automorphy

We can now describe the proof of Theorem 4.6. Let us therefore choose a representation $\rho : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{Q}}_\ell)$ of Zariski dense image. We must find a finite Galois extension L/K such that $\rho|_{\Gamma_L}$ is cuspidal automorphic. It is easy to reduce to the case where $\widehat{G}$ is simple and simply connected (equivalently: the group G is simple and has trivial centre), so we now assume this.

By Proposition 3.8, we can assume, after replacing ρ by a conjugate, that there is a number field E, a system $(\rho_\lambda)_\lambda$ of continuous homomorphisms $\rho_\lambda : \Gamma_{K,\varnothing} \to \widehat{G}(E_\lambda)$ of Zariski dense image, and an embedding $E_{\lambda_0} \hookrightarrow \overline{\mathbb{Q}}_\ell$ such that $\rho = \rho_{\lambda_0}$. If any one of the representations ρ_λ is automorphic, then they all are. We can therefore forget the original prime ℓ and think of the entire system $(\rho_\lambda)_\lambda$.

An application of a theorem of Larsen [1995] furnishes us with strong information about this system of representations:

Theorem 7.1. *With notation as above, we can assume (after possibly enlarging E and replacing each ρ_λ by a conjugate), that there exists a set $\mathfrak{L}$ of rational primes of Dirichlet density 0 with the following property: for each prime $\ell \notin \mathfrak{L}$ which splits in E and does not divide q, and for each place $\lambda|\ell$ of E, $\rho_\lambda(\Gamma_{K,\varnothing})$ has image equal to $\widehat{G}(\mathbb{Z}_\ell)$.*

It follows that for $\lambda|\ell$ ($\ell \notin \mathfrak{L}$ split in E), the residual representation $\overline{\rho}_\lambda$ can be taken to have image equal to $\widehat{G}(\mathbb{F}_\ell)$. It is easy to show that when ℓ is sufficiently large, such a residual representation satisfies the requirements of our Theorem 5.5.

We are now on the home straight. Using a theorem of Moret-Bailly and known cases of de Jong's conjecture Moret-Bailly [1990] and de Jong [2001], one can construct a finite Galois extension L/K and (after possibly enlarging E) an auxiliary system of representations $(R_\lambda : \Gamma_{L,\varnothing} \to \widehat{G}(E_\lambda))_\lambda$ satisfying the following properties:

1. For each prime-to-q place λ of $\overline{\mathbb{Q}}$, R_λ has Zariski dense image in $\widehat{G}(\overline{\mathbb{Q}}_\lambda)$.
2. There exists a place λ_1 such that $\overline{R}_{\lambda_1} \cong \overline{\rho}_{\lambda_1}|_{\Gamma_{L,\varnothing}}$, and both of these representations have image $\widehat{G}(\mathbb{F}_{\ell_1})$, where ℓ_1 denotes the residue characteristic of λ_1.
3. There exists a place λ_2 such that $\overline{R}_{\lambda_2}$ is a Coxeter parameter and $\ell_2 > \#W$, where ℓ_2 denotes the residue characteristic of λ_2.

The argument to prove the automorphy of $\rho|_{\Gamma_{L,\varnothing}}$ is now the familiar one. By Theorem 6.5, R_{λ_2} is cuspidal automorphic. Since this property moves in compatible systems for representations with Zariski dense image, R_{λ_1} is cuspidal automorphic. If ℓ_1 is chosen to be sufficiently large, then we can apply Theorem 5.5 to deduce that $\rho_{\lambda_1}|_{\Gamma_{L,\varnothing}}$ is cuspidal automorphic. Moving now in the compatible system containing $\rho_{\lambda_1}|_{\Gamma_{L,\varnothing}}$, we obtain finally the automorphy of the original representation $\rho|_{\Gamma_{L,\varnothing}}$, as desired.

One of the main attractions of our arguments is that they are uniform in the reductive group G. In particular, they are valid for exceptional groups. Using deformation theory, it is easy to find examples of global fields $K = \mathbb{F}_q(X)$ and continuous representations $\rho : \Gamma_{K,\varnothing} \to \widehat{G}(\overline{\mathbb{Q}}_l)$ of Zariski dense image. This gives, for example, the following simple corollary of Theorem 4.6:

Corollary 7.2. *Let G be the split simple group over $\mathbb{F}_q$ of type E_8; then the dual group $\widehat{G}$ is the split simple group over $\mathbb{Z}$ of type E_8. Let ℓ be a prime not dividing q. Then there exist infinitely pairs (K, ρ), where $K = \mathbb{F}_q(X)$ is a global field and $\rho : \Gamma_{K,\varnothing} \to E_8(\overline{\mathbb{Q}}_\ell)$ is a representation of Zariski dense image which is cuspidal automorphic, in the sense of Definition 4.5.*

Acknowledgments. I am very grateful to Chandrashekhar Khare, Michael Harris, and Vincent Lafforgue for their comments on a draft version of this article.

FUNCTIONAL TRANSCENDENCE AND ARITHMETIC APPLICATIONS

Jacob Tsimerman

Abstract

We survey recent results in functional transcendence theory, and give arithmetic applications to the André-Oort conjecture and other unlikely-intersection problems.

1 Introduction

The purpose of these notes is to give an introduction to the O-minimality approach to arithmetic geometric questions in the field now referred to as "Unlikely Intersections", as well as give a brief survey of recent results in the literature. We emphasize the functional transcendence results, which are both necessary for many interesting arithmetic applications, and which we hope are of independent interest. We include some recent results on variations of hodge structures, especially as we believe these are still in their infancy and could have fantastic developments in the near future. In §2, we give a survey of the types of functional transcendence statements that have stemmed from generalizing the Ax-Schanuel theorem. In §3 we introduce o-minimality and give a sort of users manual of the main results that have been useful for these sorts of applications. We then sketch the proofs of some functional transcendence results in §4. §5 is devoted to arithmetic applications, where we explain the recent developments in the André-Oort conjecture and the Zilber-Pink conjecture. We give some sketches of proofs, but we only try to convey the main ideas, rather then give complete arguments.

2 Transcendence Theory

2.1 Classical Results. Classical transcendental number theory is largely concerned with the algebraic properties of special values of special functions. We focus first on the case of exponentiation. There are the following fundamental classical results:

MSC2010: 11G10.

Theorem 2.1. *[Lindemann-Weirstrass] Let $x_1, \dots, x_n \in \overline{\mathbb{Q}}$ be linearly independent over $\mathbb{Q}$. Then $e^{x_1}, \dots, e^{x_n}$ are algebraically independent over $\overline{\mathbb{Q}}$.*

The above result implies, for example, that $\ln q$ is transcendental for every rational number q. Baker managed to prove a similar (though weaker) result for the more difficult case of ln:

Theorem 2.2. *[Baker [1975]] Let $x_1, \dots, x_n \in \overline{\mathbb{Q}}$. If $\ln x_1, \dots, \ln x_n$ are linearly independent over $\mathbb{Q}$ then they are also linearly independent over $\overline{\mathbb{Q}}$.*

In fact Baker proved a quantitative version of the above theorem. Both of the above results are encapsulated by the following conjecture of Schanuel, which seems to encapsulate all reasonable transcendence properties of the exponential function:

Conjecture 2.1. *Let $x_1, \dots, x_n \in \mathbb{C}$ be linearly independent over $\mathbb{Q}$. Then*

$$\text{tr.deg.}_{\mathbb{Q}}\mathbb{Q}(x_1, \dots, x_n, e^{x_1}, \dots, e^{x_n}) \geq n.$$

Note that in the case where the x_i are all in $\overline{\mathbb{Q}}$ one recovers the Lindemann-Weirstrass Theorem 2.1, and in the case where e^{x_i} are all in $\overline{\mathbb{Q}}$ one recovers Baker's Theorem 2.2. Schanuel's conjecture has immediate striking implications. For instance, if one takes $n = 2$ and $\{x_1, x_2\} = \{1, \pi i\}$ then an immediate corollary is that e, π are algebraically independent over $\mathbb{Q}$.

2.2 Functional Analogue. While Schanuel's Conjecture 2.1 is still out of reach, one can get a lot more traction by considering a functional analogue. From a formal perspective, we replace the pair of fields $\mathbb{Q} \subset \mathbb{C}$ by the pair $\mathbb{C} \subset \mathbb{C}[[t_1, \dots, t_m]]$. Then one has the following theorem due to Ax, referred to as the Ax-Schanuel theorem (see Ax [1971]):

Theorem 2.3. *Let $x_1, \dots, x_n \in \mathbb{C}[[t_1, \dots, t_m]]$ have no constant term and be such that they linearly independent over $\mathbb{Q}$ Then*

$$\text{tr.deg.}_{\mathbb{C}}\mathbb{C}(x_1, \dots, x_n, e^{x_1}, \dots, e^{x_n}) \geq n + \text{rank}\left(\frac{\partial x_i}{\partial t_j}\right).$$

Example. Consider $n > m$ and let $x_i = t_i$ for $i \leq m$, and x_i to be linearly independent elements in $\mathbb{C}(t_1, \dots, t_m)$ over $\mathbb{Q}$ for $i > m$. Then it follows from Theorem 2.3 that e^{x_i} are algebraically independent over $\mathbb{C}(t_1, \dots, t_m, e^{t_1}, \dots, e^{t_m})$. It immediately follows that the set $\{e^x, x \in \mathbb{C}(t_1, \dots, t_m)\backslash\mathbb{C}\}$ is linearly independent over $\mathbb{C}(t_1, \dots, t_m)$.

We pause to explain the extra term on the right hand side in Theorem 2.3. For the moment, suppose that the x_i are convergent power series in the t_j so that the x_i can be considered as functions in the t_j. Then the x_i can be thought of as a map from $\vec{x} : \mathrm{D}^m \to \mathbb{C}^n$ for some small disk D. Now by the implicit function theorem, the dimension of $\vec{x}(\mathrm{D}^m)$ is equal to rank $\left(\frac{\partial x_i}{\partial t_j}\right)$.. Thus, if x_n contributes one to rank $\left(\frac{\partial x_i}{\partial t_j}\right)$, we can consider x_n as a formal variable over $\mathbb{C}[[x_1, \dots, x_{n-1}]]$ and then x_n, e^{x_n} are easily seen to be algebraically independent over all of $\mathbb{C}[[x_1, \dots, x_{n-1}]]$.

2.3 Geometric Formulation. Note that the above suggests a geometric reformulation of the above result. Namely, let U be the image of the map $(\vec{x}, e^{\vec{x}}) : \mathrm{D}^m \to \mathbb{C}^n \times (\mathbb{C}^\times)^n$. Note that $U \subset \Gamma$ where Γ is the graph of the exponentiation map. Then the statement of Theorem 2.3 can be reinterpreted geometrically as follows:

- $\mathrm{tr.deg.}_{\mathbb{C}}\mathbb{C}(x_1, \dots, x_n, e^{x_1}, \dots, e^{x_n})$ is the dimension of the Zariski closure of U in $\mathbb{C}^n \times (\mathbb{C}^\times)^n$
- rank $\left(\frac{\partial x_i}{\partial t_j}\right)$ is the dimension of U.
- The statement that x_i have no constant terms and are are linearly independent in $\mathbb{C}(t_1, \dots, t_m)$ over $\mathbb{Q}$, implies that the projection of U to $\mathbb{C}^n$ contains the origin and is not contained in linear subspace defined over $\mathbb{Q}$. Equivalently, the projection of U to $(\mathbb{C}^\times)^n$ is not contained in a proper algebraic subgroup.

We thus have the following geometric reformulation of Ax-Schanuel (See Tsimerman [2015] for more details):

Theorem 2.4. *Let W be an irreducible algebraic variety in $\mathbb{C}^n \times (\mathbb{C}^\times)^n$, and let U be an irreducible analytic component of $W \cap \Gamma$, where Γ is the graph of the exponentiation map. Assume that the projection of U to $(\mathbb{C}^\times)^n$ is not contained in a translate of any proper algebraic subgroup. Then*

$$\dim W = \dim U + n.$$

Even though it may seem that Theorem 2.3 is more general than the above due to the possibility of the x_i being non-convergent power series in the t_j, by formulating in terms differential fields and using the Seidenberg embedding theorem one can see that they are in fact equivalent. We list also an implication of the above theorem, as we will have use for it later. As it can be seen as analogous to the classical Lindemann-Weirstrass theorem, it has been dubbed the Ax-Lindemann-Weirstrass (or often just Ax-Lindemann) theorem by Pila:

Theorem 2.5. *Let W, V be irreducible algebraic varieties in $\mathbb{C}^n$, $(\mathbb{C}^\times)^n$ respectively such that $e^W \subset V$. Then there exists a translate S of an algebraic subgroup of $(\mathbb{C}^\times)^n$ such that $e^W \subset S \subset V$*

To deduce Theorem 2.5 one may apply the conclusion of Theorem 2.4 to the subvariety $W \times V$ of $\mathbb{C}^n \times (\mathbb{C}^\times)^n$.

2.4 Generalizations to other geometric settings. Theorem 2.4 and Theorem 2.5 are stated in the context of the exponentiation map, but it is not hard to make formal generalizations to other settings. We describe now a recipe for generalizing to other contexts. One requires the following objects:

1. Two algebraic varieties $\widehat{D}, X$, an open subset $D \subset \widehat{D}$, and a holomorphic map $\pi : D \to X$. By convention, we define an algebraic subvariety of D to be an analytic component of $D \cap V$, where V is a subvariety of $\widehat{D}$.
2. A collection S of irreducible subvarieties of X called *weakly special* varieties such that their pre-image in D contains an irreducible algebraic component.

Given the above data, we may formulate an Ax-Schanuel conjecture as follows:

Conjecture 2.2. *(Ax-Schanuel for X) Let $\Gamma \subset D \times X$ be the graph of π. Let $W \subset X$ be an irreducible algebraic variety, and U an analytic component of $W \cap \Gamma$. Then if the projection of U to X does is not contained in any proper weakly special subvariety, we have*

$$\dim U = \dim W - \dim X.$$

We proceed to give some concrete examples of this principle.

2.4.1 Abelian and Semi-Abelian Varieties. Let X be a semi-abelian variety, in other words an extension of an Abelian variety by a torus. Let the dimension of the abelian part be a and of the toric part be t, and set $g = \dim X = a + t$. Then we may take $D = \widehat{D} = \mathbb{C}^g$ and write X as D/Λ for a discrete subgroup $\lambda \subset D$ of rank $2a + t$. Now we may take the weakly special varieties to be the cosets of algebraic subgroups - which are themselves necessarily semi-abelian subvarieties. Note that this case is a direct generalization of Theorem 2.4 which we may recover by setting $a = 0$. This case was settled by Ax [1972].

2.4.2 Shimura Varieties. Let S be a Shimura variety. We do not give precise definitions in this section, referring instead to surveys such as J. Milne [n.d.] and Moonen [1998] for more details. However, such varieties are naturally quotients of Symmetric spaces D by arithmetic groups, and moreover the spaces D can be identified as a quotient of real lie groups $D \cong G(\mathbb{R})/K$ for G a semisimple lie group defined over $\mathbb{Q}$, and K a maximal compact subgroup of G. This means that $G(\mathbb{R})$ acts on D, and the weakly special varieties can be characterized as the images of orbits $H(\mathbb{R}) \cdot v$, where $H \subset G$ is a semisimple lie subgroup defined over $\mathbb{Q}$ such that the orbit $H(\mathbb{R}) \cdot v$ is complex analytic. Thus, even though D and S do not form groups, the machinery of group theory is still very much present in this setting, though of course the groups are non abelian making this setting significantly more difficult then the abelian and semi-abelian case.

Example. For a positive integer n, one may take $D = \mathbb{H}^n, S = Y(1)^n$ and $\pi : D \to S$ be the j map, where $Y(1)$ is the (coarse) moduli space of complex elliptic curves and $\mathbb{H}$ is the usual upper-half plane. The weakly special shimura varieties V can be described very simply as being imposed by one of 2 types of conditions:

- One may impose a co-ordinate of S to be a constant
- One may insist that, for a fixed positive integer N, tow co-ordinates x_i, x_j of S correspond to elliptic curves which are related by a cyclic isogeny of degree N.

The above 2 operations may yield varieties that are not irreducible, so one should also be allowed to take irreducible components. This yields for a very nice combinatorial description of weakly pecial subvarieties which becomes significantly more complicated for other Shimura varieties, but in practise the explicitness of the description is rarely essential to proofs. In this context, the Theorem 2.5 was proven by Pila [2011] in his groundbreaking unconditional proof of André-Oort for $X(1)^n$, and the Theorem 2.4 was proven by Pila and Tsimerman [2016].

The general case of Theorem 2.5 was proven in Klingler, Ullmo, and Yafaev [2016] after partial progress was done by Ullmo and Yafaev [2014] for compact S, and by Pila and Tsimerman [2014] for $\mathfrak{A}_g$. The general case of Theorem 2.4 was recently announced by Mok, Pila, and Tsimerman [2017]. One may also generalize to *Mixed Shimura Varieties*, where Theorem 2.5 was proven by Gao [2017].

2.4.3 Hodge Structures. There is another generalization one may make, and that is to the setting of Hodge Structures. This setting is slightly more complicated than what we have defined so far and it doesn't exactly fit into our setup, for reasons we will describe. Nevertheless, it is important for arithmetic reasons that we will mention in later sections. For general background on Hodge Structures, we refer the reader to Voisin [2002]. We give a quick definition here.

Definition. *An integral hodge structure of weight m and dimension n consists of:*

- *A free abelian group L of dimension n*
- *An integer-valued non-degenerate quadratic form Q on L satisfying $Q(v,w) = (-1)^n Q(w,v)$*

- *A* ***Hodge decomposition*** *of complex vector spaces* $L \otimes \mathbb{C} = \oplus_{p+q=n} H^{p,q}$ *such that* $\overline{H^{p,q}} = H^{q,p}$ *and* $i^{p-q} Q(v, \bar{w})$ *is positive definite on* $H^{p,q}$.

The numbers $h^{p,q} := \dim H^{p,q}$ *are called the* Hodge numbers.

If one fixes a weight, dimension, hodge numbers, and isomorphism class of (L, Q) one obtains a complex analytic space X which parametrizes hodge structures up to isomorphism. Moreover, if one further fixes a basis for L, one obtains an open subset D of a complex Grassmanian manifold, and a holomorphic covering map $D \to X$ with Monodromy $G(\mathbb{Z})$, where $G = \mathrm{Aut}(L, Q)$. Moreover, $G(\mathbb{R})$ acts transitively on $D(\mathbb{R})$ with compact stabilizer, so we obtain a picture quite similar to the one which occurs for Shimura varieties. Indeed, by including some extra data one may recover all Shimura varieties as moduli of Hodge structures.

The reason that this setting presents significant additional complication is that for 'most' choices of Hodge numbers, Carlson and Toledo [2014] showed that X cannot be endowed with the structure of an algebraic variety. In our specific context, this makes formulating a transcendence conjecture difficult!

To resolve this problem, we note that a primary motivating reason for studying hodge structures is that for smooth projective varieties Y and a positive integer m, the cohomology group $H^m(Y, \mathbb{C})$ can naturally be given a hodge structure, with the integer lattice coming from Betti cohomology, the Hodge decomposition coming from Dolbeaut Cohomology, and the quadratic form coming from the cup product. This means that even though the moduli space X is not algebraic, for any family of smooth algebraic varieties over a base B such that the fibers have the right Hodge numbers, we get a *period map* $B \to X$. These period maps give us an algebraic structure to work with (namely, that on B) and so allows us to formulate a version of Theorem 2.4. Such a statement was conjectured by Klingler[1] in Klingler [n.d.], and was proven by Bakker and Tsimerman [2017]. The proof follows closely the structure of Mok, Pila, and Tsimerman [2017], with the primary difference being a new "volume-growth" inequality for moduli of Hodge structures in Griffiths-Transverse directions.

3 O-minimality

3.1 Definitions and Introduction. In the course of proving Theorem 2.4 as well as all its generalizations, one naturally deals with functions that are not algebraic. However, the set of all complex analytic functions can be too unwieldy, so it is natural to look for an intermediate category of functions in which to work. It turns out that one such theory which works particularly well for this class of problems is that of o-minimal structures.

[1] In fact, Klingler conjectures much more specific results

This allows us to work with enough functions to be able to talk about the transcendental covering maps in Theorem 2.4, while still maintaining many of the nice properties that algebraic functions possess.

For our purposes, a **Structure** $\mathcal{S}$ is a collection of sets $S_n \subset 2^{\mathbb{R}^n}$, where the elements of S_n are subsets of $\mathbb{R}^n$, such that the following properties hold:

- S_n is a boolean algebra
- $S_n \times S_m \subset S_{m+n}$
- If we let $\pi : \mathbb{R}^n \to \mathbb{R}^j$ be co-ordinate subspace projection, and $A \in S_n$, then $\pi(A) \in S_j$.
- The set $\{(x, x), x \in \mathbb{R}\}$ is in S_2, and the sets $\{(x, y, x + y), x, y \in \mathbb{R}\}, \{(x, y, xy), x, y, \in \mathbb{R}\}$ are in S_3.

We further say that $\mathcal{S}$ is *o-minimal* if S_1 consists precisely of finite unions of open intervals and points. We say that a set $Z \subset \mathbb{R}^n$ is *definable* in § if $Z \in S_n$, and we say that a function $f : \mathbb{R}^n \to \mathbb{R}^m$ is definable in $\mathcal{S}$ if its graph is.t turns out that o-minimal structures have a myriad of useful properties. For example, any set definable in an o-minimal structure has finitely many connected components, has a well-defined dimension, and is almost everywhere differentiable. For an introduction to the theory, see van den Dries [1998].

3.2 Examples of o-minimal structures. It follows from the definitions that the smallest possible structure is the structure $\mathbb{R}_{sa}$ which contains all semi-algebraic sets. It follows from the Tarski-Seidenberg theorem $\mathbb{R}_{sa}$ is o-minimal. It is highly non-trivial to prove that any enlargements are o-minimal.

- Gabrièlov [1968] prove that the structure $\mathbb{R}_{an}$, which is defined as the smallest structure containing all subanalytic functions is definable. Recall that a subanalytic function is a function $f : T \to \mathbb{R}$ where $T \subset \mathbb{R}^n$ is a compact ball such that f extends to an analytic function on an open neighbourhood of T.
- Building on work of Khovanskiĭ [1991], Wilkie [1996] proved that the structure $\mathbb{R}_{exp}$, which is defined as the smallest structure containing the graph of the **real** exponential function[2], is o-minimal.
- The strucure $\mathbb{R}_{an,exp}$ is defined to be the smallest structure containing $\mathbb{R}_{an}$ and $\mathbb{R}_{exp}$, and the o-minimality of this structure was shown by van den Dries and Miller

[2] The complex exponential function has countable pre-images, and so cannot be o-minimal.

[1994b]. Note that the structure generated by two o-minimal structures need not be o-minimal Rolin, Speissegger, and Wilkie [2003], so this is by no means a trivial theorem. The structure $\mathbb{R}_{an,exp}$ turns out to be large enough to encompass most functions that are needed for arithmetic applications, and so this is the structure we will ultimately work in.

3.3 Counting Rational Points in Definable Sets. One very common and useful heuristic in number theory is that sets contain "few" integer/rational points unless they have some kind of "reason" for doing so. As such, one would expect that Transcendental subvarieties contain few such points. However, one must be careful to avoid dealing with sets that are too unwieldy. For example, the graph of the function $\sin(\pi x)$ contains every integer point of the x-axis, and is quite transcendental. It turns out that for o-minimal sets such a thing can't happen, as was shown by Bombieri and Pila [1989]. To state their theorem, let us define the *height* of a rational number $x = a/b$ with $\gcd(a, b) = 1$ to be $H(x) = \max(|a|, |b|)$ and the height of a rational point $x = (x_1, \ldots, x_n)$ to be $H(x) = \max_i(H(x_i))$. For a subset $\mathbb{Z} \subset \mathbb{R}^n$ we define the counting function of Z by

$$N(Z, T) := \#\{x \in Z \cap \mathbb{Q}^n \mid H(x) \leq T\}.$$

Theorem 3.1. *Bombieri and Pila [ibid.] Let $Z \subset \mathbb{R}^2$ be a compact real-analytic transcendental curve. Then*

$$N(Z, T) = T^{o(1)}.$$

In other words, the number of points on Z grows subpolynomially.

The proof of the above theorem uses the determinant method, whereby one uses the rational points to form a determinant that has a lower bound stemming from arithmetic, and an upper bound stemming from geometry. One would like to generalize the above theorem to higher dimensions, but some care is required stemming from the fact that a transcendental surface could easily contain an algebraic curve, or even a line, and thus contain lots of rational points. As such, we define Z^{alg} to be the union of all semi-algebraic curves contained in Z. Then Pila and Wilkie [2006] prove the following higher dimensional generalization:

Theorem 3.2. *Pila and Wilkie [ibid.]*

Let $Z \subset \mathbb{R}^n$ be definable in an o-minimal structure. Then

$$N(Z - Z^{alg}, T) = T^{o(1)}.$$

In other words, the number of points on $Z - Z^{alg}$ grows subpolynomially.

One may obtain the same quality bound for counting not only rational points, but algebraic points of a bounded degree over $\mathbb{Q}$. The proof of the above theorem proceeds roughly as follows: One applies the determinant method to show that the rational points in Z lie in the intersections $Z \cap V$ of Z with "few" hypersurfaces V of small degree. One then wishes to apply the theorem inductively on dimension. The key to doing this is a parametrization theorem which means that the intersections $Z \cap V$ can be parametrized by finitely many maps with uniformly bounded derivatives as V varies in the family of all hypersurfaces of a given degree. This is where the o-minimality is crucial to the argument.

3.4 Tame complex geometry. We first say a word about extending the notion of definability to sets that aren't subsets of $\mathbb{R}^n$. First, if Z is a subset of $\mathbb{C}^n$ one may use the identification $\mathbb{C}^n \cong \mathbb{R}^{2n}$ to talk about the definability of Z. Moreover, we may talk about definable manifolds, by insisting on *finite* open covers that have an isomorphism onto a definable subset of $\mathbb{R}^m$ such that the transition maps are definable. In particular, this gives every complex algebraic variety the structure of a definable (in any structure) manifold by taking a finite affine open cover,.

Peterzil and Starchenko have a series of works Peterzil and Starchenko [2010] where they develop complex geometry in an o-minimal setting[3] where they prove tameness of complex analytic sets that are definable in an o-minimal setting. One particularly robust and applicable result to the arithmetic setting is the following version of Chows theorem, which works for any algebraic variety, not just proper varieties!

Theorem 3.3. *Peterzil and Starchenko [ibid.] Let V be a complex algebraic variety, and $S \subset V$ be a closed, complex-analytic subset, which is definable in an o-minimal structure. Then S is an algebraic subvariety of V.*

Note that complex analytic, closed subvarieties of proper algebraic varieties are definable in $\mathbb{R}_{sa}$, so Theorem 3.3 has the usual Chow theorem as an immediate consequence. Note that the above theorem is not stated in the above form in Peterzil and Starchenko [ibid.], but is easily deducible from those results. The deduction is spelled out in a few places, for example in Mok, Pila, and Tsimerman [2017].

3.5 Fundamental Domains and Definability of Uniformization Maps. In §1, we introduced the setting where we have transcendental Uniformization maps $\pi : D \to S$, where S, D are open subsets of complex algebraic varieties. One may hope for the maps π to be definable in $\mathbb{R}_{an,exp}$ with respect to the natural definable structure on D, S. However, the inverse images of points under these maps π are countable, discrete sets, and

[3] In fact, they in the more general setting of a totally-ordered field instead of $\mathbb{R}$

therefore cannot be definable in *any* o-minimal structure! Instead, what one does is restrict to a fundamental domain $\mathfrak{F} \subset D$. That is, one looks for a definable subset $\mathfrak{F}$ such that $\pi \mid \mathfrak{F}$ is an isomorphism onto S, and then asks whether that isomorphism is definable. Note that this is dependant on the fundamentalddomain that one chooses. Below we give some relevant examples:

- In the case of the exponential function $\pi : \mathbb{C}^n \to \mathbb{C}^{\times n}$, we use the fundamental domain

$$\mathfrak{F} = \{(z_1, \ldots, z_n), \Im(z_i) \in [0, 2\pi]\}.$$

  In the real coordinates $z = x + iy$ the function e^z becomes $e^x \cos(y) + ie^x \sin(y)$. Now since we are restricting y to be in a bounded interval, $\cos y, \sin y$ restricted to this interval are definable in $\mathbb{R}_{an}$ and thus $\pi \mid \mathfrak{F}$ is definable in $\mathbb{R}_{an,exp}$.

- In the case of an abelian variety, or indeed any case where S is compact, one may take for $\mathfrak{F}$ any bounded fundamental domain, and $\pi \mid \mathfrak{F}$ will be definable in $\mathbb{R}_{an}$.

- In the case of the j-function, $j : \mathbb{H} \to \mathbb{C}$, we may use the usual fundamental domain given by $\mathfrak{F} = \{z \in \mathbb{H}, \Re e(z) \in [-1/2, 1/2), |z| \geq 1\}$, and use the Laureny expansion of j in terms of $e^{2\pi iz}$ to see that $j \mid \mathfrak{F}$ is definable in $\mathbb{R}_{an,exp}$.

- In the more general case of a Shimura variety $\pi : D \to S$, where $D \cong G(\mathbb{R})/K$ and $S = D/G(\mathbb{Z})$, one may use the Iwasawa decomposition $G = NAK$ to make a Siegel set for $G(\mathbb{R})$, and translate that to a fundamental domain $\mathfrak{F}$. It is substantially more difficult to show that $\pi \mid \mathfrak{F}$ is definable in $\mathbb{R}_{an,exp}$. It was done for the moduli space $\mathfrak{A}_g$ of principally polarized abelian varieties by Peterzil and Starchenko [2013] and in general by Klingler, Ullmo, and Yafaev [2016]. This result was generalized to the Mixed Shimura case by Gao [2017].

- As mentioned before, the case $\pi : D \to X$ where D is a period domain and X parametrizes hodge structures of given hodge numbers is more difficult. Since X does not typically admit any algebraic structure it does come equipped with a definable structure either. Nevertheless, one may use any definable fundamental domain $\mathfrak{F}$ endow X with a definable $\mathbb{R}_{an,exp}$-structure. However, if we proceed with this setup, one wants the following natural property to be satisfied: Given a variation of hodge structures over an algebraic base B, one would like the period map $\psi : B \to X$ to be definable with respect to this structure. In forthcoming work of the author with Bakker, it is shown that if one uses a definable fundamental domain $\mathfrak{F}$ coming from a Siegel set, then the period maps are indeed definable.

4 Proofs of Functional Transcendence results

We attempt in this section to give a brief idea of how these results are proven. We first describe the proof of Theorem 2.5.

4.1 Ax-Lindemann Theorems. We restrict ourselves for expository purposes to the setting of a torus, and briefly explain how to adapt the methods to the setting of a Shimura variety. So suppose that $\pi : \mathbb{C}^n \to \mathbb{C}^{\times n}$ is the exponential map, and let $V \subset \mathbb{C}^n$, $W \subset \mathbb{C}^{\times n}$ be algebraic varieties such that $\pi(V) \subset W$. We pick our usual definable fundamental domain $\mathfrak{F}$, and we let $W' = (\pi \mid \mathfrak{F})^{-1}(W)$. Crucially for us W' is definable. The key idea of the proof lies in considering the following set:

$$I = \{t \in \mathbb{C}^n \mid (V + t) \cap \mathfrak{F} \subset W'.$$

It is easy to see that I is definable in $\mathbb{R}_{an,exp}$. Moreover, since $\pi^{-1}(W)$ is invariant under the monodromy group $\mathbb{Z}^n$, it follows that I contains all those elements $t \in \mathbb{Z}^n$ such that the V intersects $\mathfrak{F} - t$. There must be polynomially many of these elements (in fact, at least linearly many) and thus, by the Counting Theorem 3.2 we can conclude that I contains semialgebraic curves. It follows that there is a complex algebraic curve C such that $V + c \subset W'$ for all $c \in C$.

Now we may try to replace V by $V \cap V + C$ and use an induction argument on $\dim V - \dim W$. This will work unless V is invariant under C. If this is the case for all curves C, it would imply that the intersection of V with $\mathfrak{F} + t$ all 'look the same', or in other words that $\pi(V) = \pi(V \cap \mathfrak{F})$. But this implies that $\pi(V)$ is definable in $\mathbb{R}_{an,exp}$, and thus by the definable chows Theorem 3.3, we see that $\pi(V)$ is algebraic. The proof now follows from momodromy arguments.

To generalize the above to the context of Shimura varieties, one encounters two difficulties:

- One needs an additional argument to show that there are many elements $g \in G(\mathbb{Z})$ sich that V intersects $g \cdot \mathfrak{F}$. In the general case, one now uses a hyperbolic volume argument due to Hwang and To [2002], that says that in hyperbolic balls of radius r, the volume of a complex analytic ball must grow at least exponentially in r. By contrast, one can show using definability and siegel set arguments that the volume in any fundamental domain is bounded by a constant. Thus, any curve must pass through at least c^r fundamental domains of distance r away, and then one relates the distance of a fundamental domain $g \cdot \mathfrak{F}$ to the height of g.

- Additional care must be taken due to the non-abelian nature of the groups involved. This is indeed a difficulty, but by setting things up correctly the argument goes through.

4.1.1 Ax-Schanuel. One may use a similar setup to the above, but now we only know that $\dim(V \cap W') > \dim V + \dim W' - n$. Nontheless, we may still define

$$I = \{t \in \mathbb{C}^n \mid \dim\left((V+t) \cap \mathfrak{F} \cap W'\right) = \dim(V \cap W')$$

and conclude that I contains many points. In fact, in this setting the argument can pushed through (see Tsimerman [2015]). However, in the Shimura setting, due to the extremely non-abelian nature of the groups involved and the fact that $V \cap \pi^{-1}(W)$ is not algebraic either in D, not once its pushedforward to X, the argument seems difficult to push through. However, there is a brilliant idea of Mok [n.d.] [4] which provides a great help in this context.

Mok realizes that by working in W, one can formulate the condition of the existence of V algebraically through a differential equation, even though the map π is extremely transcendental! This means that for a given W, if one V exists giving an excessively large dimension, then there must be a whole family of such V. With this extra freedom in hand to vary V, the argument goes through.

5 Arithmetic applications

We will discuss some problems that typically fall under the ”atypical intersection” umbrella.

5.1 Langs conjecture. Consider again the setting of the torus $X = \mathbb{C}^{\times n}$. The torsion points - points whose co-ordinates are all roots of unity - are distinguished algebraic points in X, and it is natural to ask which algebraic subvarieties contain infinitely many torsion points. In fact, it turns out to be a better (and essentially equivalent question) to ask which irreducible subvarieties contain a Zariski-dense set of torsion points. It is clear that subtori do, and in fact so do coset of a subtorus by a torsion point. The converse was conjectured by Lang [1966] and proven by Raynaud [1983a,b]:

Theorem 5.1. *Let $V \subset \mathbb{C}^{\times n}$ be an irreducible subvariety containing a Zariski dense set of torsion points. Then V is a coset of a subtorus of $\mathbb{C}^{\times n}$ by a torsion point.*

Recall that we defined the weakly special subvarieties to be cosets of subtori of X. The reason we used that strange terminology, is that we say that a *special subvariety* of X is translate of a torus by a torsion point. The above theorem is easily seen to be equivalent to the following statement: *The Zariski closure of an arbitrary union of special subvarieties is a finite union of special subvarieties*.

[4] In fact, Mok uses this idea in Mok [n.d.] to prove the Ax-Lindemann conjecture for all rank-1 quotients of hyperbolic space, even non-arithmetic ones!

The statement of Lang's conjecture can be generalized to the setting of abelian varieties almost verbatim, where we replace the word ”subtorus” by ”algebraic subgroup”. The resulting conjecture is known as the Manin-Mumford conjecture, and was first proven by Raynaud [1983a,b]. Below we will give a proof of Lang's conjecture using the ideas we have developed in the previous section with o-minimality and functional transcendence, following Pila and Zannier [2008].

5.2 André-Oort conjecture. Let S be a shimura variety, and $\pi : D \to S$ be its covering by the corresponding symmetric space. There is a natural $\overline{\mathbb{Q}}$ structure on the variety S, and there are distingiushed $\overline{\mathbb{Q}}$ points on S called *CM points*. We call $V \subset S$ a *special subvariety* if V is a weakly special subvariety which contains at least one CM point, which will inn fact force V to contain a Zariski-dense set of CM points. If $S = Y(1)$ is the moduli space of elliptic curves, then the CM points correspond to those complex elliptic curves E with extra endomorphisms, so that $\mathbb{Z} \subsetneq \mathrm{End}(E)$. More generally, if $S = \mathfrak{A}_g$ is the moduli space of principally polarized abelian varieties of dimension g, than the CM points correspond to those Abelian varieties A such that the endomorphism algebras $\mathrm{End}(A) \otimes \mathbb{Q}$ contain a field of degree $2g$ over $\mathbb{Q}$. This can be intuitively thought of as saying that A has “as many symmetries as possible”. Note that it is not immediately obvious that such abelian varieties are even defined over $\overline{\mathbb{Q}}$!

The André-Oort conjecture is the natural generalization of Lang's conjecture to this setting:

Conjecture 5.1. *Let $V \subset S$ be an irreducible subvariety containing a Zariski dense set of torsion points. Then V is a special subvariety.*

There has been much work on the AO conjecture. It was first proven unconditionally for $Y(1)^2$ by André, and later proven in generality but conditionally on the generalized Riemann hypothesis in Ullmo and Yafaev [2014], building on an idea of Edixhoven [2005] who handle the case of $Y(1)^2$ conditionally. Later, Pila adapted his method with Zannier to prove the AO conjecture unconditionally for $Y(1)^n$, and it was recently proven for $\mathfrak{A}_g$. The general case remains open

5.3 Crucial Ingredient: Galois Orbits.

5.3.1 Tori. A crucial ingredient in the Pila-Zannier approach to the special point problems that we have discussed is the ability to prove lower bounds for Galois orbits of special points. In the setting of Lang's conjecture, the special points are simply torsion points of the torus, so in this setting the relevant galois action is the action of $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$ on the roots of unity. By Class field theory for $\mathbb{Q}$, we know that this action is transitive on points of exact order n for each n, so we know precisely how large the Galois orbits are.

5.3.2 Abelian Varieties. In the setting of an Abelian variety A over $\mathbb{Q}$, it is much more difficult to get a handle on the action on the torsion points of A. Given a point P of order n, the lower bound that one needs is $[\mathbb{Q}(P) : \mathbb{Q}] \gg n^\delta$ for some positive integer $\delta > 0$. There are a few was to proceed here. The Galois action on torsion points of A gives rise to a morphism $\rho_A : \mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q}) \to \mathrm{Gsp}_{2d}(\widehat{\mathbb{Z}})$ where $d = \dim A$, and the action on torsion points can be read off easily from this action. It is conjectured that the image is open in the $\widehat{\mathbb{Z}}$ points of the Mumford-Tate group. While this is still open, it follows from work of Serre that that the image contains a power of the center, $(\widehat{\mathbb{Z}}^\times)^m$, for some positive integer m. This immediately implies that the orbit of any torsion point is of size at least $|(\mathbb{Z}/n\mathbb{Z})^{\times m}| \gg n^{1-o(1)}$, which is sufficient.

There is also an analytic approach by D. W. Masser [1977] which yields this result in a form more suitable for studying families of Abelian varieties.

5.3.3 Shimura Varieties. In the setting where X is a Shimura variety and $p \in X$ is a CM point, one may use the theory of complex multiplication developed by Shimura, Taniyama, and others to relate the size of the Galois orbit of p to class groups of number fields. For example, if $X = X(1)$ and p corresponds to an elliptic curve E_p with endomorphism ring the ring of integers in $K = \mathbb{Q}(\sqrt{D})$ then the size of the Galois orbit of p is equal to the class number of K, which is asymptotic to $|D|^{\frac{1}{2}+o(1)}$. In general, there are two naturally associated tori S, T over $\mathbb{Q}$ such that the size of the Galois orbit of p is the image of the class group of S in the class group of T. Class groups of Tori can be defined naturally just as for number fields (see Shyr [1977]) and the sizes of the class groups satisfy an asymptotic Brauer-Siegel formula which gives us very precise control. However, the challenge comes from the fact that these isogenies can kill torsion of low order, and it is very difficult to obtain unconditional upper bounds on low-order torsion in class groups of number fields. In particular, it is a conjecture that for a number field K of discriminant D, fixed degree n over $\mathbb{Q}$, and a positive integer m that $|CL(K)[m]| = |D|^{o(1)}$, and yet one cannot in most cases even beat the trivial bound $|D|^{\frac{1}{2}+o(1)}$ given by Brauer-Siegel! For results in this direction see Bhargava, Shankar, Taniguchi, Thorne, Tsimerman, and Zhao [2017], Ellenberg and Venkatesh [2007]. However, we cannot even show that the class group of imaginary quadratic fields are not all mostly 5-torsion! If one assumes GRHOne can show something in this direction by using GRH to produce small split primes, and this is the primary reason that André-Oort is only known unconditionally under GRH. Nevertheless, one may push these methods to prove AO unconditionally for $\mathcal{A}_g$ for $g \le 6$. See Tsimerman [2012],Ullmo and Yafaev [2015].

5.3.4 The case of $\mathcal{A}_g$. The required lower bounds were recently established for $X = \mathcal{A}_g$ using methods different from the above in Tsimerman [2018]. As a corollary, one derives the following result (which seems to be of the same level of difficulty), which was not preivously known:

Theorem 5.2. *For each positive integer g, there are finitely many CM points in $\mathcal{A}_g(\mathbb{Q})$.*

We briefly describe the proof. Let x be a CM point in $\mathcal{A}_g$. Then x occurs in a finite collection C of those CM points with the same endomorphism ring and CM type as x. In the case of elliptic curves $g = 1$ the set C is a single Galois orbit, but for larger g that is not usually the case. Moreover, the set C is acted on by the Galois group $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$ and the orbits all have the same size. So if x is defined over $\mathbb{Q}$, then all the points in C are defined over $\mathbb{Q}$. Moreover, all the points in C are isogenous. Now one uses a famous theorem of D. Masser and Wüstholz [1993]:

Theorem 5.3. *Let A, B be isogenous abelian varieties over some number field K. Then the degree of the smallest isogeny N between them satisfies $N \leq \max(h(A), [K : \mathbb{Q}])^{c_g}$ where $h(A)$ denotes the Faltings height of A, and $c_g > 0$ is a positive constant depending only on g.*

In other words, if two abelian varieties are isogenous, then there must exist an isogeny between them whose degree is not too large. Applying the above theorem to any two points in C and using our assumption that all the points in C are defined over $\mathbb{Q}$, it follows that they all have isogenies between them of degree at most $h(A)^{c_g}$. However, there are only polynomially many isogenies of degree N that one can take, so if $h(A)$ is sufficiently small one obtains a contradiction.

Now, in general heights of abelian varieties can be quite hard to get a handle on. However, for CM abelian varieties A, Colmez [1993] has a beautiful conjecture computing the Faltings height of A in terms of certain L-values at 1 of Artin representations. This conjecture combined with standard estimates on L functions implies the desired upper bound on $h(A)$. While the Colmez conjecture is still open in general, it was recently proven independently in Andreatta, Goren, Howard, and Madapusi Pera [2018], Yuan and Zhang [2018] that if one averages over a finite family of CM types, the Colmez conjecture is true. This finite average has minimal effect from an analytic standpoint, so is enough to complete the proof.

5.4 Proof of the André-oort conjecture. Once one has the required Galois orbit lower bounds and Functional Transcendence results at ones disposal, the proofs of the André-Oort conjecture and the Lang conjecture proceed among essentially identical lines, so we give them both at once using the language of special varieties. So suppose that $\pi : D \to X$

is our covering map, $V \subset X$ is an algebraic variety and V contains a Zariski-dense set of special points. It follows that V is defined over $\overline{\mathbb{Q}}$, and thus over a number field. For simplicity of exposition we assume that V is defined over $\mathbb{Q}$, though this minimally affects the proof. Let x_i be a sequence of CM points which is Zariski-dense in V. Let $\mathfrak{F} \subset D$ be a standard fundamental domain, and consider the pre-images y_i of the x_i under $\pi \mid \mathfrak{F}$. It turns out that the y_i are all defined over number fields of bounded degree over $\mathbb{Q}$. For example, in the case of Lang's conjecture, the pre-image under $z \to e^{2\pi i z}$ of the torsion points the rational numbers , and if one restricts to a suitable fundamental domain one obtains the rational numbers between 0 and 1. Moreover, the Galois lower bounds imply that the heights of these numbers satsify $H(y_i) \ll |\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})x_i|^{\delta}$ for some fixed positive constant δ. Since V contains all of $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})x_i$, it follows that the pe-image W of V under π contains a lot of rational points. By the Counting Theorem 3.2 it follows that W must contain algebraic subvarieties containing all but finitely many of these special points. By Theorem 2.5 and its generalizations, it follows that these algebraic subvarieties must be pre-images of special varieties contained in V. We've thus succeeded in showing that all but finitely many special points in V are contained in higher dimensional special subvarieties. At this point, an induction argument using to finish the proof. We don't give the argument since it requires some deeper analysis using definability in o-minimal structures, and instead refer the interested reader to Pila and Zannier [2008] and Tsimerman [2015].

5.5 The Zilber-Pink Conjecture. Let us return to the setting of a Torus, and consider a proper subvariety $V \subset \mathbb{C}^{\times n}$. For any special subvariety (coset of a subtorus by a torsion point) T, naive dimension theory suggests that the dimension of $V \cap T$ is $\dim V + \dim T - n$. Thus, whenever $\dim(V \cap T) + \dim n > \dim V + \dim T$ we call $V \cap T$ an *unlikely intersection* for V. Notice that if T is a point, then V only intersects T if V contains T, in which case the intersection will be unlikely. Thus this concept generalizes the special point problems studied above. Of course, unlikely intersections can be easily constructed. For example, one may take V to be a subvariety of a subtorus. Then all of V is an unlikely intersection for V! More subtly, one may take any codimension ≥ 2 special variety T, take a codimension 1 subvariety $U \subset T$ and then arbitrarily take V to be another variety containing U as a divisor. However, one has the following conjecture, made by Bombieri-Masser-Zannier:

Conjecture 5.2. *Bombieri, D. Masser, and Zannier [1999] and Zilber [2002]*

Let $V \subset \mathbb{C}^{\times n}$ be a proper subvariety. Then there are finitely many unlikely intersections for V which are maximal *under inclusion.*

One may of course easily generalize to the setting of abelian varieties or (mixed) Shimura varieties, and it is in this general setting that the Zilber-Pink conjecture occurs. One may generalize the Pila-Zannier method to this setting, but this conjecture is substantially more difficult than the corresponding one for special point problems. For one thing, the required functional transcendence input is the Ax-Schanuel Theorem rather then the easier Ax-Lindemann theorem. However, this has been established in (essentially) complete generality so is no longer an obstruction. However, the lower bounds for Galois orbits that are required seem completely out of reach in general. In the André-Oort conjecture, we are interested in lower bounds of CM points, for which we have all the understanding provided by the theory of complex multiplication, and even here the problem is not solved. For the Zilber-Pink conjecture, one must understand Galois orbits of $V \cap T$, and these have no discernible special structure.

Nonetheless, there are impressive partial results. In the setting of a Torus, the result is known if V is a curve by Bombieri, D. Masser, and Zannier [1999]. In the shimura variety setting, It is proven by Habegger-Pila that if $C \subset Y(1)^n$ is a curve where the degrees of the n projections $C \to Y(1)$ are all different, then the Zilber-Pink conjecture holds. Their proof uses the Masswer-Wüstholz theorem in a very clever way to get prove the required Galois lower bounds. This result was recently partially generalized to certain curves in $\mathfrak{A}_g$ by Orr [2017].

5.6 Results on integral points. In recent, as of yet unpublished work, Lawrence-Venkatesh have come up with a new method by which to use transcendence results to prove powerful finiteness results concerning *integer points* on Varieties. There are sometimes called Shafarevich-type theorems after Shafarevich's theorem that there do not exist elliptic curves over $\operatorname{Spec} \mathbb{Z}$. Briefly, their idea is as follows. Consider a smooth, projective family $Y \to B$ over some algebraic variety $B/\mathbb{Q}$, such that some fibral cohomology group $H^n(Y_b, \mathbb{C})$ is non-zero and the corresponding period map $\psi : B \to X = D/\Gamma$ is not constant. Then one may use global results on Faltings to show that the Galois representations $\rho_b : \mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q}) \to H^n(Y_b, \mathbb{Q}_p)$ occur in finitely many isomorphism classes, as b varies over the integer points $B(\mathbb{Z})$. The reason one requires integer rather than rational points is so that one may control how many primes of bad reduction ρ_b has. Now consider a "p-adic lift" of ψ, which looks like $\tilde{\psi} : B(\mathbb{Q}_p) \to D(\mathbb{Q}_p)$.By results of p-adic hodge theory, the finiteness of Galois representations of the ρ_b implies that $\tilde{\psi}(B(\mathbb{Z}))$ is contained in an algebraic subvariety H of D. Now if $B(\mathbb{Z})$ is infinite, or Zariski-dense, one obtains a p-adic violation of a version of the Ax-Schanuel Theorem 2.4. In fact, this last part is not a complication, since one may formally deduce the p-adic Ax-Schanuel theorem from the complex version proven in Bakker and Tsimerman [2017]

Of course, we are skirting a myriad of complexities, but they can already prove the Mordell conjecture[5] using their methods - for which they do not require the Ax-Schanuel theorem, so it seems quite possible that this method has the potential to prove much more.

[5] The paper in its current form only handles certain cases, but they now claim the full result

Acknowledgments. It is a pleasure to thank Jonathan Pila and Peter Sarnak for many discussions regarding the above topics, and for teaching me much of what I know about the subject.

SHARP SPHERE PACKINGS

Maryna Viazovska

Abstract

In this talk we will speak about recent progress on the sphere packing problem. The packing problem can be formulated for a wide class of metric spaces equipped with a measure. An interesting feature of this optimization problem is that a slight change of parameters (such as the dimension of the space or radius of the spheres) can dramatically change the properties of optimal configurations. We will focus on those cases when the solution of the packing problem is particularly simple. Namely, we say that a packing problem is sharp if its density attains the so-called linear programming bound. Several such configurations have been known for a long time and we have recently proved that the E_8 lattice sphere packing in $\mathbb{R}^8$ and the Leech lattice packing in $\mathbb{R}^{24}$ are sharp. Moreover, we will discuss common unusual properties of shared by such configurations and outline possible applications to Fourier analysis.

1 Introduction

The classical sphere packing problem asks for the densest possible configuration of non-overlapping equal balls in the three dimensional Euclidean space. This natural and even naive question remained open for several centuries and has driven a lot of research in geometry, combinatorics and optimization. The complete proof of the sphere packing problem was given by T. Hales in 1998 Hales [2005].

A similar question can be asked for Euclidean spaces of dimensions other then three or for spaces with other geometries, such as a sphere, a projective space, or the Hamming space. The packing problem is not only an exciting mathematical puzzle, it also plays a role in computer science and signal processing as a mathematical model of the error correcting codes.

In this paper we will focus on the upper bounds for the sphere packing densities. There exist different methods for proving such bounds. One conceptually simple and still rather

MSC2010: 94B65.

powerful approach is the linear programming. We are particularly interested in those packing problems, which can be completely solved by this method. We will call such arrangements of balls the *sharp packings*.

The sharp packings have many interesting properties. In particular, the distribution of pairwise distances between the centers of sharply packed spheres gives rise to summation and interpolation formulas. In the last section of this paper we will discuss a new interpolation formula for the Schwartz functions on the real line.

2 Linear programming bounds for sphere packings in metric spaces

Let (M, dist) be a metric space equipped with a measure μ. For $x \in M$ and $r > 0$ we denote by $B(x,r)$ the open ball with center x and radius r. Let X be a discrete subset of M such that $\mathrm{dist}(x,y) \geq 2r$ for any distinct $x, y \in X$. Then the set $\mathcal{P} := \cup_{x \in X} B(x,r)$ is a *sphere packing* in M. We define the *density* of $\mathcal{P}$ as

$$\Delta_{\mathcal{P}} := \sup_{x_0 \in M} \limsup_{R \to \infty} \frac{\mu(\mathcal{P} \cap B(x_0, R))}{\mu(B(x_0, R))}.$$

Our goal is to search for densest possible configurations and to prove upper bounds on the packing density.

The *linear programming* is a powerful and simple method to prove upper bounds for the packing problems. This technique was successfully applied to obtain upper bounds in a wide range of discrete optimization problems such as error-correcting codes Delsarte [1972], equal weight quadrature formulas Delsarte, Goethals, and Seidel [1977], and spherical codes Kabatiansky and Levenshtein [1978] and Pfender and Ziegler [2004]. In this section we explain the idea behind this method, consider several examples, and discuss the limitations of this approach.

The essence of the linear programming method is the replacement of a complicated geometrical optimization problem by a simpler convex optimization problem.

We say that a function $g : \mathbb{R}_{\geq 0} \to \mathbb{R}$ is *geometrically positive* (with respect to a metric space M) if

$$\sum_{x,y \in Y} g(\mathrm{dist}(x,y)) \geq 0$$

for all finite subsets $Y \subset M$.

We can obtain an upper bound for the packing density by solving the following convex optimization problem. For simplicity we assume that M is compact.

Lemma 2.1. *Fix $r > 0$. Let $g_r : \mathbb{R}_{\geq 0} \to \mathbb{R}$ be a function and c_0 be a positive constant such that*

(i) $g_r - c_0$ is geometrically positive
(ii) $g_r(t) \le 0$ for all $t \in [2r, \infty)$. Then any packing of balls of radius r in M has cardinality at most

$$\frac{g_r(0)}{c_0}.$$

Proof. Let $X \subset M$ be a subset such that $\operatorname{dist}(x, y) \ge 2r$ for any pair of distinct points $x, y \in X$. Then condition (i) implies

$$\sum_{x,y \in X} g_r(\operatorname{dist}(x, y)) = \sum_{x,y \in X} (g_r(\operatorname{dist}(\mathrm{x}, \mathrm{y})) - c_0) + |X|^2 c_0 \ge |X|^2 c_0.$$

On the other hand, by condition (ii)

$$\sum_{x,y \in X} g_r(\operatorname{dist}(x, y)) = |X| g_r(0) + \sum_{\substack{x,y \in X \\ x \ne y}} g_r(\operatorname{dist}(x, y)) \le |X| g_r(0).$$

Hence, we arrive at

$$|X| \le \frac{g_r(0)}{c_0}.$$

□

Unfortunately, the description of the cone of geometrically positive functions is usually a very difficult problem. Therefore, we will consider a smaller cone, the cone of so-called positive-definite functions. A function $p : \mathbb{R}_{\ge 0} \to \mathbb{R}$ is *positive definite* (with respect to a metric space M) if

$$\sum_{x,y \in Y} w_x \, w_y \, p(\operatorname{dist}(x, y)) \ge 0$$

for all finite subsets $Y \subset M$ and all collections of real weights $\{w_y\}_{y \in Y}$. For metric spaces M with a big isometry group the cone of positive definite functions has a simple description in terms of representation theory.

Theorem 2.2. *(Bocher 1941) Let G be a topological group acting continuously on a topological space M. For every G-invariant positive-definite kernel $p : M \times M \to \mathbb{C}$, there exists a unitary representation V of G and a continuous, G-equivariant map $\phi : M \to V$ such that $p(x, y) = \langle \phi(x), \phi(y) \rangle$ for all $x, y \in M$.*

For example, the following theorem characterizes positive definite functions on the standard sphere $S^{d-1} = \{x \in \mathbb{R}^d \mid \|x\|^2 = 1\}$. Let $P_k^d(t)$ denote the degree k ultraspherical (i.e. Gegenbauer) polynomial, normalized with $P_k^d(1) = 1$. These polynomials are orthogonal with respect to the measure $(1 - t^2)^{(d-3)/2} \, dt$ on $[-1, 1]$.

Theorem 2.3. *(Schoenberg [1942]) A function $g : [0,2] \to \mathbb{R}$ is positive definite with respect to the sphere S^{d-1} if and only if*

$$g(s) = \sum_{k=0}^{\infty} c_k P_k^d(1 - \frac{1}{2}s^2)$$

where $c_k \geq 0$.

H. Cohn and N. Elkies have applied the linear programming technique to the sphere packing problem in Euclidean space Cohn and Elkies [2003]. This problem is rather subtle since the Euclidean space in non-compact and the Lebesgue measure of the whole space is not finite.

Let us setup some notations in order to formulate the main result of Cohn and Elkies [ibid.]. The *Fourier transform* of an L^1 function $f : \mathbb{R}^d \to \mathbb{C}$ is defined as

$$\mathfrak{F}(f)(y) = \widehat{f}(y) := \int\limits_{\mathbb{R}^d} f(x)\, e^{-2\pi i x\cdot y}\, dx, \quad y \in \mathbb{R}^d$$

where $x \cdot y = \frac{1}{2}\|x\|^2 + \frac{1}{2}\|y\|^2 - \frac{1}{2}\|x - y\|^2$ is the standard scalar product in $\mathbb{R}^d$. A C^∞ function $f : \mathbb{R}^d \to \mathbb{C}$ is called a *Schwartz function* if it tends to zero as $\|x\| \to \infty$ faster then any inverse power of $\|x\|$, and the same holds for all partial derivatives of f. The set of all Schwartz functions is called the *Schwartz space*. The Fourier transform is an automorphism of this space. We will also need the following wider class of functions. We say that a function $f : \mathbb{R}^d \to \mathbb{C}$ is *admissible* if there is a constant $\delta > 0$ such that $|f(x)|$ and $|\widehat{f}(x)|$ are bounded above by a constant times $(1 + |x|)^{-d-\delta}$. The following theorem is the key result of Cohn and Elkies [ibid.]:

Theorem 2.4 (Cohn and Elkies [ibid.]). *Suppose that $f : \mathbb{R}^d \to \mathbb{R}$ is an admissible function, $r_0 \in \mathbb{R}_{>0}$ and they satisfy:*

(2-1) $$f(x) \leq 0 \text{ for } \|x\| \geq r_0,$$

(2-2) $$\widehat{f}(x) \geq 0 \text{ for all } x \in \mathbb{R}^d$$

and

(2-3) $$f(0) = \widehat{f}(0) = 1.$$

Then the density of d-dimensional sphere packings is bounded above by

$$\frac{\pi^{\frac{d}{2}} r_0^d}{2^d\, \Gamma(\frac{d}{2} + 1)} = \frac{f(0)}{\widehat{f}(0)} \cdot \operatorname{Vol} B_d(0, \frac{r_0}{2}).$$

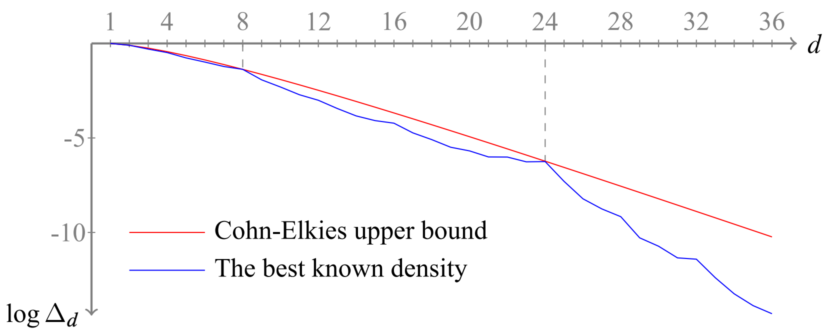

Figure 1: Upper and lower bounds for Δ_d

The *sphere packing constant* Δ_d is the supremum of all densities of sphere packings in $\mathbb{R}^d$.

Cohn and Elkies have numerically applied Theorem 2.4 to the sphere packing constant in dimensions from 1 to 36. The numerical results obtained in Cohn and Elkies [ibid.] are illustrated in Figure 1. The red line represents an upper bound obtained from Theorem 2.4 and the blue line shows the density of the best known configuration in each dimension.

3 Sharp linear programming bounds

A natural question is whether the linear programming bounds can be sharp. As we have relaxed our original optimization problem, we do not expect sharp bounds in general. However, we know several examples when the linear programming technique provides a complete solution to the optimization problem.

A beautiful example is the computation of the kissing number in dimensions 8 and 24. We recall, that the *kissing number* $K(d)$ is the maximal number of "blue" spheres that can touch a "red" sphere of the same size in d-dimensional Euclidean space. It was proven by Odlyzko and Sloane [1979] and independently by Levenshtein [1979] that $K(8) = 240$ and $K(24) = 196560$. The proof of this result is based on the linear programming method. Let us consider the kissing problem in dimension 8 in more detail. The kissing configuration can be described as follows. Consider 112 vectors of type $(0^6, \pm 2^2)$ that is, with 2 non-zero coordinates, which are ± 2 and 128 vectors of type $(\pm 1^8)$ with an even number of positive components. All the $122 + 128 = 240$ vectors have length $2\sqrt{2}$. The minimum distance between these vectors also equals $2\sqrt{2}$. Therefore, they form a kissing configuration. The only missing step is a construction of a suitable positive definite function p_8. Consider the following polynomial on $[-1,1]$:

$$p_8(t) := (t+1)^2\,(t+\frac{1}{2})^2\,t^2\,(t-\frac{1}{2}).$$

The coefficients c_k of the expansion of p_8 in Gegenbauer polynomials are all non-negative and $p_8(1)/c_0 = 240$.

The dimensions 8 and 24 are also special for the sphere packing problem in the Euclidean space. On the Figure 1 we can see that the blue line representing a lower bound on the sphere packing constant and the red line representing Cohn-Elkies bound come very close together at the dimensions 8 and 24. In Cohn and Elkies [2003] Cohn and Elkies proved the following estimates

Theorem 3.1 (Cohn and Elkies [ibid.]). *We have*

$$\Delta_8 \leq 1.00016\,\Delta_{E_8},$$

$$\Delta_{24} \leq 1.019\,\Delta_{\Lambda_{24}}.$$

Here Δ_{E_8} denotes the density of the E_8-lattice packing in $\mathbb{R}^8$ and $\Delta_{\Lambda_{24}}$ denotes the density of the Leech lattice packing in $\mathbb{R}^{24}$.

It is proven in M. S. Viazovska [2017] and Cohn, Kumar, Miller, Radchenko, and M. Viazovska [2017] that the Cohn-Elkies linear programming bounds are indeed sharp in these dimensions. The sphere packing problem in dimensions 8 and 24 will be discussed in more detail in the next section.

At the end of this section, we would like to mention several packing problems for which the numerical linear programming bounds are extremely close to the known lower bounds, however the question whether these bounds are sharp is still open. The first example, is the packing of equal disks in dimension 2. The packing problem itself has been solved long time ago Thue [1910], Fejes [1943] by a geometric method. The numerical results of Cohn and Elkies [2003] suggest that the linear programming bound is also sharp in this case, however the exact solution is not known yet.

There is a numerical evidence that the packing problem can be solved by linear programming also for other convex center symmetric bodies in $\mathbb{R}^2$. H. Cohn and G. Minton have numerically studied the packings with translates 2-dimensional of L_p-balls using linear programming bounds proven in Cohn and Elkies [ibid., Theorem B.1]. Recall, that for $p > 0$ a p-ball in $\mathbb{R}^d$ is the set of points $x = (x_1, \ldots, x_d)$ such that

$$|x_1|^p + \ldots + |x_d|^p \leq 1.$$

Cohn and Minton conjecture that the resulting bounds are sharp. Thanks to a theorem proven by L. Fejes Tóth we know that the optimal packing of congruent convex center symmetric bodies in $\mathbb{R}^2$ is always a lattice packing. An open question is whether this result can be proven by linear programming.

Finally, interesting numerical results has been obtained for translative packings of L_p-balls in $\mathbb{R}^3$. On Figure 2 we plot the upper and lower bounds for such packings computed in Dostert [2017]. We know that the classical sphere packing problem in dimension 3 can not be solved by linear programming. However, for L_p-balls with parameter p in the interval $(1.2, 1.4)$ the lower and upper bounds come extremely close. So there is a hope that these bounds are sharp for some values of p.

4 The sphere packing problem in dimensions 8 and 24

In this section we will consider the sphere packing problem in the Euclidean spaces of dimensions 8 and 24.

It the 8-dimensional Euclidean space there exists a highly structured configuration – the E_8 lattice, which we have already mentioned in Section 3. The E_8-lattice $\Lambda_8 \subset \mathbb{R}^8$ is given by

$$\Lambda_8 = \{(x_i) \in \mathbb{Z}^8 \cup (\mathbb{Z} + \tfrac{1}{2})^8 | \ \textstyle\sum_{i=1}^8 x_i \equiv 0 \pmod 2\}.$$

Λ_8 is the unique even, unimodular lattice of rank 8. The minimal distance between two points in Λ_8 is $\sqrt{2}$. The E_8-lattice sphere packing is the packing of unit balls with centers at $\sqrt{2}\Lambda_8$.

The following theorem implies that the optimality of the E_8-lattice sphere packing can be proven by the Cohn-Elkies method.

Theorem 4.1. *(M. S. Viazovska [2017]) There exists a radial Schwartz function $f_{E_8} : \mathbb{R}^8 \to \mathbb{R}$ which satisfies:*

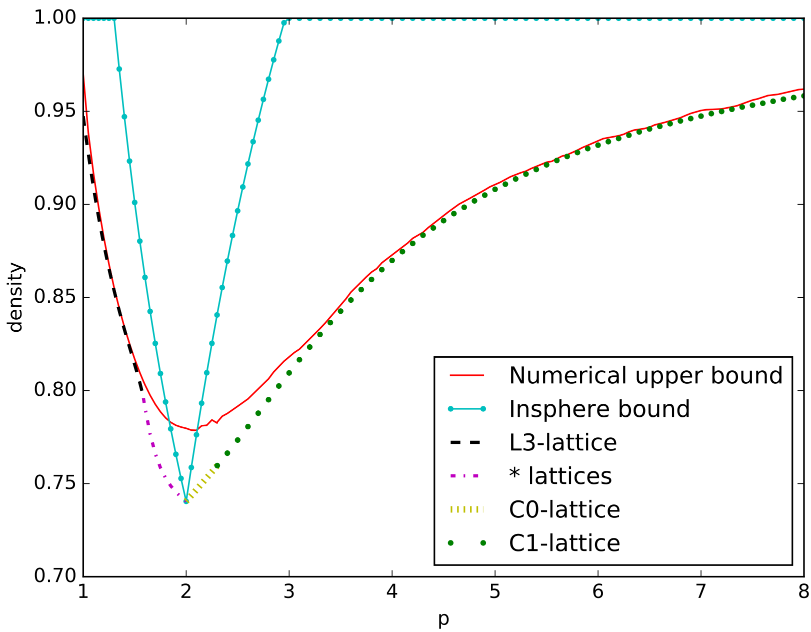
$$f_{E_8}(x) \le 0 \text{ for } \|x\| \ge \sqrt{2}$$
$$\widehat{f}_{E_8}(x) \ge 0 \text{ for all } x \in \mathbb{R}^8$$
$$f_{E_8}(0) = \widehat{f}_{E_8}(0) = 1.$$

An immediate corollary of Theorems 2.4 and 4.1.

Theorem 4.2. *No packing of unit balls in Euclidean space $\mathbb{R}^8$ has density greater than that of the E_8 lattice packing. Therefore $\Delta_8 = \frac{\pi^4}{384} \approx 0.25367$.*

Also in dimension 24 there exists a lattice with unusually tight structure. The Leech lattice Λ_{24} is an even, unimodular lattice of rank 24. The minimal distance between two points in Λ_{24} is 2, and it is the only even, unimodular lattice of rank 24 with this property. The Leech lattice sphere packing is the packing of unit balls with centers at Λ_{24}. The

Figure 2: Lower and upper bounds for the density of translative packings of p-balls in $\mathbb{R}^3$ computed in Dostert [2017].



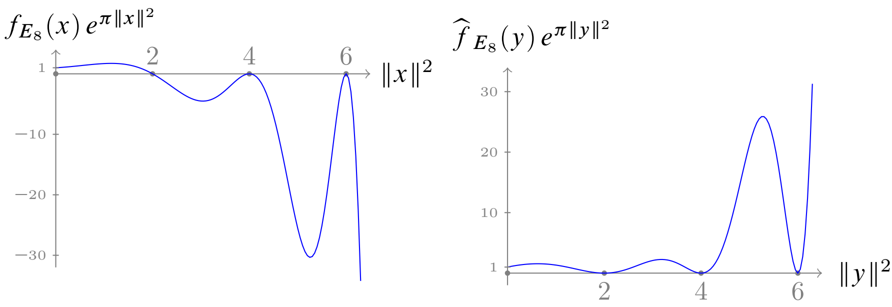


Figure 3: Plot of the functions f_{E_8} and $\widehat{f}_{E_8}$

optimality of this packing also has been proved by the Cohn-Elkies linear programming method.

Theorem 4.3. *(Cohn, Kumar, Miller, Radchenko, and M. Viazovska [2017]) There exists a radial Schwartz function $f_{\Lambda_{24}} : \mathbb{R}^{24} \to \mathbb{R}$ which satisfies:*

$$f_{\Lambda_{24}}(x) \leq 0 \textit{ for } \|x\| \geq 2$$
$$\widehat{f}_{\Lambda_{24}}(x) \geq 0 \textit{ for all } x \in \mathbb{R}^{24}$$
$$f_{\Lambda_{24}}(0) = \widehat{f}_{\Lambda_{24}}(0) = 1.$$

This result immediately implies

Theorem 4.4. *(Cohn, Kumar, Miller, Radchenko, and M. Viazovska [ibid.]) No packing of unit balls in the Euclidean space $\mathbb{R}^{24}$ has density greater than that of the Leech lattice packing. Therefore $\Delta_{24} = \frac{\pi^{12}}{12!} \approx 0.00193$.*

Remarks:

1. Without loss of generality we may assume that f_{E_8} is radial.

2. By the Poisson summation formula we have

$$f_{E_8}(0) \geq \sum_{\ell \in \Lambda_8} f_{E_8}(\ell) = \sum_{\ell \in \Lambda_8} \widehat{f}_{E_8}(\ell) \geq \widehat{f}_{E_8}(0).$$

This can happen only if $f_{E_8}(\sqrt{2n}) = \widehat{f}_{E_8}(\sqrt{2n}) = 0$ for all $n \in \mathbb{Z}_{>0}$.

5 Fourier interpolation

The idea behind our construction of f_{E_8} and $f_{\Lambda_{24}}$ is the hypothesis that a radial Schwartz function p can be uniquely reconstructed from the values

$$\{p(\sqrt{2n}),\, p'(\sqrt{2n}),\, \widehat{p}(\sqrt{2n}),\, \widehat{p}'(\sqrt{2n})\}_{n=0}^{\infty}$$

The proof of this statement is a goal an ongoing project of the author in collaboration with H. Cohn, A. Kumar, S. D. Miller, and D. Radchenko.

In this section we will present a simpler first degree interpolation formula of this type.

Theorem 5.1. *(Radchenko, Viazovska Radchenko and M. Viazovska [2017]) There exists a collection of Schwartz functions $b_0, a_n\colon \mathbb{R}\to\mathbb{R}$ with the property that for any Schwartz function $p\colon \mathbb{R}\to\mathbb{R}$ and any $x\in\mathbb{R}$ we have*

$$\begin{aligned} p(x) =&c_0(x)\, p'(0) + \sum_{n\in\mathbb{Z}} a_n(x)\, p(\operatorname{sign}(n)\sqrt{|n|}) \\ &+ \widehat{c}_0(x)\, p'(0) + \sum_{n\in\mathbb{Z}} \widehat{a}_n(x)\widehat{p}(\operatorname{sign}(n)\sqrt{|n|}), \end{aligned} \tag{5-1}$$

where the right-hand side converges absolutely.

Moreover, we can describe all possible collections of values of a Schwartz function at the points $\{\pm\sqrt{n}\}_{n=0}^{\infty}$.

Denote by $\mathfrak{s}$ the vector space of all rapidly decaying sequences of real numbers, i.e., sequences $(x_n)_{n\geq 0}$ such that for all $k>0$ we have $n^k x_n\to 0, n\to\infty$.

We denote by $\mathcal{S}$ the space of Schwartz functions on $\mathbb{R}$. Consider the map $\Psi\colon \mathcal{S}\to \mathbb{R}^2\oplus\mathfrak{s}\oplus\mathfrak{s}$ given by

$$\Psi(p) = \left(p'(0), \widehat{p}'(0), (p(\operatorname{sign}(n)\sqrt{|n|}))_{n\in\mathbb{Z}}, (\widehat{p}(\operatorname{sign}(n)\sqrt{|n|}))_{n\in\mathbb{Z}}\right).$$

Theorem 5.2. *(Radchenko, Viazovska Radchenko and M. Viazovska [ibid.]) The map Ψ is an isomorphism between the space of Schwartz functions and the vector space* $\ker L\subset \mathbb{R}^2\oplus\mathfrak{s}\oplus\mathfrak{s}$, *where $L\colon \mathbb{R}^2\oplus\mathfrak{s}\oplus\mathfrak{s}\to\mathbb{R}^2$ is the linear map*

$$\begin{aligned} L :&(x_0', y_0', (x_n)_{n\in\mathbb{Z}}, (y_n)_{n\in\mathbb{Z}}) \mapsto \\ &\Bigg(\sum_{n\in\mathbb{Z}} x_{n^2} - \sum_{n\in\mathbb{Z}} y_{n^2}, \\ &2x_0' + \sum_{n\in\mathbb{Z}} \operatorname{sign}(n)\frac{r_3(|n|)\,x_n}{\sqrt{|n|}} - 2iy_0' - \sum_{n\in\mathbb{Z}} i\operatorname{sign}(n)\frac{r_3(|n|)y_n}{\sqrt{|n|}}\Bigg). \end{aligned}$$

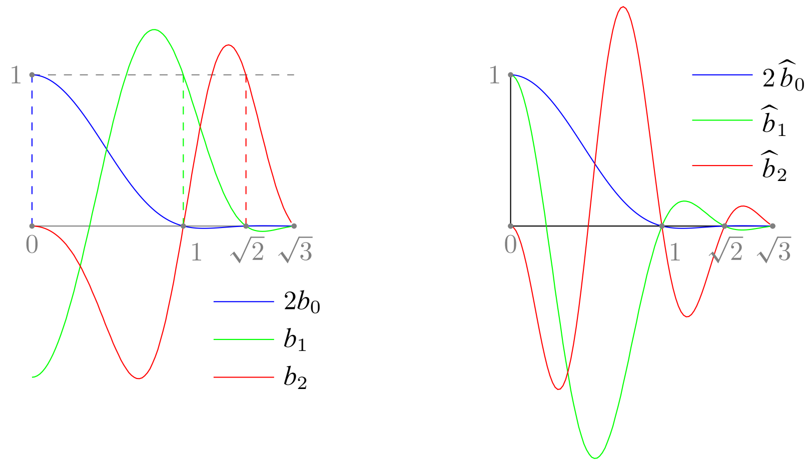

Figure 4: Plots of $b_n(x) := a_n(x) + a_n(-x)$ and $\widehat{b}_n$ for $n = 0, 1, 2$.

Also Theorem 5.1 allows us to construct an unusual family of discrete measures on the real line. A *cristalline measure* on $\mathbb{R}^d$ is a tempered distribution μ such that μ and $\widehat{\mu}$ are both charges with locally finite support. A simplest example of a cristalline measure is the *Dirac comb*

$$\mu_{\text{Dirac}} = \sum_{n\in\mathbb{Z}} \delta_n.$$

Recently, Lev and Olevskii [2015] have proven that crystalline measures with uniformally discrete support and spectrum (the support of the Fourier transform) can be obtained from the Dirac comb by dilations, shifts, multiplication on exponentials, and taking linear combinations.

Theorem 5.3. *(Lev and Olevskii [ibid.]) Let μ be a crystalline measure on $\mathbb{R}$ with uniformally discrete support and spectrum. Then the support of μ is contained in a finite union of translates of a certain lattice L. Moreover, μ is of the form*

$$\mu = \sum_{j=1}^{N} P_j \sum_{\lambda\in L+\theta_j} \delta_\lambda$$

where θ_j, $j = 1, \ldots, N$ are real numbers and P_j, $j = 1, \ldots, N$ are trigonometric polynomials.

The interpolation formula implies that there exists a continuous family of *exotic* crystalline measures

$$\mu_x := \delta_x + \delta_{-x} - \sum_{n=0}^{\infty} b_n(x)\,(\delta_{\sqrt{n}} + \delta_{-\sqrt{n}}).$$

Let us briefly explain our strategy for the construction of the interpolating basis a_n, c_0 introduced in Theorem 5.1. We will separately consider the odd and even components of the Schwartz functions. We set $b_n(x) = a_n(x) + a_n(-x)$. Then the symmetry implies $b_n = b_{-n}$.

Let us consider the generating series formed by the functions $\{b_n\}_{n=0}^{\infty}$ and their Fourier transforms. For $x \in \mathbb{R}$ and a complex number τ with $\Im(\tau) > 0$ we define

$$F(x,\tau) := \sum_{n=0}^{\infty} b_n(x)\, e^{\pi i n \tau}$$

$$\widetilde{F}(x,\tau) := \sum_{n=0}^{\infty} \widehat{b}_n(x)\, e^{\pi i n \tau}.$$

We will show that these two functions satisfy a functional equation with respect to the variable τ. Indeed, the interpolation formula interpolation formula (5-1) applied to the Gaussian $e^{\pi i x^2 \tau}$ gives

$$e^{\pi i x^2 \tau} = F(x,\tau) + \frac{1}{\sqrt{-i\tau}}\widetilde{F}(x, \frac{-1}{\tau}).$$

In Radchenko and M. Viazovska [2017] we solve this functional equation using the theory of modular integrals. A similar idea also leads to the constuction of functions f_{E_8} and $f_{\Lambda_{24}}$ in Theorems 4.1 and 4.3.

CHARACTERISTIC SUBSETS AND THE POLYNOMIAL METHOD

Miguel N. Walsh

Abstract

We provide an informal discussion of the polynomial method. This is a tool of general applicability that can be used to exploit the algebraic structure arising in some problems of arithmetic nature.

1 Introduction

1.1 The polynomial method. This article provides an informal discussion of the polynomial method. For us, this is the idea that when studying a problem with an underlying algebraic structure, a set S may admit a simpler "characteristic subset" $A \subseteq S$ that controls S, in the sense that a polynomial vanishing at A with sufficiently high multiplicity is forced to vanish at all or most points of S. By using dimension counting arguments in the spirit of Siegel's lemma, one may then exploit the simplicity of A to find a polynomial with suitable characteristics vanishing at most points of S.

This idea has been applied in a wide variety of contexts. Our choice of topics is largely based on personal taste, but we do try to convey the multitude of areas where it is relevant, the similarities in how the method is applied in them and some connections that exist between the different subjects. A variant of the method where the dimension counting arguments are used to find a polynomial that produces an adequate partition of the given points, instead of vanishing at them, has proven remarkably useful in recent work and is also treated in this article. We do not present proofs, but many are discussed. We refer the reader to Guth [2016c] and Tao [2014] for some further surveys on this circle of ideas.

Part of this article was written while the author was a Clay Research Fellow.
MSC2010: primary 11B30; secondary 52C10, 42B10, 11L07, 14G05, 37A45.

1.2 Notation. Before we proceed let us summarise the notation that will be used. Given two quantities X and Y, we will write either $X = O(Y)$ or $X \lesssim Y$ to mean that there exists some absolute constant C such that the inequality $X \leq CY$ holds. If this constant depends on some other parameter d, we may indicate this using a subscript and write $X = O_d(Y)$ or $X \lesssim_d Y$. If A is a finite set of points, $|A|$ will stand for its cardinality. We shall write $\mathbb{F}_q$ for the finite field with q elements, while the notation $\mathbb{F}$ alone is meant to stand for an arbitrary field. Finally, given a polynomial $P \in \mathbb{F}[x_1, \ldots, x_n]$, we shall write $Z(P) = \{x \in \mathbb{F}^n : P(x) = 0\}$ for its zero set.

2 Incidence problems

2.1 Incidence geometry and its applications. We shall choose incidence geometry as our starting point and therefore spend some time motivating this subject. Some of the questions incidence geometry is concerned with rank among the simplest questions one can formulate in mathematics, but to define its problems broadly we consider the following set-up. Let V be an algebraic variety over a field $\mathbb{F}$, T a finite family of subvarieties of V and S a finite set of points inside of V. Incidence geometry is then mainly concerned with how the quantity

$$I(S,T) = |\{(s,t) \in S \times T : s \in t\}|,$$

which counts the number of incidences between S and T, relates to the sizes of S and T.

For example, when the variety V above is equal to $\mathbb{R}^n$ and T is just an arbitrary finite family of lines, we may ask for the maximal number of incidences that can occur between a set of points and a set of lines. A classical result of Szemerédi and Trotter [1983] gives in this case the sharp asymptotic bound

$$I(S,T) \lesssim |S|^{2/3}|T|^{2/3} + |S| + |T|,$$

where the implicit constant is uniform among all choices of S and T. If, more generally, we ask what happens when T is a finite family of algebraic curves of degree at most d, then a corresponding bound of the form

$$I(S,T) \lesssim_d |S|^{\frac{d^2+1}{2d^2+1}}|T|^{\frac{2d^2}{2d^2+1}} + |S| + |T|,$$

was established by Pach and Sharir [1998].

These two results constitute very simple instances of the general context described before. There is a vast literature dealing with many different cases that may arise, with T ranging from families of circles to high-dimensional varieties and with $\mathbb{F}$ ranging from a finite field to the complex numbers. While in principle there is no reason why some general unifying results could not be established, they certainly seem hard to come by. Similarly, obtaining sharp asymptotic bounds that avoid extra factors depending on $|S|$ or $|T|$ tends to be an additional challenge. Even when $V = \mathbb{R}^n$ and each element of T is a hypersurface defined by a single irreducible polynomial of bounded degree this question is not fully settled.

The simplicity of its questions is arguably one of the things that makes incidence geometry attractive and it is also this simplicity what makes its results find natural applications in different contexts. To give an example of this, let us discuss a very simple and direct connection to arithmetic combinatorics. To a finite set of points A in $\mathbb{R}^n$, say, we can associate the sets

$$A + A = \{a + a' : a, a' \in A\},$$

and

$$A \cdot A = \{a \cdot a' : a, a' \in A\}.$$

It is expected that both sets cannot be small simultaneously Erdős and Szemerédi [1983] and an estimate of this form was established by Elekes [1997] using incidence geometry. His idea was to consider the set of all lines of the form $y = (x - a)a'$, with $a, a' \in A$. Clearly, when $x = b + a$ for some $b \in A$, we get that $y = a'b \in A \cdot A$. As a consequence, we see that each of these lines touches $|A|$ points of the grid $(A+A)\times(A\cdot A)$. If both $A+A$ and $A \cdot A$ were to be small, this would then mean that these lines are highly incident to each other. So much so in fact, that they would contradict the Szemerédi-Trotter theorem. Thus we get the desired result.

Incidence bounds in the broader context we have described at the beginning of this section give rise to more general results concerning the size of

$$f(A_1, \ldots, A_m) = \{f(a_1, \ldots, a_m) : a_1 \in A_1, \ldots, a_m \in A_m\},$$

where f is a polynomial and $A_1, \ldots, A_m$ are finite sets of points (see for example Elekes and Szabó [2012]). Results of this type can in particular be applied to obtain randomness extractors, opening the door for incidence geometry to be applied in theoretical computer science Dvir [2010]. It should also be noted that the above sum-product phenomenon, as it is known, and the related concept of expansion, are pervasive throughout different parts of mathematics and have found a number of remarkable applications. See, for example, this survey by Helfgott [2015] and Green's 2014 ICM article Green [2014] for some discussion.

Sometimes problems can be encapsulated as incidence questions in more subtle ways. An example is provided by the Erdős distinct distances conjecture Erdős [1946], which asked for a bound on the minimal number of pairwise distances determined by n distinct points in the plane. Here Elekes and Sharir [2010] started with the simple observation that two pairs of points at the same distance determine two segments of the same length and so there exists some rigid motion taking one segment to the other. As it happens, given two points $x, y \in \mathbb{R}^2$, the set of rigid motions that take x to y can essentially be viewed as a line in $\mathbb{R}^3$ under an appropriate parametrisation of most of $\mathrm{SE}(2)$ (the special Euclidean group in two-dimensions). As a consequence, two pairs x_1, x_2 and y_1, y_2 at the same distance correspond to an intersection between the line of motions that send x_1 to x_2 and the line of motions that send y_1 to y_2. In paritcular, n points determining few distances lead to a set of highly incident lines in $\mathbb{R}^3$. Continuing this sort of arguments and exploiting some additional properties of the resulting set of lines, they managed to reduce Erdős' conjecture to an incidence question that was subsequently settled by Guth and Katz [2015].

Finally, the nature of incidence geometry also makes it a good source of toy models for more difficult problems. One notorious example is given by the following well-known conjecture in geometric measure theory.

Conjecture 2.1 (Kakeya problem)**.** *A set $E \subseteq R^n$ containing a unit line segment in every direction must have Hausdorff dimension equal to n.*

A counterexample to this problem would certainly be reminiscent of the existence of a set of lines being highly incident to each other while satisfying some restricting conditions regarding their directions. This problem served as a motivation for a large body of work in incidence geometry and we will now see how it led to the introduction of the polynomial method in this area.

2.2 Enter the polynomial method. There a number of ways of formulating toy models for the Kakeya problem in incidence geometry. A particularly straightforward way of doing so is to formulate the problem over $\mathbb{F}_q$, where the discrete nature of this space naturally turns it into a question about incidences. The resulting Kakeya problem over finite fields was answered in the affirmative by Dvir [2009]. Precisely, he established the following result.

Theorem 2.2 (Kakeya over finite fields)**.** *Let $K \subseteq \mathbb{F}_q^n$ be a set containing a line in every direction. Then $|K| \gtrsim q^n$.*

This question was originally posed by Wolff [1999] and attracted considerable attention. Despite the large amount of work that preceded his article, Dvir's proof is extremely simple. What distinguishes it is its introduction of the polynomial method as the main tool to attack the problem. While this tool had barely been used in this or related areas before, the situation would change dramatically after this result.

The polynomial method is largely concerned with finidng a polynomial with suitable properties vanishing at most points of a set of interest. To find such a polynomial, an important role is played by the following simple observation, usually attributed to Thue and Siegel, which allows us to bound the degree of a polynomial vanishing on an arbitrary set.

Lemma 2.3 (Siegel's lemma). *For every set finite $S \subseteq \mathbb{F}^n$ there exists a non-zero polynomial $P \in \mathbb{F}[x_1, \ldots, x_n]$, of degree $\lesssim_n |S|^{1/n}$, vanishing on S.*

The proof is extremely simple, consisting only of a dimension counting argument. There are so many different polynomials of degree $\lesssim_n |S|^{1/n}$ that at least two of them, say P_1 and P_2, must take the same values on S. Therefore $P = P_1 - P_2$ is of the form we want. The same kind of argument can be used to force some additional properties on the polynomial P, like having integer coefficients or vanishing to high multiplicity on our set of points.

To obtain a polynomial of low degree vanishing on a given set S, the polynomial method combines the above lemma with what might be called the idea of characteristic subsets (here we are using the notation of M. N. Walsh [2012b]). We informally define these as follows.

Definition 2.4 (Characteristic subset). A set $A \subseteq S$ is said to be a characteristic subset of S if any polynomial of low complextiy that vanishes with a certain multiplicity on A must also vanish at all or most points of S.

What exactly does it mean for a polynomial P to have low complexity depends very much on what is needed in the given problem, though it always implies that the degree of P should be small. In some cases, we may also require the coefficients to be small or restricted to the integers, or both. Clearly, if a set S admits a characteristic subset A of small size, then we can find a polynomial of low degree vanishing at all or most points of S by applying Siegel's lemma to A. As we will see during this article, this idea is a central part of the polynomial method.

Let us now see how it applies to the proof of Theorem 2.2. Dvir's crucial observation is that any set $K \subseteq \mathbb{F}_q^n$ containing a line in every direction must be a characteristic subset of $\mathbb{F}_q^n$. This is easiest to see looking at the corresponding projective space. If P is a polynomial of degree strictly less than q vanishing on an affine line in every direction, by Bezout's theorem its homogenisation must also contain the hyperplane at infinity in its zero set and this necessarily implies that P vanishes at the whole space. As a consequence, if we could find a nontrivial polynomial of degree less than q that vanishes on K, it would also have to vanish on $\mathbb{F}_q^n$, which is impossible. Comparing this observation with Siegel's lemma, we conclude that it must be $|K| \gtrsim_n q^n$.

2.3 Polynomial partitioning.

The idea of characteristic subsets will also play a role in incidence geometry results over $\mathbb{R}^n$. For example, if we are given a highly incidence family of lines T, we may be able to find a subset of lines $T' \subseteq T$ such that any polynomial of low degree P vanishing on all the elements of T' must also vanish on most elements of T. The reason why this may work is that, given the highly incident nature of T, we may be able to find a small subset $T' \subseteq T$ such that most elements $t \in T$ will be incident to many lines in T'. As a consequence, a polynomial P vanishing on T' will vanish at many points of such t. If the degree of P is sufficiently small, Bezout's theorem would then force P to vanish on all of t as desired. This kind of approach is often called degree-reduction in this context.

Although arguments like this tend to be useful, it turns out that a substantial addition to the polynomial method is required in order to make progress on incidence problems taking place in $\mathbb{R}^n$. Since the original work of Szemerédi and Trotter, a central idea in incidence geometry has been to partition the space into cells in a way that limits how many of these cells the elements of T may intersect. This plays into the intuitive notion that the varieties being studied in an incidence problem should spread out across space, thus forbidding them to cluster into a highly incident configuration. As it turns out, polynomials can be used to obtain such a partition of space in an extremely structured way. Indeed, the following result was establish by Guth and Katz [2015] when trying to adapt Dvir's polynomial method to incidence questions over Euclidean space.

Theorem 2.5 (Polynomial partitioning of $\mathbb{R}^n$). *For every finite set $S \in \mathbb{R}^n$ and every choice of an integer $M \geq 1$, there exists some nonzero polynomial $P \in \mathbb{R}[x_1, \ldots, x_n]$ of degree $\lesssim_n M$ such that each connected component of $\mathbb{R}^n \setminus Z(P)$ contains at most $\lesssim_n \frac{|S|}{M^n}$ points of S.*

By an old result of Petrovskiĭ and Oleĭnik [1949] it is known that if P is a polynomial in n variables of degree $O(M)$, then $\mathbb{R}^n \setminus Z(P)$ can have at most $O(M^n)$ connected components. Theorem 2.5 then says that at any level M of our choice and for any set S, we can partition the points of S as efficiently as possible among the connected components of the complement of a polynomial of degree at most $O(M)$. The generality of such a statement is quite striking. There is one caveat, however, which is that the result does not rule out the possibility that some of the points of S actually lie inside of $Z(P)$. But this in itself may be an advantage, since we may be able to exploit the additional structure of having a proper subvariety covering our set of points in order to attack the problem that we are interested in.

Let us now briefly discuss how a partition of S of the above type can be used to tackle questions in incidence geometry. For simplicity, let us assume we are studying the incidences of S with a set of lines T and let us apply Theorem 2.5 to S for an adequate choice of M. Then we obtain a partition by the zero set of some polynomial P of degree $O(M)$ in such a way that each connected component of $\mathbb{R}^n \setminus Z(P)$ contains very few points of S. But since a line that is not properly contained in $Z(P)$ can touch this zero set in at most $\deg(P)$ places, it follows that such a line can only intersect $\deg(P)+1 = O(M)$ of the components of $\mathbb{R}^n \setminus Z(P)$. In other words, each component contains few points and each line intersects few components. Combining this observation with a trivial incidence estimate in each component coming from the Cauhcy-Schwarz inequality, this readily provides a sharp incidence bound upon making an adequate choice of the parameter M.

It then remains to deal with the incidences occurring inside of $Z(P)$. This points out why the general context described at the beginning of this section can be relevant even if one is only interested in estimates over $\mathbb{R}^n$. To obtain sharp estimates in this case, the study of $Z(P)$ sometimes requires one to pay attention to more subtle algebraic properties of the subvarieties involved (see for example Katz's ICM 2014 article Katz [2014]), but many times even this can be avoided if one is willing to settle for slightly weaker bounds.

In any case, the fact that the problem is reduced to the study of subvarieties is not capricious. To see this, consider for example the task of estimating the number of incidences between a set of points and a set of lines in $\mathbb{R}^3$. The first part of the argument above that deals with the incidences occurring inside the cells, when applied in $\mathbb{R}^3$, leads to a bound that improves the one provided by the Szemerédi-Trotter theorem. However, the latter result is sharp in $\mathbb{R}^2$ and so it is clear that this improvement is not possible in general. Indeed, an example showing that the Szemerédi-Trotter theorem is optimal in $\mathbb{R}^2$ can obviously be replicated inside any plane of $\mathbb{R}^3$. This is a general phenomenon: incidence bounds can be worse than expected if the elements of T cluster inside lower-dimensional varieties. In their work, Guth and Katz managed to obtain an improved bound in $\mathbb{R}^3$ under the assumption that such a clustering fails to take place. Part of the remarkable effectiveness of the polynomial method as discussed above is that it provides optimal bounds outside of the zero set of a certain polynomial and thus singles out the correct obstruction, that is, the possibility that many incidences are occurring inside lower-dimensional varieties.

3 Number theory

3.1 Stepanov's method. We will now depart from the incidence geometry questions discussed in the previous section and see how the polynomial method makes an appearance throughout a range of topics in number theory. We will see how it was recently used in the study of the distribution of sets in residue classes mod p and to bound the number of rational points on curves. However, the polynomial method in this context is not new and was used by Stepanov [1969], and later Bombieri [1974], in the related topic of estimating the number of $\mathbb{F}_q$-points on a curve. Precisely, they provided an alternative proof of the following estimate, equivalent to the Riemann Hypothesis for curves over finite fields.

Theorem 3.1 (Hasse-Weil bound)**.** *Let $\mathcal{C}$ be a nonsingular absolutely irreducible projective curve of genus g defined over $\mathbb{F}_q$. Then, writing $\mathcal{C}(q)$ for the number of $\mathbb{F}_q$-points of*

$\mathcal{C}$*, we have the estimate*

$$|\mathcal{C}(q) - (q+1)| \leq 2g\sqrt{q}.$$

The story of the Riemann Hypothesis for curves over finite fields is well-known. It was originally conjectured by Artin [1924], with the case of elliptic curves being established by Hasse [1936]. The general result was famously obtained by Weil [1949] in work that laid the foundation of modern algebraic geometry. However, an alternative proof that is more elementary was subsequently found by Stepanov in special cases using what we would now call the polynomial method. His method was subsequently used by Bombieri to produce a very simple argument that handles the result in full generality.

Let us now briefly discuss how the proof works. The lower bound on $\mathcal{C}(q)$ provided by Theorem 3.1 can be easily derived from the upper bound by means of a lifting trick, so we will just discuss how the latter is established. We are interested in an upper bound on the number of $\mathbb{F}_q$-points lying inside a curve $\mathcal{C}$, or in other words, the number of points x inside of this curve that are invariant under the Frobenius map $\mathrm{Frob}(x) = x^q$. By looking at the cartesian product $\mathcal{C} \times \mathcal{C}$, we see that it will suffice to provide an upper bound for the size of the intersection of two curves in this cartesian product: the curve $\mathcal{C}_1 = \{(x, y) \in \mathcal{C} \times \mathcal{C} : x = y\}$ and the curve $\mathcal{C}_2 = \{(x, y) \in \mathcal{C} \times \mathcal{C} : \mathrm{Frob}(x) = y\}$.

A naive application of Bezout's theorem to bound the size of this intersection would fail to produce the kind of bound we want. On the other hand, Bezout's theorem does tell us that given an irreducible curve of bounded degree, a polynomial of low degree vanishing with high multiplicity on a large subset of this curve must vanish on the whole curve. Applying this to our problem we conclude that if $\mathcal{C}_1 \cap \mathcal{C}_2$ is large, then it must be a characteristic subset of $\mathcal{C}_2$. Thus in order to prove Theorem 3.1 it would suffice to construct a polynomial of low degree vanishing with high multiplicity on $\mathcal{C}_1$, but not vanishing on $\mathcal{C}_2$. This in turn follows from a combination of the Riemann-Roch theorem and the same kind of dimension counting arguments used in the proof of Siegel's lemma.

3.2 The inverse sieve problem. One of the main topics in analytic number theory is the study of the distribution of sets in residue classes mod p. Many times, the goal is to show that a special set, like the primes, is essentially equidistributed among these classes. It is then natural to wonder what kind of structure may cause a set to be badly distributed in residue classes and in particular, whether an inverse theorem may be obtained characterising all sets exhibiting bad behaviour.

As we have just seen, algebraic curves constitute one such example and in general, so do algebraic sets of higher dimension. That abnormal behaviour should always be attributable to the presence of algebraic structure was suggested by a number of authors. The following result established a conjecture of Helfgott and Venkatesh [2009] to this effect.

Theorem 3.2 (M. N. Walsh [2014]). *Let $S \subseteq \{1, \dots, N\}^d$ occupy $\ll p^\kappa$ residue classes for every prime p and some real number $0 \le \kappa < d$. Then, for every $\varepsilon > 0$, there exists some nonzero $P \in \mathbb{Z}[x_1, \dots, x_d]$ of degree $\ll_{\kappa,d,\varepsilon} (\log N)^{\frac{\kappa}{d-\kappa}}$ vanishing on at least $(1-\varepsilon)|S|$ points of S.*

The assumption that the set occupies few classes is not prohibitive and can be replaced by an estimate on its L^2-norm mod p. Furthermore, it was shown in M. N. Walsh [2012b] that the polynomial P can be taken to have degree $O(1)$ as long as the set S satisfies some regularity assumptions. In fact, these assumptions are automatically met if the set S is not small, as conjectured in Helfgott and Venkatesh [2009].

These results are essentially sharp and their proof employs the polynomial method. The argument goes more or less as follows. If S occupies few residue classes mod p for many primes p, it should be possible to find a very small set $A \subseteq S$ that, for many primes p, contains a representative of many of the classes occupied by S mod p. We claim that A is then a characteristic subset of S. Indeed, suppose P is a polynomial with small coefficients and small degree that vanishes on A. By construction of A, we find that to most elements $s \in S$ we can associate many primes p_i such that $s \equiv x_i \pmod{p_i}$ for some $x_i \in A$ and so, in particular, $P(s) \equiv P(x_i) \pmod{p_i}$. The fact that P vanishes on A then implies that every such p_i must divide $P(s)$. But since P has small coefficients and small degree, $|P(s)|$ is small, and so the only way this can happen is if $P(s) = 0$. We have thus shown that A is indeed a characteristic subset of S. The result then follows from applying Siegel's lemma to find a polynomial of low degree vanishing on A.

There is an interesting question that remains when considering one dimensional sets $S \subseteq \{1, \dots, N\}$. We know by the large sieve inequality that a set occupying approximately half of the residue classes mod p, for all primes p, can have size at most $O(N^{1/2})$. On the other hand, the squares in $\{1, \dots, N\}$ show that this estimate is sharp. The question arises whether every set of comparable size occupying at most half the residue classes mod p, for every prime p, must be correlated to the set of squares. This question can be generalised a bit further (see M. N. Walsh [2012b]). Given the arguments described above, one would expect that the polynomial method should be useful to make progress on this problem, although this has not been achieved so far (but see Green and Harper [2014] and Hanson [2017] for some partial progress by means of different tools).

3.3 The determinant method. The polynomial method has also been used effectively to bound the number of points S of bounded height that an algebraic variety can have over $\mathbb{Z}$ or $\mathbb{Q}$. As in Stepanov's method, the problem does not lie in finding an adequate characteristic subset A for S, since in this context this is generally accomplished by simply picking a maximal algebraically independent subset of S. The actual difficulty lies instead in finding an appropriate polynomial vanishing on A. This gives rise to the study of a certain system of linear equations and in particular, to estimates on the size of the determinants associated with this system. As a consequence, this form of the polynomial method has been known as the determinant method in this context. It dates back to the work of Bombieri and Pila [1989], with subsequent improvements of this method being obtained by Heath-Brown [2002] and Salberger [2010], among others.

For the rest of this discussion let us assume for simplicity that A lies inside a plane curve $\mathcal{C}$ defined by an irreducible polynomial f. The task of finding a polynomial vanishing on A may seem circular, since after all, we already know that f vanishes on A. The idea is instead to show that the dimension of the space of polynomials of small degree vanishing on A is big. Big enough, in fact, as to guarantee the existence of at least one polynomial g in this space that is not divisible by f. Since S must then lie in $\mathcal{C} \cap Z(g)$, a bound for its size readily follows from Bezout's theorem.

While the Stepanov-Bombieri argument required us at this stage to improve on Siegel's lemma by means of a dimension counting argument relying on the Riemann-Roch theorem, the improvement of Siegel's lemma needed here can be obtained through the following estimate of Bombieri and Vaaler on the space of solutions of a system of linear equations over the integers.

Theorem 3.3. *Bombieri and Vaaler [1983] Let $\sum_{k=1}^{r} b_{mk} x_k = 0$, $m = 1, \dots, s$, be a system of s linearly independent equations in $r > s$ unknowns, with integer coefficients b_{mk}. Then, there exists a nontrivial integer solution $(x_1, \dots, x_r)$ satisfying the bound*

$$\max_{1 \le i \le r} |x_i| \le \left(D^{-1} \sqrt{\left|\det\left(BB^T\right)\right|} \right)^{\frac{1}{r-s}}. \tag{3-1}$$

Here $B = (b_{mk})$ is the $s \times r$ matrix of coefficients, B^T its transpose, and D is the greatest common divisor of the determinants of the $s \times s$ minors of B.

When trying to find a polynomial of small degree that vanishes on A, the system of equations we are interested in is the one where the coefficients b_{mk} are given by the values taken by the monomials of small degree when evaluated at the elements of A. It is the presence of the factor D^{-1} in the above statement what provides an improvement over the classical form of Siegel's lemma.

We already know that as a consequence of the Hasse-Weil bound, the rows of the resulting matrix of coefficients B will occupy few residue classes mod p for many primes p, exceptions occurring only when $\mathcal{C}$ has a singular reduction mod p. On the other hand, the discussion of the previous subsection would suggest that a system of linear equations whose coefficients occupy few residue classes mod p, for many primes p, should be easier to solve. In a sense, Theorem 3.3 formalises this idea. Indeed, if the rows of B occupy few classes mod p then we would expect its minors to be divisible by a high power of p. A concrete estimate of this form is established in Salberger's work, giving rise to a strong lower bound on the size of D. This lower bound, when combined with Theorem 3.3, forces A to be small and as a consequence, the dimension of the space of polynomials vanishing on A to be large, as desired.

Let us finally remark that it is an interesting feature of the polynomial method that when the points being studied are already known to lie in the zero set of a polynomial with either large coefficients or large degree, this can usually be used to obtain stronger estimates. As noted by Ellenberg and Venkatesh [2005], something like this holds true in this context. In particular, it can be used to produce an improved lower bound for the left-hand side of (3-1), by assuming for the sake of contradiction that all solutions are multiples of f. This in turn gives rise to improved bounds for S when f has a large coefficient and in particular, manages to compensate a loss that appears in Salberger's bound in this case. Combining the ideas we have discussed, a uniform bound of the form $O_d(N^{2/d})$ was obtained in M. N. Walsh [2015] for the number of rational points of height at most N that an irreducible curve of degree d can have. It is easy to see that this bound is asymptotically sharp upon consideration of the equation $y = x^d$.

3.4 Exponential sums and Montgomery's conjecture. We finish this section with a brief discussion of some connections between the topics studied so far. On the one hand, the problems treated in the previous section are naturally related with each other, with such incidence problems ultimately leading to the Kakeya problem over $\mathbb{R}^n$ and the more general Stein's restriction conjecture in harmonic analysis. As we shall see in Section 4.4, the polynomial method can be extended to make progress on these problems as well.

On the other hand, we have seen that the number-theoretic topics discussed in this section are also quite interconnected. Furthermore, estimates like the large sieve inequality and the Riemann Hypothesis for curves over finite fields lead into the general area of exponential sums, where some of the most far-reaching conjectures in analytic number theory have been formulated. An outstanding example is the exponent pairs conjecture Iwaniec and Kowalski [2004], an open problem that has among its consequences the Lindelöf Hypothesis. This part of mathematics gives us an excuse to join the two lines of enquiry we have covered so far in this article. In particular, not only the density hypothesis for the zeros of the Riemann zeta function but also the Kakeya problem would follow from a positive answer to the following conjecture about exponential sums.

Conjecture 3.4 (Montgomery's Conjecture Montgomery [1971]). *For any real number $r \geq 1$ and any sequence of complex numbers $(a_n)_{n=1}^N$ with $|a_n| \leq 1$, the estimate*

$$\frac{1}{T}\int_0^T \left|\sum_{n=1}^{N} a_n n^{is}\right|^{2r} ds \lesssim_\varepsilon N^{r+\varepsilon},$$

holds for all $T \geq N^r$ and all $\varepsilon > 0$.

That this implies the Kakeya problem can be seen upon rephrasing the latter as a question about the existence of small subsets of $\mathbb{F}_p$ containing large arithmetic progressions with each possible common difference Bourgain [1991]. There is indeed a good amount of work making progress on the Kakeya problem employing tools from arithmetic combinatorics.

While this shows that analytic number theory could be used to make progress on problems related to the Kakeya problem, the opposite is also true, with progress on questions related to restriction theory being used recently to yield results in analytic number theory. Indeed, the l^2-decoupling theory started by Bourgain and Demeter [2015], a family of results in the spirit of the restriction conjecture whose proof relies on the multilinear Kakeya inequality among other things, has been used to establish Vinogradov's main conjecture in analytic number theory Bourgain, Demeter, and Guth [2016]. Previous to this work, the best result on this problem had been obtained by Wooley [2012] by means of his efficient congruencing mod p method. Finally, the set of ideas surrounding the decoupling theory was also used by Bourgain to improve the best-known exponent towards the Lindelöf Hypothesis Bourgain [2017].

It is then fair to ask to what extent the polynomial method is a tool that finds applications on a wide variety of contexts and to what extent it reflects underlying phenomenona in somewhat interconnected families of results.

4 Further topics

4.1 Baker's theorem. In order to emphasise the recurring features of the polynomial method, let us briefly discuss one last example of an application that would seem to have little connection to the topics discussed in the rest of this article, besides its link to arithmetic. Our choice is Baker's classical result in transcendental number theory regarding linear forms in logarithms Baker [1968]. For simplicity, let us discuss the integer case, where we are seeking uniform lower bounds over expressions of the form $\sum_{i=1}^{m} b_i \log a_i$, where the a_i are multiplicatively independent integers and the b_i are integers not all equal to zero.

To attack this problem, we will consider the curve $\mathcal{C} = (a_1^t, \dots, a_m^t)$, and more generally, subsets of this curve of the form

$$\mathcal{C}_N = \{(a_1^n, \dots, a_m^n) : n = 1, \dots, N\},$$

for positive integers N. Looking at the corresponding Vandermonde matrix of coefficients, the fact that the a_i are multiplicatively independent easily implies that no polynomial P of small degree, relative to N, can vanish at all points of $\mathcal{C}_N$.

A polynomial P evaluated at the curve $\mathcal{C} = (a_1^t, \dots, a_m^t)$ may be seen as a function of the parameter t. With this point of view, we claim that we can find some value N_0, relatively small with respect to N, such that $\mathcal{C}_{N_0}$ is a characteristic subset of $\mathcal{C}_N$. Indeed, suppose we are given some polynomial P with integer coefficients and low degree that vanishes at $\mathcal{C}_{N_0}$ with some large multiplicity J with respect to the variable t. Then, $\mathcal{C}$ being an analytic curve, this will force $\frac{d^j}{dt^j} P$ to take small values in a neighbourhood of $\mathcal{C}_{N_0}$, as long as j is at least slightly smaller than J. In particular, this will happen at all points of $\mathcal{C}_{N_1}$, provided N_1 is an integer not much larger than N_0. If J is sufficiently large, we can then iterate this argument enough times as to guarantee that P itself takes small values at all points of $\mathcal{C}_N$. But since P takes integer values, the only way this can happen is if P is in fact zero at all points of $\mathcal{C}_N$.

Since $\mathcal{C}_{N_0}$ is a characteristic subset of $\mathcal{C}_N$, we know, by our observation regarding the Vandermonde matrix, that no polynomial with integer coefficients and low degree can vanish with high multiplicity at $\mathcal{C}_{N_0}$. On the other hand, if $\sum_{i=1}^m b_i \log a_i$ were to be small, an argument like in the proof of Siegel's lemma can be used to contradict this fact. Indeed, for any polynomial P with integer coefficients, a relation of this kind between the $\log a_i$ significantly restricts the range of values that the derivatives of P with respect to t can take at any given point of $\mathcal{C}_{N_0}$. In particular, this allows us to find two polynomials P_1, P_2 with integer coefficients and abnormally low degree such that, with respect to t, their first J derivatives take the same values at $\mathcal{C}_{N_0}$, for some large value of J. The polynomial $P = P_1 - P_2$ then gives us the desired contradiction.

The generality of Baker's result makes it applicable in a number of different contexts, thus implicitly extending the range of problems where the polynomial method may have some relevance. As a curious example, the integer version just discussed was used by Bourgain, Lindenstrauss, Michel, and Venkatesh [2009] to provide effective proofs of a family of results relating to Furstenberg's $\times 2 \times 3$ conjecture in ergodic theory Furstenberg [1967]. These include the well-known Rudolph-Johnson theorem Rudolph [1990] and Johnson [1992], establishing the conjecture in the positive entropy case, and Furstenberg's topological result, showing that $\mathbb{R}/\mathbb{Z}$ has no infinite closed subset other than itself that is invariant under multiplication by a pair of multiplicatively independent integers Furstenberg [1967]. One may wonder whether proofs that use the polynomial method in an explicit way may contribute to understand better such applications of Baker's theorem.

4.2 Structure and randomness. It may be worthwhile to give some brief consideration to how the polynomial method fits with the general phenomenon of structure-randomness decompositions that is pervasive throughout analysis. The idea of the latter is that it tends to be possible to decompose an object of interest into a part that detects the structure of the problem being studied and a random part that is, in a sense, completely independent from this information. In the context of Hilbert spaces, this observation can be formalised by noting that given a distinguished set Σ of bounded functions, any bounded element of the Hilbert space may be written in the form $\sum_j \lambda_j \sigma_j + g$, where the sum of the coefficients λ_j is uniformly bounded, $\sigma_j \in \Sigma$ for every j, and g is essentially orthogonal to Σ, in the sense that $\langle g, \sigma \rangle$ is small for every $\sigma \in \Sigma$. We refer the reader to this article Gowers [2010] of Gowers for an elegant discussion of this and more general decompositions.

The polynomial method may be considered a useful complement to the structure-randomness approach when the arithmetic of the problem gives rise to an underlying algebraic structure. The characteristic subsets notation used in M. N. Walsh [2012b, 2014] and in the present article is, in fact, inspired by the concept of characteristic factors that plays the role of the structured part in several problems in ergodic theory Furstenberg [1967], Furstenberg and Weiss [1996], and Host and Kra [2005]. In the same way that information about the behaviour of a polynomial on a set can be deduced from what happens in a characteristic subset, the behaviour of nonconventional ergodic averages over a set of functions can be deduced from what happens in the corresponding characteristic factors. This is exactly what these decompositions seek to accomplish.

Structure-randomness decompositions are a flexible tool that can be substantially refined when a small error term is allowed in the decompositions. This played an important role in the convergence result of M. N. Walsh [2012a] and we refer again to Gowers' article Gowers [2010] for a general discussion. As noted by Lovász and Szegedy [2007], these more general decompositions can be seen as versions of the Szemerédi regularity lemma Szemerédi [1978]. The regularity lemma was itself the key tool used to obtain the cell-decomposition in the original proof of the Szemerédi-Trotter theorem and, in this sense, the polynomial partitioning method of Guth an Katz may be seen as an instance of these general decomposition results where the algebraic nature of the decomposition is made more explicit.

4.3 Polynomial partitioning over varieties. In order to apply the polynomial method efficiently over general varieties some further improvements may be needed. During the discussion of the determinant method, we observed how the polynomial method could be made more effective when the points being studied lie in the zero set of some polynomial with large coefficients. One may similarly wonder whether knowing that the points lie inside of an algebraic variety of high degree may also lead to improved estimates. Since it is known that the dimension of the polynomial ring associated with a variety increases in proportion with its degree Nesterenko [1984], it is logical to suspect that a corresponding improvement may be achieved on the kind of dimension counting arguments that are ubiquitous in the polynomial method. Indeed, combining this kind of observations with the type of tools used to prove Theorem 2.5, we can obtain the following result.

Theorem 4.1 (Polynomial partitioning over varieties M. Walsh [n.d.]). *Given any real algebraic variety $V \subseteq \mathbb{R}^n$ of dimension d, any set of points $S \subseteq V$ and any integer $M \geq 1$, there exists some polynomial $P \in \mathbb{R}[x_1, \dots, x_n]$ of degree $\lesssim_{d,n} M$, not vanishing identically on V, such that each connected component of $V \setminus Z(P)$ contains at most $\lesssim_{d,n} \frac{|S|}{M^d \deg(V)}$ points of S.*

That this should hold was already conjectured in Basu and Sombra [2016]. A more general sharp estimate was obtained in M. Walsh [n.d.] by including an additional explicit dependence on the degrees of the various individual polynomials defining the variety V. Notice that a particular case of the above result is a version of Siegel's lemma that allows us to find a polynomial of degree $\lesssim_{d,n} \frac{|S|^{1/d}}{\deg(V)^{1/d}}$ that vanishes on S without vanishing identically on V.

As we saw in Section 2.3, both the nature of incidence geometry and of polynomial partitioning techniques lead to the consideration of lower-dimensional algebraic varieties, even for problems that originally take place over $\mathbb{R}^n$. Without proper tools to handle varieties of high degree, the polynomial partitioning needs to be truncated as to produce only varieties of low degree, leading to suboptimal bounds. Estimates like Theorem 4.1 may prove useful in providing a unified approach to manage these problems and produce sharp bounds.

Nevertheless, to make this work, we saw that a second result that is needed is a bound on how many of the components produced by the above partitioning result can be touched by a given algebraic variety W. In general, by work of Milnor [1964] and Thom [1965], we have bounds that give a good dependence in terms of the degree of the partitioning polynomial, but not in terms of W. Some progress on this issue has been made by Barone and Basu [2012], who were able to obtain an estimate with a good dependence on the product of the degrees of the polynomials defining W, with this result being subsequently applied in incidence geometry Basu and Sombra [2016].

Since in general estimates like Theorem 4.1 can only be expected to yield a saving proportional to the degree of the variety V itself, it may be necessary to obtain a version of the result of Barone and Basu that depends only on the degree of W, instead of depending on the product of the degrees of the polynomials defining it. A step in this direction was taken in M. Walsh [n.d.] where a bound with a main term of the desired form was obtained. Nevertheless, the error term in this estimate is not optimal and it remains an interesting problem to improve it. In fact, it is shown in M. Walsh [ibid.] that a suitable refinement can indeed be combined with Theorem 4.1 to attain sharp incidence bounds that currently remain out of reach.

4.4 Restriction estimates. The proof of Theorem 4.1 combines algebraic estimates for the size of ideals with tools like the polynomial ham-sandwich theorem, the latter being a result that lies at the heart of polynomial partitioning results since the original work of Guth and Katz. The classical ham-sandwich theorem states that given n open sets in $\mathbb{R}^n$, they can always be simultaneously bisected by a suitable hyperplane. The polynomial ham-sandwich theorem extends this claim to show that we can always bisect a larger number of open sets as long as, instead of restricting to hyperplanes, we allow the bisection to be performed by hypersurfaces of a correspondingly large degree.

This bisecting result can be further put to use to extend the scope of the polynomial method to the Kakeya conjecture in Euclidean space. This conjecture can be sen as a question about estimating the minimal possible volume that can be attained by a collection of tubes pointing in a large number of quantitatively distinct directions. Covering this union by a family of small cubes and replacing the notion of a polynomial vanishing at a point by that of a polynomial bisecting a cube, the ideas surrounding the polynomial method can be extended from the discrete case to this continuous setting.

Recall that to find characteristic subsets we have relied heavily on estimates on the intersection of algebraic sets. For example, that given a polynomial P not vanishing identically on a given line, this line can only intersect $Z(P)$ in at most $\deg(P)$ points. In order to carry the polynomial method to this new context, we need to find analogues of these estimates that hold true for tubes. For example, we may observe that if a polynomial P takes small values at more than $C \deg(P)$ points along a fixed tube, for some sufficiently large constant C, then it must also take small values at most places that lie between these points. Similarly, another alternative is to consider the directed volume of a surface, allowing one more or less to conclude that a polynomial P can cut a tube transversally in at most $O(\deg(P))$ places.

By introducing these ideas, Guth essentially showed in Guth [2016b] that a counterexample to the Kakeya problem in $\mathbb{R}^3$ can be approximated by a polynomial of the smallest possible degree allowed by the Crofton formula, and used this to obtain graininess estimates in the spirit of Katz, Łaba, and Tao [2000]. He also combined these ideas with slightly more sophisticated tools from algebraic topology, involving cohomology classes and Lusternik-Schnirelmann theory, to obtain the first proof Guth [2010] of the endpoint case of the multilinear Kakeya inequality of Bennett, Carbery, and Tao [2006].

It is even possible to extend the polynomial method further to make progress on the more general restriction conjecture of Stein [1979]. Here, by applying a decomposition into wave packets, we can translate the problem into a question about overlapping patterns of tubes and this can be treated in a similar spirit as the incidence geometry questions that we discussed in Section 2.3. Indeed, the polynomial partitioning method works in a very similar way, as long as we replace the zero set of the partitioning polynomial by its neighbourhood, as to be able to bound the number of cells of the resulting partition that a tube can intersect Guth [2016a]. It should be remarked that this approach helps to highlight the role played by low degree varieties in hypothetical counterexamples to this conjecture. Whether this kind of ideas based on the polynomial method will lead to further progress on this sort of problems remains an interesting question.

PERIODS, CYCLES, AND L-FUNCTIONS: A RELATIVE TRACE FORMULA APPROACH

Wei Zhang (张伟)

Abstract

This is a report for the author's talk in ICM-2018. Motivated by the formulas of Gross–Zagier and Waldspurger, we review conjectures and theorems on automorphic period integrals, special cycles on Shimura varieties, and their connection to central values of L-functions and their derivatives. We focus on the global Gan–Gross–Prasad conjectures, their arithmetic versions and some variants in the author's joint work with Rapoport and Smithling. We discuss the approach of relative trace formulas and the arithmetic fundamental lemma conjecture. In the function field setting, Z. Yun and the author obtain a formula for higher order derivatives of L-functions in terms of special cycles on the moduli space of Drinfeld Shtukas.

Contents

Research of W. Zhang partially supported by the NSF grant DMS #1601144, and a Simmons fellowship.
MSC2010: primary 11F67; secondary 11F70, 11G40, 14C25, 14G35, 14H60.
Keywords: L-functions, Shimura varieties, Drinfeld Shtukas, Special cycles, Relative trace formula, Gross–Zagier formula, Waldspurger formula, Rapoport–Zink spaces, Spherical subgroup.

1 Introduction

We begin with a special case of Pell's equation

$$x^2 - py^2 = 1, \quad x, y \in \mathbb{Z},$$

where $p \equiv 1 \bmod 4$ is a prime number. Let K be the real quadratic field $\mathbb{Q}[\sqrt{p}]$ and O_K its ring of integers. Then most solutions to Pell's equation can be extracted from the group of units in O_K, which is known to be the product of $\{\pm 1\}$ and an infinite cyclic group generated by a fundamental unit. In 1830s, Dirichlet systematically constructed units in O_K using special values of trigonometric functions:

$$\theta_p = \frac{\prod_{a \not\equiv \square \bmod p} \sin \frac{a\pi}{p}}{\prod_{b \equiv \square \bmod p} \sin \frac{b\pi}{p}}, \quad 0 < a, b < p/2,$$

where $\square \bmod p$ denotes a square residue. Dirichlet also showed that the obstruction for θ_p to be a fundamental unit is the class group of K, with the help of an infinite series

$$L\left(s, \left(\frac{\cdot}{p}\right)\right) = \sum_{n \geq 1,\, p \nmid n} \left(\frac{n}{p}\right) n^{-s}, \quad s \in \mathbb{C}, \quad \mathrm{Re}(s) > 1.$$

Here $\left(\frac{\cdot}{p}\right)$ denotes the Legendre symbol for quadratic residues. This is now called a Dirichlet L-series, and it has holomorphic continuation to $s \in \mathbb{C}$ with a simple zero at $s = 0$. What Dirichlet discovered can be stated as two formulas for the value at $s = 0$ of the first derivative: the first one is in terms of θ_p,

$$L'\left(0, \left(\frac{\cdot}{p}\right)\right) = \log \theta_p, \tag{1-1}$$

and the second one is in terms of the class number h_p and the fundamental unit $\epsilon_p > 1$,

$$L'\left(0, \left(\frac{\cdot}{p}\right)\right) = h_p \log \epsilon_p. \tag{1-2}$$

Dirichlet also proved two formulas for an imaginary quadratic field. For simplicity, let $p \equiv 7 \bmod 8$ be a prime. Now the L-series $L\left(s, \left(\frac{\cdot}{p}\right)\right)$ does not vanish at $s = 0$. His first formula states

$$L\left(0, \left(\frac{\cdot}{p}\right)\right) = \sum_{0 < a < p/2} \left(\frac{a}{p}\right), \tag{1-3}$$

and the second one is in terms of the class number h_{-p} of $\mathbb{Q}[\sqrt{-p}]$

$$L\left(0,\left(\frac{\cdot}{p}\right)\right)=h_{-p}. \tag{1-4}$$

A non-trivial corollary is a finite expression for the class number

$$h_{-p}=\sum_{0<a<p/2}\left(\frac{a}{p}\right),$$

i.e., the difference between the number of square residues and of non-square residues in the interval $(0,p/2)$.

In 1952, Heegner discovered a way to construct rational points (over some number fields) on elliptic curves using special values of modular functions, in a manner similar to Dirichlet's solutions to Pell's equation. For instance, the elliptic curve

$$E:y^2=x^3-1728$$

is parameterized by modular functions (γ_2,γ_3), where

$$\gamma_2(z)=\frac{E_4}{\eta^8}=\frac{1+240\sum_{n=1}^{\infty}\sigma_3(n)q^n}{q^{1/3}\prod_{n=1}^{\infty}(1-q^n)^8},\qquad \gamma_3(z)=\frac{E_6}{\eta^{12}}=\frac{1-504\sum_{n=1}^{\infty}\sigma_5(n)q^n}{q^{1/2}\prod_{n=1}^{\infty}(1-q^n)^{12}}.$$

Here as customary, $z\in\mathcal{H}$ is on the upper half plane, and $q=e^{2\pi iz}$. Then Heegner's strategy is to evaluate (γ_2,γ_3) at z in an auxiliary imaginary quadratic field K to construct points of E with coordinates in an abelian extension of K. The theorem of Gross and Zagier [1986] then relates the Néron–Tate heights of Heegner's points to special values of the *first order* derivatives of certain L-functions, providing an analog of Dirichlet's formula for a real quadratic field (1-1). In this new context, an analog of Dirichlet's formula for an imaginary quadratic field (1-3) is the theorem of Waldspurger [1985] relating toric period integrals (cf. Section 2.2.1) to special values of L-functions of the same sort as in the work of Gross and Zagier.

A natural question is to generalize the constructions of Dirichlet and of Heegner to higher dimensional algebraic varieties, and at the same time to generalize their relation to appropriate L-values. As a partial answer to this question, in this report we will consider some special algebraic cycles on Shimura varieties, cf. Section 3.1.1. A class of such special cycles are the arithmetic diagonal cycles that appear in the arithmetic Gan–Gross–Prasad conjecture Gan, Gross, and Prasad [2012, §27].

A parallel question is the generalization of the formulas of Dirichlet (1-3) and of Waldspurger to automorphic L-functions on a higher rank reductive group G over a global field

F. In this direction, we will consider automorphic period integrals for a spherical subgroup H of G, i.e.,

$$\int_{\mathrm{H}(F)\backslash \mathrm{H}(\mathbb{A})} \phi(h)\, dh,$$

where ϕ is a function on $\mathrm{G}(F)\backslash\mathrm{G}(\mathbb{A})$, and $\mathbb{A}$ the the ring of adèles of F. The central object is the quotient $\mathrm{H}(F)\backslash\mathrm{H}(\mathbb{A})$ sitting inside $\mathrm{G}(F)\backslash\mathrm{G}(\mathbb{A})$. This paradigm may be viewed as a degenerate case of special cycles sitting inside the ambient Shimura variety.

To study the relationship between automorphic periods and L-values, Jacquet invented the relative trace formula, cf. Jacquet [2005]. In W. Zhang [2012b] we adopted the relative trace formula approach to study height pairings of special cycles in the arithmetic Gan–Gross–Prasad conjecture. In this context, we formulated local conjectures (on intersection numbers of the arithmetic diagonal cycle on Rapoport–Zink spaces), namely the *arithmetic fundamental lemma* conjecture (cf. W. Zhang [ibid.]), and the *arithmetic transfer* conjecture by Rapoport, Smithling and the author (cf. Rapoport, Smithling, and W. Zhang [2017a] and Rapoport, Smithling, and W. Zhang [2018]). In this report we will review the approach, the conjectures and the status.

Another natural question is in the direction of higher order derivatives of L-functions in the Gross–Zagier formula. In Yun and W. Zhang [2017] Yun and the author found a geometric interpretation of the higher order derivative in the functional field setting, in terms of special cycles on the moduli stack of Drinfeld Shtukas with multiple number of modifications, cf. Section 4. To generalize this to the number field case, one is led to the tantalizing question of finding Shtukas over number fields.

Limited by the length of this report, we will not discuss the analog of the class number formula (1-2) and (1-4) in our setting. In the context of elliptic curves over $\mathbb{Q}$, this is the conjectural formula of Birch and Swinnerton–Dyer. When the analytic rank is one (resp. zero), we have an equivalent statement in terms of the divisibility of Heegner points (resp. of normalized toric period integrals), thanks to the formula of Gross–Zagier (resp. of Waldspurger). Much of the equivalent statement has been proved in the past thirty years. Beyond elliptic curves (or modular forms on GL_2), there have been many recent developments where special cycles play a crucial role in the study of Selmer groups of Bloch–Kato type. We hope to return to this topic on another occasion.

Acknowledgments. The author thanks B. Gross, M. Rapoport, Y. Sakellaridis, B. Smithling and S. Zhang for helpful comments.

Notation. Let F be a global field (unless otherwise stated), i.e., a number filed or a function field (of a geometrically connected smooth proper curve X over a finite field $k = \mathbb{F}_q$). Let $\mathbb{A} = \mathbb{A}_F = \prod_v' F_v$ be the ring of adèles, the restricted direct product over all completions F_v of F. The ring of integers in a non-archimedean local field F_v is denoted by O_{F_v}. For a subset of places S, we let $\mathbb{A}_S = \prod'_{v\in S} F_v$. When F is a number field, we write $\mathbb{A} = \mathbb{A}_f \times \mathbb{A}_\infty$, where $\mathbb{A}_f$ is the ring of the finite adèles and $\mathbb{A}_\infty = F \otimes_{\mathbb{Q}} \mathbb{R}$.

For a field extension F'/F and an algebraic group G over F', we denote by $\mathrm{R}_{F'/F}\mathrm{G}$ the Weil restriction of scalars. We denote by $\mathbb{G}_m$ the multiplicative group.

2 Automorphic periods and L-values

2.1 Spherical pairs and automorphic periods.

2.1.1 Automorphic quotient. Let G be an algebraic group over F. We define the *automorphic quotient* associated to G to be the quotient topological space

$$[\mathrm{G}] := \mathrm{G}(F)\backslash\mathrm{G}(\mathbb{A}). \tag{2-1}$$

Let $K \subset \mathrm{G}(\mathbb{A})$ be a subgroup. When F is a function field, we assume that K is a compact open subgroup of $\mathrm{G}(\mathbb{A})$. When F is a number field, we assume that K is a product $K_f \cdot K_\infty$ where $K_f \subset \mathrm{G}(\mathbb{A}_f)$ is a compact open subgroup, and K_∞ is a suitable subgroup of $\mathrm{G}(\mathbb{A}_\infty)$. We then define a quotient

$$[\mathrm{G}]_K := \mathrm{G}(F)\backslash\left[\mathrm{G}(\mathbb{A})/K\right]. \tag{2-2}$$

When F is a function field, this is a discrete set (or naturally as a groupoid). When $F = k(X)$, $\mathrm{G} = \mathrm{GL}_n$, and $K = \prod_v \mathrm{GL}_n(O_{F_v})$, the groupoid $[\mathrm{G}]_K$ is naturally isomorphic to the groupoid $\mathrm{Bun}_n(k)$, the k-points of Bun_n (the stack of vector bundles of rank n on X).

2.1.2 Automorphic period. From now on let G be a reductive group over F. Let $\mathrm{H} \subset \mathrm{G}$ be a subgroup. Let Z_{G} be the center of G and let $Z = \mathrm{H} \cap Z_{\mathrm{G}}$. Let $\mathcal{Q}_0(\mathrm{G})$ be the space of cuspidal automorphic forms on $[\mathrm{G}]$, invariant under the action of $Z(\mathbb{A})$. Then the *automorphic H-period integral* is defined by

$$\begin{aligned} \mathcal{P}_{\mathrm{H}}\colon \mathcal{Q}_0(\mathrm{G}) &\longrightarrow \mathbb{C} \\ \phi &\longmapsto \int_{Z(\mathbb{A})\backslash[\mathrm{H}]} \phi(h)\, dh. \end{aligned}$$

Remark 2.1. The name "automorphic period" is different from the period in the context of comparison theorems between various cohomology theories. However, some special cases of the automorphic period integrals may yield periods in the de Rham–Betti comparison theorem. For instance, this happens when the integral can be turned into the form

$\int_{Z(\mathbb{A})\backslash[\mathrm{H}]_{K_{\mathrm{H}}}} \omega_\phi$ for a closed differential form ω_ϕ on the real manifold $[\mathrm{G}]_K$ for suitable K, and $K_{\mathrm{H}} = K \cap \mathrm{H}(\mathbb{A})$.

Let π be a (unitary throughout the article) cuspidal automorphic representation of $\mathrm{G}(\mathbb{A})$. For simplicity, we assume that there is a unique embedding $\pi \hookrightarrow \mathcal{A}_0(\mathrm{G})$ (in many applications this is the case). We consider the restriction of $\mathcal{P}_{\mathrm{H}}$ to π; this defines an element in $\mathcal{P}_{\mathrm{H},\pi} \in \mathrm{Hom}_{\mathrm{H}(\mathbb{A})}(\pi, \mathbb{C})$.

Definition 2.2 (Jacquet)**.** A cuspidal automorphic representation π is *(globally) distinguished by* H if the linear functional $\mathcal{P}_{\mathrm{H},\pi} \in \mathrm{Hom}_{\mathrm{H}(\mathbb{A})}(\pi, \mathbb{C})$ does not vanish, i.e., there exists some $\phi \in \pi$ such that $\mathcal{P}_{\mathrm{H}}(\phi) \neq 0$.

It is also natural to consider a twisted version. Let χ be a character of $Z(\mathbb{A})\mathrm{H}(F)\backslash\mathrm{H}(\mathbb{A})$. We define the automorphic (H, χ)-period integral $\mathcal{P}_{\mathrm{H},\chi}$ in a similar manner,

$$\mathcal{P}_{\mathrm{H},\chi}(\phi) = \int_{Z(\mathbb{A})\backslash[\mathrm{H}]} \phi(h)\chi(h)\, dh.$$

If π is distinguished by H, then $\mathrm{Hom}_{\mathrm{H}(\mathbb{A})}(\pi, \mathbb{C}) \neq 0$, and in particular, $\mathrm{Hom}_{\mathrm{H}(F_v)}(\pi_v, \mathbb{C}) \neq 0$ for every place v. We then say that π_v is (locally) distinguished by $\mathrm{H}(F_v)$ if $\mathrm{Hom}_{\mathrm{H}(F_v)}(\pi_v, \mathbb{C}) \neq 0$. Very often the automorphic period integral $\mathcal{P}_{\mathrm{H}}$ behaves nicely only when the pair (H, G) satisfies certain nice properties, such as

(i) the multiplicity-one property $\dim \mathrm{Hom}_{\mathrm{H}(F_v)}(\pi_v, \mathbb{C}) \leq 1$ holds for all v, or the multiplicity can be described in a certain nice way, and

(ii) the locally distinguished representations can be characterized in terms of L-parameters.

Jacquet and his school have studied the distinction for many instances (locally and globally, cf. Jacquet [2005]). A large class of (H, G) called *spherical pairs* are expected to have the above nice properties, according to the work of Sakellaridis [2008] and his joint work with Sakellaridis and Venkatesh [2012].

2.1.3 Spherical pairs. Let (H, G) be over a field F (now arbitrary). The reductive group G acts on G/H by left multiplication. If F is an algebraically closed field, we say that the pair (H, G) is *spherical* if a Borel subgroup B of G has an open dense orbit on G/H Sakellaridis [2008]. Over a general field F, the pair (H, G) is said to be *spherical* if its base change to an algebraic closure of F is spherical. We then call H a spherical subgroup of G.

Here are some examples.

(i) Whittaker pair (N, G), where G is quasi-split, and N is a maximal nilpotent subgroup.

(ii) The pair $(\mathrm{G}, \mathrm{G} \times \mathrm{G})$ with the diagonal embedding.

(iii) Symmetric pair (H, G), where H is the fixed point locus of an involution $\theta : \mathrm{G} \to \mathrm{G}$. This constitutes a large class of spherical pairs, including

- the unitary periods of Jacquet and Ye (cf. the survey Offen [2009]), where $\mathrm{G} = \mathrm{R}_{F'/F}\mathrm{GL}_n$, and H is a unitary group attached to a Hermitian space with respect to a quadratic extension F'/F. This period is related to the quadratic base change for the general linear group.
- the Flicker–Rallis periods W. Zhang [2014a, §3.2], where $\mathrm{G} = \mathrm{R}_{F'/F}\mathrm{GL}_n$, and $\mathrm{H} = \mathrm{GL}_n$, for quadratic F'/F. This period is related to the quadratic base change for the unitary group.
- the linear periods of Friedberg–Jacquet Friedberg and Jacquet [1993], where $\mathrm{H} = \mathrm{GL}_{n/2} \times \mathrm{GL}_{n/2}$ embeds in $\mathrm{G} = \mathrm{GL}_n$ by

$$(a, d) \longmapsto \mathrm{diag}(a, d).$$

(iv) the Rankin–Selberg pair (named after its connection to Rankin–Selberg convolution L-functions), where $\mathrm{G} = \mathrm{GL}_{n-1} \times \mathrm{GL}_n$, and $\mathrm{H} = \mathrm{GL}_{n-1} \hookrightarrow G$ with the embedding

$$g \longmapsto (g,\ \mathrm{diag}(g, 1)).$$

(There are also spherical subgroups of $\mathrm{GL}_m \times \mathrm{GL}_n$ when $|n - m| > 1$ involving non-reductive subgroups.)

(v) the Gan–Gross–Prasad pairs $(\mathrm{SO}_{n-1}, \mathrm{SO}_{n-1} \times \mathrm{SO}_n)$ and $(\mathrm{U}_{n-1}, \mathrm{U}_{n-1} \times \mathrm{U}_n)$; see Section 2.2.2. They resemble the Rankin–Selberg pairs. (There are also spherical subgroups of $\mathrm{SO}_m \times \mathrm{SO}_n$ and $\mathrm{U}_m \times \mathrm{U}_n$ when $|n - m| > 1$ involving non-reductive subgroups).

2.2 The global Gan–Gross–Prasad conjecture and the Ichino–Ikeda refinement. Let F be a number field for the rest of this section.

2.2.1 Waldspurger formula. Let B be a quaternion algebra over F and let $\mathrm{G} = B^\times$ (as an F-algebraic group). Let F'/F be a quadratic extension of number fields and denote by T the torus $\mathrm{R}_{F'/F}\mathbb{G}_m$. Let $F' \hookrightarrow B$ be an embedding of F-algebras, and $\mathrm{T} \hookrightarrow \mathrm{G}$ the induced embedding of F-algebraic groups. Then (T, G) is a spherical pair. In Waldspurger [1985], Waldspurger studied the automorphic period integral $\mathcal{P}_{T,\chi}$ (sometimes called the *toric* period), and he proved an exact formula relating the square $|\mathcal{P}_{T,\chi}|^2$ to a certain central L-value.

Below we will consider one generalization of Waldspurger's formula to higher rank groups, i.e., the global conjectures of Gan–Gross–Prasad and Ichino–Ikeda. For this report, we implicitly assume the endoscopic classification of Arthur for orthogonal and unitary groups.

2.2.2 The global Gan–Gross–Prasad conjecture. Gan, Gross, and Prasad [2012] proposed a series of precise conjectures regarding the local and global distinction for (H, G) when G is a classical group (orthogonal, unitary and symplectic), extending the conjectures of Gross and Prasad [1992, 1994] for orthogonal groups.

We recall their global conjectures in orthogonal and Hermitian cases. For simplicity, we restrict to the case when the spherical subgroup is reductive. Let F be a number field, and let $F' = F$ in the orthogonal case and F' a quadratic extension of F in the Hermitian case. Let W_n be a non-degenerate orthogonal space or Hermitian space with F'-dimension n. Let $W_{n-1} \subset W_n$ be a non-degenerate subspace of codimension one. Let G_i be $\mathrm{SO}(W_i)$ or $\mathrm{U}(W_i)$ for $i = n-1, n$, and $\delta : \mathrm{G}_{n-1} \hookrightarrow \mathrm{G}_n$ the induced embedding. Let

$$\mathrm{G} = \mathrm{G}_{n-1} \times \mathrm{G}_n, \qquad \mathrm{H} = \mathrm{G}_{n-1}, \tag{2-3}$$

with the "diagonal" embedding $\Delta : \mathrm{H} \hookrightarrow \mathrm{G}$ (i.e., the graph of δ). The pair (H, G) is spherical and we call it the *Gan–Gross–Prasad pair*.

Let $\pi = \pi_{n-1} \boxtimes \pi_n$ be a tempered cuspidal automorphic representation of $\mathrm{G}(\mathbb{A})$. The central L-values of certain automorphic L-functions $L(s, \pi, R)$ show up in their conjecture, where R is a finite dimensional representation of the L-group ${}^L\mathrm{G}$, cf. Gan, Gross, and Prasad [2012, §22]. We can describe the L-function as the Rankin–Selberg convolution of suitable automorphic representations on general linear groups. For $i \in \{n-1, n\}$, let $\Pi_{i,F'}$ be the endoscopic functoriality transfer of π_i from G_i to suitable $\mathrm{GL}_N(\mathbb{A}_{F'})$: in the Hermitian case, this is the base change of π_i to $\mathrm{GL}_i(\mathbb{A}_{F'})$; and in the orthogonal case, this is the endoscopic transfer from $\mathrm{G}_i(\mathbb{A})$ to $\mathrm{GL}_i(\mathbb{A})$ (resp. $\mathrm{GL}_{i-1}(\mathbb{A})$) if i is even (resp. odd). Then the L-function $L(s, \pi, R)$ can be defined more explicitly as the Rankin–Selberg convolution L-function $L(s, \Pi_{n-1,F'} \times \Pi_{n,F'})$.

We are ready to state the global Gan–Gross–Prasad conjecture Gan, Gross, and Prasad [ibid., §24].

Conjecture 2.3. *Let π be a tempered cuspidal automorphic representation of $\mathrm{G}(\mathbb{A})$. The following statements are equivalent.*

(i) *The automorphic* H*-period integral does not vanish on π, i.e., $\mathcal{P}_{\mathrm{H}}(\phi) \neq 0$ for some $\phi \in \pi$.*

(ii) *The space $\mathrm{Hom}_{\mathrm{H}(\mathbb{A})}(\pi, \mathbb{C}) \neq 0$ and the central value $L(\frac{1}{2}, \pi, R) \neq 0$.*

Remark 2.4. It is known that the pair $(\mathrm{H}(F_v), \mathrm{G}(F_v))$ satisfies the multiplicity one property by Aizenbud, Gourevitch, Rallis, and Schiffmann [2010] for p-adic local fields, and by Sun and C.-B. Zhu [2012] for archimedean local fields. The local conjectures of Gan, Gross, and Prasad Gan, Gross, and Prasad [2012, §17] specify the member π_v in a generic Vogan L-packet (cf. Gan, Gross, and Prasad [ibid., §9-11]) with $\dim \mathrm{Hom}_{\mathrm{H}(F_v)}(\pi_v, \mathbb{C}) =$

1, in terms of local root numbers associated to the L-parameter. Their local conjectures are mostly proved by Gan, Gross, Prasad, and Waldspurger [2012] and Mœglin and Waldspurger [2012] (p-adic orthogonal groups), and Beuzart-Plessis [2015a] and Beuzart-Plessis [2015b] (unitary groups over p-adic and archimedean local fields). He [2017] gives an alternative proof for discrete series representations of unitary groups over archimedean local fields.

We have the following result.

Theorem 2.5. *Let* $\mathrm{G} = \mathrm{U}(W_{n-1}) \times \mathrm{U}(W_n)$ *for Hermitian spaces* $W_{n-1} \subset W_n$ *over a quadratic extension* F' *of* F. *Let* π *be a tempered cuspidal automorphic representation of* $\mathrm{G}(\mathbb{A})$ *such that there exist a non-archimedean place* v *of* F *split in* F' *where* π_v *is supercuspidal. Then Conjecture 2.3 holds.*

This was proved in W. Zhang [2014b] under a further condition on the archimedean places, which was later removed by Xue [n.d.]. The local condition above was due to a simple version of the Jacquet–Rallis relative trace formula in W. Zhang [2014b], cf. Section 5.2. Chaudouard and Zydor [2016] and Zydor [2015] have made progress towards the full relative trace formula that should remove the local condition.

Remark 2.6. Ginzburg, Jiang, and Rallis [2004, 2009] have proved the direction (i) $\Longrightarrow$ (ii) of Conjecture 2.3 for both the orthogonal and Hermitian cases when the group G is quasi-split and the representation π is (globally) generic (cf. Jiang and L. Zhang [2015, Theorem 5.7].

2.2.3 Ichino–Ikeda refinement. For many applications, we would like to have a refined version of the Gan–Gross–Prasad conjecture, analogous to the Waldspurger formula for the toric period $\mathcal{P}_{\mathrm{T},\chi}$ in Section 2.2.1. We recall the refinement of Ichino and Ikeda [2010] (for orthogonal groups; later their idea was carried out for unitary groups by N. Harris in Harris [2014]).

Let $L(s, \pi, \mathrm{Ad})$ be the adjoint L-function (cf. Gan, Gross, and Prasad [2012, §7]). Denote $\Delta_n = L(M^\vee(1))$ where $M^\vee$ is the motive dual to the motive M associated to G_n by Gross [1997]. It is a product of special values of Artin L-functions. We will be interested in the following combination of L-functions,

$$\mathcal{L}(s, \pi) = \Delta_n \frac{L(s, \pi, R)}{L(1, \pi, \mathrm{Ad})}. \tag{2-4}$$

We also write $\mathcal{L}(s, \pi_v)$ for the corresponding local factor at a place v.

Let π_v be an irreducible tempered unitary representation of $\mathrm{G}(F_v)$ with an invariant inner product $\langle \cdot, \cdot \rangle_v$. Ichino and Ikeda construct a canonical element in the space

$\mathrm{Hom}_{\mathrm{H}(F_v)}(\pi_v, \mathbb{C}) \otimes \mathrm{Hom}_{\mathrm{H}(F_v)}(\overline{\pi}_v, \mathbb{C})$ by integrating matrix coefficients: for $\phi_v, \varphi_v \in \pi_v$,

$$\widetilde{\alpha}_v(\phi_v, \varphi_v) = \int_{\mathrm{H}(F_v)} \langle \pi_v(h)\phi_v, \varphi_v\rangle_v \, dh. \tag{2-5}$$

Ichino and Ikeda showed that the integral converges absolutely for all (tempered) π. In fact, the convergence holds for any *strongly tempered* pair (H, G), cf. Sakellaridis and Venkatesh [2012]. When π_v is unramified and the vectors ϕ_v, φ_v are fixed by a hyperspecial compact open $\mathrm{G}(O_{F_v})$ such that $\langle \phi_v, \varphi_v\rangle_v = 1$, we have

$$\widetilde{\alpha}_v(\phi_v, \varphi_v) = \mathscr{L}(\frac{1}{2}, \pi_v) \cdot \mathrm{vol}(\mathrm{H}(O_{F_v})).$$

We normalize the local canonical invariant form:

$$\alpha_v(\phi_v, \varphi_v) = \frac{1}{\mathscr{L}(\frac{1}{2}, \pi_v)} \widetilde{\alpha}_v(\phi_v, \varphi_v). \tag{2-6}$$

We endow $\mathrm{H}(\mathbb{A})$ (resp. $\mathrm{G}(\mathbb{A})$) with their Tamagawa measures and $[\mathrm{H}]$ (resp. $[\mathrm{G}]$) with the quotient measure by the counting measure on $\mathrm{H}(F)$ (resp. $\mathrm{G}(F)$). We choose the Haar measure dh on $\mathrm{H}(\mathbb{A})$ and the measures dh_v on $\mathrm{H}(F_v)$ such that $dh = \prod_v dh_v$. Let $\langle \phi, \varphi\rangle_{\mathrm{Pet}}$ be the Petersson inner product of $\phi, \varphi \in \pi = \otimes_v \pi_v$, and choose the local inner products $\langle \cdot, \cdot\rangle_v$ such that $\langle \phi, \varphi\rangle = \prod_v \langle \phi_v, \varphi_v\rangle_v$ for $\phi = \otimes_v \phi_v$ and $\varphi = \otimes_v \varphi_v$.

We can now state the Ichino–Ikeda conjecture Ichino and Ikeda [2010, Conj. 1.5 and 2.1] that refines the global Gan–Gross–Prasad Conjecture 2.3.

Conjecture 2.7. *Let π be a tempered cuspidal automorphic representation of* $\mathrm{G}(\mathbb{A})$. *Then for $\phi = \otimes_v \phi_v \in \pi$,*

$$\left|\mathscr{P}_{\mathrm{H}}(\phi)\right|^2 = 2^{-\beta_\pi} \mathscr{L}(1/2, \pi) \prod_v \alpha_v(\phi_v, \phi_v), \tag{2-7}$$

where β_π is the rank of a finite elementary 2*-group associated to the L-parameter of π.*

Remark 2.8. If $\mathrm{Hom}_{\mathrm{H}(\mathbb{A})}(\pi, \mathbb{C}) = 0$, both sides of (2-7) vanish.

Remark 2.9. In the orthogonal case and $n = 3$, the refined conjecture is exactly the same as the formula of Waldspurger. When $n = 4$ the conjecture is proved by Ichino [2008]. Little is known in the higher rank case, cf. the survey Gan [2014].

In the Hermitian case and $n = 2$, the conjecture follows from Waldspurger's formula Harris [2014]. In general, we have the following result, due to the author W. Zhang [2014a] and Beuzart-Plessis [2016].

Theorem 2.10. *Let* $\mathrm{G} = \mathrm{U}(W_{n-1}) \times \mathrm{U}(W_n)$ *for Hermitian spaces* $W_{n-1} \subset W_n$ *over a quadratic extension* F' *of* F. *Let* π *be a tempered cuspidal automorphic representation of* $\mathrm{G}(\mathbb{A})$. *Assume that*

(i) *there exists a non-archimedean place* v *of* F *split in* F' *such that* π_v *is supercuspidal, and*

(ii) *all archimedean places of* F *are split in* F'.

Then Conjecture 2.7 holds.

For some ingredients of the proof, see Section 5.2.3.

2.2.4 Reformulation in terms of spherical characters. Let π be a cuspidal automorphic representation of $\mathrm{G}(\mathbb{A})$. We define the *global spherical character* $\mathbb{I}_\pi$ as the distribution on $\mathrm{G}(\mathbb{A})$

$$\mathbb{I}_\pi(f) := \sum_{\phi \in \mathrm{OB}(\pi)} \mathscr{P}_{\mathrm{H}}(\pi(f)\phi)\overline{\mathscr{P}_{\mathrm{H}}(\phi)}, \quad f \in \mathscr{C}_c^\infty(\mathrm{G}(\mathbb{A})), \tag{2-8}$$

where the sum runs over an orthonormal basis $\mathrm{OB}(\pi)$ of π (with respect to the Petersson inner product). Note that $\mathbb{I}_\pi$ is an *eigen-distribution* for the spherical Hecke algebra $\mathscr{H}^S(\mathrm{G})$ away from a sufficiently large set S (including all bad primes), in the sense that for all $f = f_S \otimes f^S$ with $f^S \in \mathscr{H}^S(\mathrm{G})$ and $f_S \in \mathscr{C}_c^\infty(\mathrm{G}(\mathbb{A}_S))$,

$$\mathbb{I}_\pi(f) = \lambda_{\pi^S}\left(f^S\right) \mathbb{I}_\pi\left(f_S \otimes 1_{K^S}\right), \tag{2-9}$$

where λ_{π^S} is the "eigen-character" of $\mathscr{H}^S(\mathrm{G})$ associated to π^S.

We define the *local spherical character* in terms of the local canonical invariant form α_v in (2-6),

$$\mathbb{I}_{\pi_v}(f_v) := \sum_{\phi_v \in \mathrm{OB}(\pi_v)} \alpha_v(\pi_v(f_v)\phi_v, \phi_v), \quad f_v \in \mathscr{C}_c^\infty(\mathrm{G}(F_v)), \tag{2-10}$$

where the sum runs over an orthonormal basis $\mathrm{OB}(\pi_v)$ of π_v.

In W. Zhang [2014a, Conj. 1.6] the author stated an alternative version of the Ichino–Ikeda conjecture in terms of spherical characters.

Conjecture 2.11. *Let* π *be a tempered cuspidal automorphic representation of* $\mathrm{G}(\mathbb{A})$. *Then for all pure tensors* $f = \bigotimes_v f_v \in \mathscr{C}_c^\infty(\mathrm{G}(\mathbb{A}))$,

$$\mathbb{I}_\pi(f) = 2^{-\beta_\pi} \mathscr{L}(1/2, \pi) \prod_v \mathbb{I}_{\pi_v}(f_v).$$

By W. Zhang [2014a, Lemma 1.7], this conjecture is equivalent to Conjecture 2.7. This new formulation is more suitable for the relative trace formula approach, cf. Section 5.2.3. This also inspires us to state a version of the refined arithmetic Gan–Gross–Prasad conjecture where the Ichino–Ikeda formulation does not seem to apply directly, cf. Section 3.2.3, Conjecture 3.5.

3 Special cycles and L-derivatives

3.1 Special pairs of Shimura data and special cycles.

3.1.1 . To describe our set-up, we introduce the concept of *a special pair of Shimura data*. Let $\mathbb{S}$ be the torus $\mathrm{R}_{\mathbb{C}/\mathbb{R}}\mathbb{G}_m$ over $\mathbb{R}$ (i.e., we view $\mathbb{C}^\times$ as an $\mathbb{R}$-group). Recall that a Shimura datum $\big(\mathrm{G}, X_{\mathrm{G}}\big)$ consists of a reductive group G over $\mathbb{Q}$, and a $\mathrm{G}(\mathbb{R})$-conjugacy class $X_{\mathrm{G}} = \{h_{\mathrm{G}}\}$ of $\mathbb{R}$-group homomorphisms $h_{\mathrm{G}} : \mathbb{S} \to \mathrm{G}_{\mathbb{R}}$ (sometimes called Shimura homomorphisms) satisfying Deligne's list of axioms Deligne [1971, p. 1.5]. In particular, X_{G} is a Hermitian symmetric domain.

Definition 3.1. A *special pair* of Shimura data is a homomorphism Deligne [ibid., p. 1.14] between two Shimura data

$$\delta\colon \big(\mathrm{H}, X_{\mathrm{H}}\big) \longrightarrow \big(\mathrm{G}, X_{\mathrm{G}}\big)$$

such that

(i) the homomorphism $\delta : \mathrm{H} \to \mathrm{G}$ is injective such that the pair (H, G) is spherical, and

(ii) the dimensions of X_{H} and X_{G} (as complex manifolds) satisfy

$$\dim_{\mathbb{C}} X_{\mathrm{H}} = \left\lfloor \frac{\dim_{\mathbb{C}} X_{\mathrm{G}}}{2} \right\rfloor.$$

In particular, we enhance a spherical pair (H, G) to a homomorphism of Shimura data $(\mathrm{H}, X_{\mathrm{H}}) \to (\mathrm{G}, X_{\mathrm{G}})$.

Remark 3.2. It seems an interesting question to enumerate special pairs of Shimura data. In fact, we may consider the analog of special pairs of Shimura data in the context of *local Shimura data* Rapoport and Viehmann [2014]. It seems more realistic to enumerate the pairs in the local situation.

For a Shimura datum $(\mathrm{G}, X_{\mathrm{G}})$ we have a projective system of *Shimura varieties* $\{\mathrm{Sh}_K(\mathrm{G})\}$, indexed by compact open subgroups $K \subset \mathrm{G}(\mathbb{A}_f)$, of smooth quasi-projective varieties (for neat K) defined over a number field E—the reflex field of $(\mathrm{G}, X_{\mathrm{G}})$.

For a special pair of Shimura data $(\mathrm{H}, X_{\mathrm{H}}) \to (\mathrm{G}, X_{\mathrm{G}})$, compact open subgroups $K_{\mathrm{H}} \subset \mathrm{H}(\mathbb{A}_f)$ and $K_{\mathrm{G}} \subset \mathrm{G}(\mathbb{A}_f)$ such that $K_{\mathrm{H}} \subset K_{\mathrm{G}}$, we have a finite morphism (over the reflex field of $(\mathrm{H}, X_{\mathrm{H}})$)

$$\delta_{K_{\mathrm{H}},K_{\mathrm{G}}} : \mathrm{Sh}_{K_{\mathrm{H}}}(\mathrm{H}) \longrightarrow \mathrm{Sh}_{K_{\mathrm{G}}}(\mathrm{G}).$$

The cycle $z_{K_{\mathrm{H}},K_{\mathrm{G}}} := \delta_{K_{\mathrm{H}},K_{\mathrm{G}},*}[\mathrm{Sh}_{K_{\mathrm{H}}}(\mathrm{H})]$ on $\mathrm{Sh}_{K_{\mathrm{G}}}(\mathrm{G})$ will be called the *special cycle* (for the level $(K_{\mathrm{H}}, K_{\mathrm{G}})$). Very often we choose $K_{\mathrm{H}} = K_{\mathrm{G}} \cap \mathrm{H}(\mathbb{A}_f)$ in which case we simply denote the special cycle by $z_{K_{\mathrm{G}}}$.

Remark 3.3. (i) Note that here our special cycles are different from those appearing in S. S. Kudla, Rapoport, and Yang [2006] and S. Kudla and Rapoport [2014].

(ii) When $\dim_{\mathbb{C}} X_{\mathrm{G}}$ is even, the special cycles are in the middle dimension. When $\dim_{\mathbb{C}} X_{\mathrm{G}}$ is odd, the special cycles are just below the middle dimension, and we will say that they are in the *arithmetic middle dimension* (in the sense that, once extending both Shimura varieties to suitable integral models, we obtain cycles in the middle dimension).

The special cases in the middle dimension are very often related to the study of Tate cycles and automorphic period integrals, e.g., in the pioneering example of Harder, Langlands, and Rapoport [1986], and many of its generalizations.

Below we focus on the case where the special cycles are in the arithmetic middle dimension.

3.1.2 Gross–Zagier pair.

In the case of the Gross–Zagier formula Gross and Zagier [1986], one considers an embedding of an *imaginary* quadratic field F' into $\mathrm{Mat}_{2,\mathbb{Q}}$ (the algebra of 2×2-matrices), and the induced embedding

$$\mathrm{H} = \mathrm{R}_{F'/\mathbb{Q}}\mathbb{G}_m \hookrightarrow \mathrm{G} = \mathrm{GL}_{2,\mathbb{Q}}.$$

Note that $\mathrm{H}_{\mathbb{R}} \simeq \mathbb{C}^\times$ as $\mathbb{R}$-groups (upon a choice of embedding $F' \hookrightarrow \mathbb{C}$). This defines $h_{\mathrm{H}} : \mathbb{S} \to \mathrm{H}_{\mathbb{R}}$, and its composition with the embedding $\mathrm{H}_{\mathbb{R}} \to \mathrm{G}_{\mathbb{R}}$ defines $h_{\mathrm{G}} : \mathbb{S} \to \mathbb{G}_{\mathbb{R}}$. We obtain a special pair $(\mathrm{H}, X_{\mathrm{H}}) \to (\mathrm{G}, X_{\mathrm{G}})$, where

$$\dim X_{\mathrm{G}} = 1, \qquad \dim X_{\mathrm{H}} = 0.$$

In the general case, we replace $F'/\mathbb{Q}$ by a CM extension F'/F of a totally real number field F, and replace $\mathrm{Mat}_{2,\mathbb{Q}}$ by a quaternion algebra B over F that is ramified at all but one archimedean places of F. X. Yuan, S. Zhang, and the author proved Gross–Zagier formula in this generality in Yuan, S.-W. Zhang, and W. Zhang [2013].

3.1.3 Gan–Gross–Prasad pair. Let (H, G) be the Gan–Gross–Prasad pair in Section 2.2.2, but viewed as algebraic groups over $\mathbb{Q}$ (i.e., the pair $(\mathrm{R}_{F/\mathbb{Q}}\mathrm{H}, \mathrm{R}_{F/\mathbb{Q}}\mathrm{G})$). The groups are associated to an embedding $W_{n-1} \subset W_n$ of orthogonal or Hermitian spaces (with respect to F'/F). Now we impose the following conditions.

(i) F is a totally real number field, and in the Hermitian case F'/F is a CM (=totally imaginary quadratic) extension.

(ii) For an archimedean place $\varphi \in \mathrm{Hom}(F, \mathbb{R})$, denote by $\mathrm{sgn}_\varphi(W)$ the signature of $W \otimes_{F,\varphi} \mathbb{R}$ as an orthogonal or Hermitian space over $F' \otimes_{F,\varphi} \mathbb{R}$. Then there exists a distinguished real place $\varphi_0 \in \mathrm{Hom}(F, \mathbb{R})$ such that

$$\mathrm{sgn}_\varphi(W_n) = \begin{cases} (2, n-2), & \varphi = \varphi_0 \\ (0, n), & \varphi \in \mathrm{Hom}(F, \mathbb{R}) \setminus \{\varphi_0\} \end{cases}$$

in the orthogonal case, and

$$\mathrm{sgn}_\varphi(W_n) = \begin{cases} (1, n-1), & \varphi = \varphi_0 \\ (0, n), & \varphi \in \mathrm{Hom}(F, \mathbb{R}) \setminus \{\varphi_0\} \end{cases}$$

in the Hermitian case. In addition, the quotient W_n/W_{n-1} is negative definite at every $\varphi \in \mathrm{Hom}(F, \mathbb{R})$ (so the signature of W_{n-1} is given by similar formulas).

Then Gan, Gross, and Prasad Gan, Gross, and Prasad [2012, §27] prescribe Shimura data that enhance the embedding $\mathrm{H} \hookrightarrow \mathrm{G}$ to a homomorphism of Shimura data $(\mathrm{H}, X_{\mathrm{H}}) \to (\mathrm{G}, X_{\mathrm{G}})$, where the dimensions are

$$\begin{cases} \dim X_{\mathrm{G}} = 2n-5, & \dim X_{\mathrm{H}} = n-3, \quad \text{in the orthogonal case,} \\ \dim X_{\mathrm{G}} = 2n-3, & \dim X_{\mathrm{H}} = n-2, \quad \text{in the Hermitian case.} \end{cases}$$

3.2 The arithmetic Gan–Gross–Prasad conjecture.

3.2.1 Height pairings. Let X be a smooth proper variety over a number field E, and let $\mathrm{Ch}^i(X)$ be the group of codimension-i algebraic cycles on X modulo rational equivalence. We have a cycle class map

$$\mathrm{cl}_i : \mathrm{Ch}^i(X)_{\mathbb{Q}} \longrightarrow H^{2i}(X),$$

where $H^{2i}(X)$ is the Betti cohomology $H^*\big(X(\mathbb{C}), \mathbb{C}\big)$. The kernel is the group of cohomologically trivial cycles, denoted by $\mathrm{Ch}^i(X)_0$.

Conditional on some standard conjectures on algebraic cycles, there is a height pairing defined by Beilinson and Bloch,

$$(3\text{-}1)\qquad (\ ,\ )_{\mathrm{BB}}\colon \mathrm{Ch}^i(X)_{\mathbb{Q},0}\times \mathrm{Ch}^{d+1-i}(X)_{\mathbb{Q},0}\longrightarrow \mathbb{R},\quad d=\dim X.$$

This is unconditionally defined when $i = 1$ (the Néron–Tate height), or when X is an abelian variety Künnemann [2001]. In some situations, cf. Rapoport, Smithling, and W. Zhang [2017b, §6.1], one can define the height pairing unconditionally in terms of the arithmetic intersection theory of Arakelov and Gillet–Soulé Gillet and Soulé [1990, §4.2.10]. This is the case when there exists a smooth proper model $\mathcal{X}$ of X over O_E (this is also true for Deligne–Mumford (DM) stacks X and $\mathcal{X}$).

3.2.2 The arithmetic Gan–Gross–Prasad conjecture. We consider the special cycle in the Gan–Gross–Prasad setting Section 3.1.3, which we also call the *arithmetic diagonal cycle* Rapoport, Smithling, and W. Zhang [2017b]. We will state a version of the arithmetic Gan–Gross–Prasad conjecture assuming some standard conjectures on algebraic cycles (cf. Rapoport, Smithling, and W. Zhang [ibid., §6]), in particular, that we have the height pairing (3-1).

For each $K\subset \mathrm{G}(\mathbb{A}_f)$, one can construct "Hecke–Kunneth" projectors that project the total cohomology of the Shimura variety $\mathrm{Sh}_K(\mathrm{G})$ (or its toroidal compactification) to the odd-degree part (cf. Rapoport, Smithling, and W. Zhang [ibid., §6.2] in the Hermitian case; the same proof works in the orthogonal case). Then we apply this projector to define a cohomologically trivial cycle $z_{K,0}\in \mathrm{Ch}^{n-1}\big(\mathrm{Sh}_K(\mathrm{G})\big)_0$ (with $\mathbb{C}$-coefficient). The classes $\{z_{K,0}\}_{K\subset \mathrm{G}(\mathbb{A}_f)}$ are independent of the choice of our projectors (cf. Rapoport, Smithling, and W. Zhang [ibid., Remark 6.11]), and they form a projective system (with respect to push-forward).

We form the colimit

$$\mathrm{Ch}^{n-1}\big(\mathrm{Sh}(\mathrm{G})\big)_0 := \varinjlim_{K\subset \mathrm{G}(\mathbb{A}_f)} \mathrm{Ch}^{n-1}\big(\mathrm{Sh}_K(\mathrm{G})\big)_0.$$

The height pairing with $\{z_{K,0}\}_{K\subset \mathrm{G}(\mathbb{A}_f)}$ defines a linear functional

$$\mathcal{P}_{\mathrm{Sh}(\mathrm{H})}\colon \mathrm{Ch}^{n-1}\big(\mathrm{Sh}(\mathrm{G})\big)_0 \longrightarrow \mathbb{C}\ .$$

This is the arithmetic version of the automorphic period integral in Section 2.1.2. The group $\mathrm{G}(\mathbb{A}_f)$ acts on the space $\mathrm{Ch}^{n-1}\big(\mathrm{Sh}(\mathrm{G})\big)_0$. For any representation π_f of $\mathrm{G}(\mathbb{A}_f)$, let $\mathrm{Ch}^{n-1}\big(\mathrm{Sh}(\mathrm{G})\big)_0[\pi_f]$ denote the π_f-isotypic component of the Chow group

$$\mathrm{Ch}^{n-1}\big(\mathrm{Sh}(\mathrm{G})\big)_0$$

We are ready to state the arithmetic Gan–Gross–Prasad conjecture Gan, Gross, and Prasad [2012, §27], parallel to Conjecture 2.3.

Conjecture 3.4. *Let π be a tempered cuspidal automorphic representation of* $\mathrm{G}(\mathbb{A})$*, appearing in the cohomology* $H^*(\mathrm{Sh}(\mathrm{G}))$*. The following statements are equivalent.*

(i) *The linear functional $\mathcal{P}_{\mathrm{Sh(H)}}$ does not vanish on the π_f-isotypic component*

$$\mathrm{Ch}^{n-1}\big(\mathrm{Sh}(\mathrm{G})\big)_0[\pi_f].$$

(ii) *The space* $\mathrm{Hom}_{\mathrm{H}(\mathbb{A}_f)}(\pi_f, \mathbb{C}) \neq 0$ *and the first order derivative* $L'(\frac{1}{2}, \pi, R) \neq 0$.

In the orthogonal case with $n \leq 4$, and when the ambient Shimura variety is a curve ($n = 3$), or a product of three curves ($n = 4$), the conjecture is unconditionally formulated. The case $n = 3$ is proved by X. Yuan, S. Zhang, and the author in Yuan, S.-W. Zhang, and W. Zhang [2013]; in fact we proved a refined version. When $n = 4$ and in the triple product case (i.e., the Shimura variety $\mathrm{Sh}_K(\mathrm{G})$ is a product of three curves), X. Yuan, S. Zhang, and the author formulated a refined version of the above conjecture and proved it in some special cases, cf. Yuan, S.-W. Zhang, and W. Zhang [n.d.].

3.2.3 Reformulation in terms of spherical characters. In the Hermitian case, Rapoport, Smithling, and the author in Rapoport, Smithling, and W. Zhang [2017b] stated a version of the arithmetic Gan–Gross–Prasad conjecture that does not depend on standard conjectures on algebraic cycles.

In fact we work with a variant of the Shimura data defined by Gan, Gross, and Prasad Gan, Gross, and Prasad [2012, §27]. We modify the groups $\mathrm{R}_{F/\mathbb{Q}}\mathrm{G}$ and $\mathrm{R}_{F/\mathbb{Q}}\mathrm{H}$ defined previously

$$\begin{aligned}
\mathrm{Z}^{\mathbb{Q}} &:= \mathrm{GU}_1 = \big\{ z \in \mathrm{R}_{F'/\mathbb{Q}}\mathbb{G}_m \bigm| \mathrm{Nm}_{F'/F}(z) \in \mathbb{G}_m \big\}, \\
\widetilde{\mathrm{H}} &:= \mathrm{G}\left(\mathrm{U}_1 \times \mathrm{U}(\mathrm{W_{n-1}})\right) = \big\{ (z,h) \in \mathrm{Z}^{\mathbb{Q}} \times \mathrm{GU}(W_{n-1}) \bigm| \mathrm{Nm}_{F'/F}(z) = c(h) \big\}, \\
\widetilde{\mathrm{G}} &:= \mathrm{G}\left(\mathrm{U}_1 \times \mathrm{U}(\mathrm{W_{n-1}}) \times \mathrm{U}(\mathrm{W_n})\right) \\
&= \big\{ (z,h,g) \in \mathrm{Z}^{\mathbb{Q}} \times \mathrm{GU}(W_{n-1}) \times \mathrm{GU}(W_n) \bigm| \mathrm{Nm}_{F'/F}(z) = c(h) = c(g) \big\},
\end{aligned}$$

where the symbol c denotes the unitary similitude factor. Then we have

$$\widetilde{\mathrm{H}} \xrightarrow{\sim} \mathrm{Z}^{\mathbb{Q}} \times \mathrm{R}_{F/\mathbb{Q}}\mathrm{H}\,, \qquad \widetilde{\mathrm{G}} \xrightarrow{\sim} \mathrm{Z}^{\mathbb{Q}} \times \mathrm{R}_{F/\mathbb{Q}}\mathrm{G}\,. \tag{3-2}$$

We then define natural Shimura data $\big(\widetilde{\mathrm{H}}, \{h_{\widetilde{\mathrm{H}}}\}\big)$ and $\big(\widetilde{\mathrm{G}}, \{h_{\widetilde{\mathrm{G}}}\}\big)$, cf. Rapoport, Smithling, and W. Zhang [2017b, §3]. This variant has the nice feature that the Shimira varieties are of PEL type, i.e., the canonical models are related to moduli problems of abelian varieties with polarizations, endomorphisms, and level structures, cf. Rapoport, Smithling, and W. Zhang [ibid., §4–§5].

For suitable Hermitian spaces and a special level structure $K^{\circ}_{\widetilde{G}} \subset \widetilde{G}(\mathbb{A}_f)$, we can even define *smooth* integral models (over the ring of integers of the reflex field) of the Shimura variety $\mathrm{Sh}_{K^{\circ}_{\widetilde{G}}}(\widetilde{G})$. For a general CM extension F'/F, it is rather involved to state this level structure Rapoport, Smithling, and W. Zhang [ibid., Remark 6.19] and define the integral models Rapoport, Smithling, and W. Zhang [ibid., §5]. For simplicity, from now on we consider a special case, when $F = \mathbb{Q}$ and $F' = F[\varpi]$ is an imaginary quadratic field. We further assume that the prime 2 is split in F'. We choose $\varpi \in F'$ such that $(\varpi) \subset O_{F'}$ is the product of all ramified prime ideals in $O_{F'}$.

We first define an auxiliary moduli functor $\mathcal{M}_{(r,s)}$ over $\operatorname{Spec} O_{F'}$ for $r + s = n$ (similar to S. Kudla and Rapoport [2014, §13.1]). For a locally noetherian scheme S over $\operatorname{Spec} O_{F'}$, $\mathcal{M}_{(r,s)}(S)$ is the groupoid of triples (A, ι, λ) where

- (A, ι) is an abelian scheme over S, with $O_{F'}$-action $\iota : O_{F'} \to \mathrm{End}(A)$ satisfying the Kottwitz condition of signature (r, s), and

- $\lambda : A \to A^{\vee}$ is a polarization whose Rosati involution induces on $O_{F'}$ the non-trivial Galois automorphism of F'/F, and such that $\ker(\lambda)$ is contained in $A[\iota(\varpi)]$ of rank $\#(O_{F'}/(\varpi))^n$ (resp. $\#(O_{F'}/(\varpi))^{n-1}$) when $n = r + s$ is even (resp. odd). In particular, we have $\ker(\lambda) = A[\iota(\varpi)]$ if $n = r + s$ is even.

Now we assume that $(r, s) = (1, n-1)$ or $(n-1, 1)$. We further impose the *wedge condition* and the *(refined) spin condition*, cf. Rapoport, Smithling, and W. Zhang [2017b, §4.4]. The functor is represented by a Deligne–Mumford stack again denoted by $\mathcal{M}_{(r,s)}$. It is *smooth* over $\operatorname{Spec} O_{F'}$, despite the ramification of the field extension $F'/\mathbb{Q}$, cf. Rapoport, Smithling, and W. Zhang [ibid., §4.4]. Then we have an integral model of copies of the Shimura variety $\mathrm{Sh}_{K^{\circ}_{\widetilde{G}}}(\widetilde{G})$ defined by

$$\mathcal{M}_{K^{\circ}_{\widetilde{G}}}(\widetilde{G}) = \mathcal{M}_{(0,1)} \times_{\operatorname{Spec} O_{F'}} \mathcal{M}_{(1,n-2)} \times_{\operatorname{Spec} O_{F'}} \mathcal{M}_{(1,n-1)}.$$

(In Rapoport, Smithling, and W. Zhang [ibid., §5.1] we do cut out the desired Shimura variety with the help of a sign invariant. Here, implicitly we need to replace this space by its toroidal compactification.)

We now describe the arithmetic diagonal cycle (or rather, its integral model) for the level $K^{\circ}_{\widetilde{H}} = K^{\circ}_{\widetilde{G}} \cap \widetilde{H}(\mathbb{A}_f)$. When n is odd (so $n-1$ is even), we define

$$\mathcal{M}_{K^{\circ}_{\widetilde{H}}}(\widetilde{H}) = \mathcal{M}_{(0,1)} \times_{\operatorname{Spec} O_{F'}} \mathcal{M}_{(1,n-2)},$$

and we can define an embedding explicitly by "taking products" (one sees easily that the conditions on the kernels of polarizations are satisfied):

(3-3)
$$\begin{array}{ccc} \mathfrak{M}_{K^{\circ}_{\widetilde{\mathrm{H}}}}(\widetilde{\mathrm{H}}) & \longrightarrow & \mathfrak{M}_{K^{\circ}_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}}) \\ (A_0, \iota_0, \lambda_0, A^\flat, \iota^\flat, \lambda^\flat) & \longmapsto & (A_0, \iota_0, \lambda_0, A^\flat, \iota^\flat, \lambda^\flat, A^\flat \times A_0, \iota^\flat \times \iota_0, \lambda^\flat \times \lambda_0). \end{array}$$

When n is even, the situation is more subtle; see Rapoport, Smithling, and W. Zhang [2017b, §4.4].

With the smooth integral model, we have an unconditionally defined height pairing (3-1) on $X = \mathrm{Sh}_{K^{\circ}_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}})$. Now we again apply a suitable Hecke–Kunneth projector to the cycle z_K for $K = K^{\circ}_{\widetilde{\mathrm{G}}}$, and we obtain a cohomologically trivial cycle $z_{K,0} \in \mathrm{Ch}(\mathrm{Sh}_{K^{\circ}_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}}))_0$. We define

(3-4)
$$\mathrm{Int}(f) = \Big(R(f) * z_{K,0},\ z_{K,0}\Big)_{\mathrm{BB}}, \quad f \in \mathcal{H}\left(\widetilde{\mathrm{G}}, K^{\circ}_{\widetilde{\mathrm{G}}}\right),$$

where $R(f)$ is the associated Hecke correspondence. Let $\mathcal{H}^{\mathrm{ram}_{F'}}(\widetilde{\mathrm{G}})$ be the spherical Hecke algebra away from the set $\mathrm{ram}_{F'}$ of primes ramified in F'/F.

Parallel to Conjecture 2.11, we can state an alternative version of the arithmetic Gan–Gross–Prasad conjecture in terms of spherical characters for the special level $K^{\circ}_{\widetilde{\mathrm{G}}}$.

Conjecture 3.5. *There is a decomposition*

$$\mathrm{Int}(f) = \sum_{\pi} \mathrm{Int}_\pi(f), \quad \textit{for all } f \in \mathcal{H}\left(\widetilde{\mathrm{G}}, K^{\circ}_{\widetilde{\mathrm{G}}}\right),$$

where the sum runs over all automorphic representations of $\widetilde{\mathrm{G}}(\mathbb{A})$ *that appear in the cohomology* $H^*(\mathrm{Sh}_{\widetilde{G},K_{\mathrm{G}}})$ *and are trivial on* $Z^{\mathbb{Q}}(\mathbb{A})$, *and* Int_π *is an eigen-distribution for the spherical Hecke algebra* $\mathcal{H}^{\mathrm{ram}_{F'}}(\widetilde{\mathrm{G}})$ *with eigen-character* $\lambda_{\pi^{\mathrm{ram}_{F'}}}$ *in the sense of* (2-9).

If such a representation π *is tempered, then*

$$\mathrm{Int}_\pi(f) = 2^{-\beta_\pi} \mathcal{L}'(1/2, \pi) \prod_{v<\infty} \mathbb{I}_{\pi_v}(f_v).$$

Here the constant β_π is the same as in Section 2.2.4, and there is a natural extension of the local spherical characters $\mathbb{I}_{\pi_v}$ to the triple $(\widetilde{\mathrm{G}}, \widetilde{\mathrm{H}}, \widetilde{\mathrm{H}})$.

Remark 3.6. Conjecture 3.5 can be viewed as a refined version of the arithmetic Gan–Gross–Prasad Conjecture 3.4. Other refinements were also given in by the author W. Zhang [2009] and independently by S. S. Zhang [2010]. Both of them rely on standard conjectures on height pairings, and hence are conditional.

4 Shtukas and higher Gross–Zagier formula

Now let F be the function field of a geometrically connected smooth proper curve X over a finite field $k = \mathbb{F}_q$. We may consider the analog of the special pair of Shimura data (cf. 3.1.1) in the context of Shtukas. Now there is much more freedom since we do not have the restriction from the archimedean place. One may choose an r-tuple of coweights of G to define G–Shtukas (with r-modifications), and the resulting moduli space lives over the r-fold power

$$X^r = \underbrace{X \times_{\operatorname{Spec} k} \dots \times_{\operatorname{Spec} k} X}_{r \text{ times}}.$$

This feature is completely missing in the number field case, where we only have two available options:

(i) when $r = 0$, the automorphic quotient $[\mathrm{G}]_K$ plays an analogous role, cf. 2.1.1.

(ii) when $r = 1$, we have Shimura varieties $\mathrm{Sh}_{K_\mathrm{G}}(\mathrm{G})$ associated to a Shimura datum $(\mathrm{G}, \{h_\mathrm{G}\})$. These varieties live over Spec E for a number field E.

In Yun and W. Zhang [2017] Yun and the author studied a simplest case, i.e., the special cycle on the moduli stack of rank two Shtukas with arbitrary number r of modifications. We connect their intersection numbers to the r-th order derivative of certain L-functions. We may view the result as an analog of Waldspurger's formula (for $r = 0$) and the Gross–Zagier formula (for $r = 1$).

4.1 The Heegner–Drinfeld cycle. Let $\mathrm{G} = \mathrm{PGL}_2$ and let Bun_2 be the stack of rank two vector bundles on X. The Picard stack Pic_X acts on Bun_2 by tensoring the line bundle. Then $\mathrm{Bun}_\mathrm{G} = \mathrm{Bun}_2 / \mathrm{Pic}_X$ is the moduli stack of G-torsors over X.

Let r be an *even* integer. Let $\mu \in \{\pm\}^r$ be an r-tuple of signs such that exactly half of them are equal to $+$. Let Hk_2^μ be the Hecke stack, i.e., $\mathrm{Hk}_2^\mu(S)$ is the groupoid of data

$$(\mathcal{E}_0, \cdots, \mathcal{E}_r, x_1, \cdots, x_r, f_1, \cdots, f_r),$$

where the $\mathcal{E}_i$'s are vector bundles of rank two over $X \times S$, the x_i's are S-points of X, each f_i is a minimal upper (i.e., increasing) modification if $\mu_i = +$, and minimal lower (i.e., decreasing) modification if $\mu_i = -$, and the i-th modification takes place along the graph of $x_i : S \to X$,

$$\mathcal{E}_0 \overset{f_1}{\dashrightarrow} \mathcal{E}_1 \overset{f_2}{\dashrightarrow} \cdots \overset{f_r}{\dashrightarrow} \mathcal{E}_r .$$

The Picard stack Pic_X acts on Hk_2^μ by simultaneously tensoring the line bundle. Define $\mathrm{Hk}_\mathrm{G}^\mu = \mathrm{Hk}_2^\mu / \mathrm{Pic}_X$. Recording $\mathcal{E}_i$ defines a projection $p_i : \mathrm{Hk}_\mathrm{G}^\mu \to \mathrm{Bun}_\mathrm{G}$.

The moduli stack $\mathrm{Sht}_{\mathrm{G}}^{\mu}$ of Drinfeld G-Shtukas of type μ for the group G is defined by the cartesian diagram

$$\begin{array}{ccc} \mathrm{Sht}_{\mathrm{G}}^{\mu} & \longrightarrow & \mathrm{Hk}_{\mathrm{G}}^{\mu} \\ \downarrow & & \downarrow {\scriptstyle (p_0, p_r)} \\ \mathrm{Bun}_{\mathrm{G}} & \xrightarrow{(\mathrm{id},\mathrm{Fr})} & \mathrm{Bun}_{\mathrm{G}} \times \mathrm{Bun}_{\mathrm{G}} \end{array} . \tag{4-1}$$

The stack $\mathrm{Sht}_{\mathrm{G}}^{\mu}$ is a Deligne–Mumford stack over X^r, and the natural morphism

$$\pi_{\mathrm{G}}^{\mu} : \mathrm{Sht}_{\mathrm{G}}^{\mu} \longrightarrow X^r$$

is smooth of relative dimension r.

Let $\nu : X' \to X$ be a finite étale cover of degree 2 such that X' is also geometrically connected. Denote by $F' = k(X')$ the function field. Let $\mathrm{T} = (\mathrm{R}_{F'/F}\mathbb{G}_m)/\mathbb{G}_m$ be the non-split torus associated to the double cover X' of X. The stack $\mathrm{Sht}_{\mathrm{T}}^{\mu}$ of T-Shtukas is defined analogously, with the rank two bundles $\mathcal{E}_i$ replaced by line bundles $\mathcal{L}_i$ on X', and the points x_i on X'. Then we have a map

$$\pi_{\mathrm{T}}^{\mu} : \mathrm{Sht}_{\mathrm{T}}^{\mu} \longrightarrow X'^r$$

which is a torsor under the finite Picard stack $\mathrm{Pic}_{X'}(k)/\mathrm{Pic}_X(k)$. In particular, $\mathrm{Sht}_{\mathrm{T}}^{\mu}$ is a proper smooth Deligne–Mumford stack over $\mathrm{Spec}\, k$.

There is a natural finite morphism of stacks over X^r, induced by the natural map $\nu_* : \mathrm{Pic}_{X'} \to \mathrm{Bun}_2$,

$$\mathrm{Sht}_{\mathrm{T}}^{\mu} \longrightarrow \mathrm{Sht}_{\mathrm{G}}^{\mu} .$$

It induces a finite morphism

$$\theta^{\mu} : \mathrm{Sht}_{\mathrm{T}}^{\mu} \longrightarrow \mathrm{Sht}_{\mathrm{G}}'^{\mu} := \mathrm{Sht}_{\mathrm{G}}^{\mu} \times_{X^r} X'^r .$$

This defines a class in the Chow group of proper cycles of dimension r with $\mathbb{Q}$-coefficients,

$$Z_{\mathrm{T}}^{\mu} := \theta_*^{\mu}[\mathrm{Sht}_{\mathrm{T}}^{\mu}] \in \mathrm{Ch}_{c,r}(\mathrm{Sht}_{\mathrm{G}}'^{\mu})_{\mathbb{Q}}. \tag{4-2}$$

In analogy to the Heegner cycle in the Gross–Zagier formula Gross and Zagier [1986] and Yuan, S.-W. Zhang, and W. Zhang [2013] in the number field case, we call Z_{T}^{μ} the *Heegner–Drinfeld cycle* in our setting.

Remark 4.1. The construction of the Heegner–Drinfeld cycle extends naturally to higher rank Shtukas (of rank n over X', respectively rank $2n$ over X) of type $\mu = (\mu_1, \cdots, \mu_r)$. Here μ_i are coweights of GL_n (or GL_{2n}) given by $(\pm 1, 0, \cdots, 0) \in \mathbb{Z}^n$ (or $\mathbb{Z}^{2n}$).

4.2 Taylor expansion of L-functions. Consider the middle degree cohomology with compact support

$$V = \mathrm{H}_c^{2r}((\mathrm{Sht}'^{\mu}_G) \otimes_k \overline{k}, \overline{\mathbb{Q}}_\ell)(r).$$

This vector space is endowed with the cup product

$$(\cdot,\cdot) : V \times V \longrightarrow \overline{\mathbb{Q}}_\ell \ .$$

Let ℓ be a prime number different from p. Let $K = \prod_v \mathrm{G}(O_{F_v})$, and let $\mathscr{H}_{\overline{\mathbb{Q}}_\ell} = \mathscr{H}(\mathrm{G}(\mathbb{A}), K)$ be the spherical Hecke algebra with $\overline{\mathbb{Q}}_\ell$-coefficients. For any maximal ideal $\mathfrak{m} \subset \mathscr{H}_{\overline{\mathbb{Q}}_\ell}$, we define the generalized eigenspace of V with respect to $\mathfrak{m}$ by

$$V_{\mathfrak{m}} = \cup_{i>0} V[\mathfrak{m}^i].$$

We also define a subspace V_{Eis} with the help of an *Eisenstein ideal*, cf Yun and W. Zhang [2017, §4.1.2]. Then we prove that there is a spectral decomposition, i.e., an orthogonal decomposition of $\mathscr{H}_{\overline{\mathbb{Q}}_\ell}$-modules,

$$V = V_{\mathrm{Eis}} \oplus \left(\bigoplus_{\mathfrak{m}} V_{\mathfrak{m}} \right), \tag{4-3}$$

where $\mathfrak{m}$ runs over a finite set of maximal ideals of $\mathscr{H}_{\overline{\mathbb{Q}}_\ell}$, and each $V_{\mathfrak{m}}$ is an $\mathscr{H}_{\overline{\mathbb{Q}}_\ell}$-module of finite dimension over $\overline{\mathbb{Q}}_\ell$ supported at the maximal ideal $\mathfrak{m}$; see Yun and W. Zhang [ibid., Thm. 7.16] for a more precise statement.

Let π be an everywhere unramified cuspidal automorphic representation π of $\mathrm{G}(\mathbb{A})$. The standard L-function $L(\pi, s)$ is a polynomial of degree $4(g-1)$ in $q^{-s-1/2}$, where g is the genus of X. Let $\pi_{F'}$ be the base change to F', and let $L(\pi_{F'}, s)$ be its standard L-function. Let $L(\pi, \mathrm{Ad}, s)$ be the adjoint L-function of π and define

$$\mathscr{L}(\pi_{F'}, s) = \epsilon(\pi_{F'}, s)^{-1/2} \frac{L(\pi_{F'}, s)}{L(\pi, \mathrm{Ad}, 1)}, \tag{4-4}$$

where the the square root is understood as $\epsilon(\pi_{F'}, s)^{-1/2} = q^{4(g-1)(s-1/2)}$. In particular, we have a functional equation:

$$\mathscr{L}(\pi_{F'}, s) = \mathscr{L}(\pi_{F'}, 1-s).$$

We consider the Taylor expansion at the central point $s = 1/2$:

$$\mathscr{L}(\pi_{F'}, s) = \sum_{r \geq 0} \mathscr{L}^{(r)}(\pi_{F'}, 1/2) \frac{(s-1/2)^r}{r!},$$

i.e.,

$$\mathcal{L}^{(r)}(\pi_{F'}, 1/2) = \frac{d^r}{ds^r}\Big|_{s=0} \left(\epsilon(\pi_{F'}, s)^{-1/2} \frac{L(\pi_{F'}, s)}{L(\pi, \mathrm{Ad}, 1)} \right).$$

If r is odd, by the functional equation we have

$$\mathcal{L}^{(r)}(\pi_{F'}, 1/2) = 0.$$

Now we fix an isomorphism $\mathbb{C} \simeq \overline{\mathbb{Q}}_\ell$. Let $\mathfrak{m} = \mathfrak{m}_\pi$ be the kernel of the associated character $\lambda_\pi : \mathcal{H}_{\overline{\mathbb{Q}}_\ell} \to \overline{\mathbb{Q}}_\ell$, and rename $V_\mathfrak{m}$ in (4-3) as V_π. Then our main result in Yun and W. Zhang [2017] relates the r-th Taylor coefficient to the self-intersection number of the π-component of the Heegner–Drinfeld cycle $\theta^\mu_*[\mathrm{Sht}^\mu_\mathrm{T}]$.

Theorem 4.2. *Let π be an everywhere unramified cuspidal automorphic representation of $\mathrm{G}(\mathbb{A})$. Let $[\mathrm{Sht}^\mu_\mathrm{T}]_\pi \in V_\pi$ be the projection of the cycle class of $\mathrm{cl}\left(\theta^\mu_*[\mathrm{Sht}^\mu_\mathrm{T}]\right) \in V$ to the direct summand V_π under the decomposition (4-3). Then*

$$\frac{1}{2(\log q)^r} |\omega_X| \, \mathcal{L}^{(r)}(\pi_{F'}, 1/2) = \left([\mathrm{Sht}^\mu_\mathrm{T}]_\pi, \quad [\mathrm{Sht}^\mu_T]_\pi \right),$$

where ω_X is the canonical divisor, and $|\omega_X| = q^{-2g+2}$.

Remark 4.3. Here we only consider étale double covers X'/X, and everywhere unramified π (whence the L-function has nonzero Taylor coefficients in even degrees only). In Yun and W. Zhang [n.d.], Yun and the author are extending the theorem above to the case when X'/X is ramified at a finite set R and π has Iwahori levels at Σ such that $R \cap \Sigma = \varnothing$.

4.3 Comparison with the conjecture of Birch and Swinnerton-Dyer. Let π be as in Theorem 4.2, and ρ_π the associated local system of rank two over the curve X by the global Langlands correspondence. Let $W'_\pi = H^1\left(X' \times \bar{k},\ \rho_\pi\right)$, a $\overline{\mathbb{Q}}_\ell$-vector space with the Frobenius endomorphism Fr. The L-function $L(\pi_{F'}, s)$ is then given by

$$L(\pi_{F'}, s - 1/2) = \det\left(1 - q^{-s}\,\mathrm{Fr} \,\middle|\, W'_\pi\right).$$

In particular, the dimension of the eigenspace $W'^{\,\mathrm{Fr}=q}_\pi$ is at most $\mathrm{ord}_{s=1/2} L(\pi_{F'}, s)$ (the conjectural semi-simplicity of Fr implies an equality). It is *expected* that, the complex $\mathbf{R}\pi^\mu_{\mathrm{G},!}\overline{\mathbb{Q}}_\ell$ on X^r decomposes as a direct sum of $\mathcal{H}_{\overline{\mathbb{Q}}_\ell}$-modules

$$\mathbf{R}\pi^\mu_{\mathrm{G},!}\overline{\mathbb{Q}}_\ell = \Big(\bigoplus_{\pi \text{ cuspidal}} \pi^K \otimes (\underbrace{\rho_\pi \boxtimes \cdots \boxtimes \rho_\pi}_{r \quad \text{times}}) \Big) \bigoplus \text{"a direct summand"},$$

such that $V_\pi = V_{\mathfrak{m}_\pi}$ in (4-3) (for $\mathfrak{m}_\pi = \ker(\lambda_\pi)$) corresponds to $\pi^K \otimes W'^{\otimes r}_\pi$. From now on we assume this decomposition. Then the cohomology class of the Heegner–Drinfeld cycle defines an element $Z_\pi^\mu \in \pi^K \otimes W_\pi'^{\otimes r}$. One can show that Z_π^μ is an eigen-vector for the operator $\mathrm{id} \otimes \mathrm{Fr}^{\otimes r}$ with eigenvalue q^r. Then Theorem 4.2 shows that this class does not vanish when $r \geq \mathrm{ord}_{s=1/2} L(\pi_{F'}, s)$, provided that $L(\pi_{F'}, s)$ is not a constant.

Conjecture 4.4. *Let* $r = \mathrm{ord}_{s=1/2} L(\pi_{F'}, s)$. *The class* Z_π^μ *belongs to*

$$\pi^K \otimes \wedge^r \left(W_\pi'^{\mathrm{Fr}=q}\right).$$

Note that the generalization of the conjecture of Birch and Swinnerton-Dyer to function fields by Artin and Tate predicts that $\dim W_\pi'^{\mathrm{Fr}=q} = \mathrm{ord}_{s=1/2} L(\pi_{F'}, s)$.

We have a similar conjecture when X'/X is ramified at a finite set R and π has Iwahori levels at Σ such that $R \cap \Sigma = \varnothing$, cf. Yun and W. Zhang [ibid.]. In a forthcoming work, Yun and the author plan to prove that

(i) Let $r_0 \geq 0$ be the smallest integer r such that $Z_\pi^\mu \neq 0$ for some $\mu \in \{\pm\}^r$. Then $\dim W_\pi'^{\mathrm{Fr}=q} = r_0$, and the class Z_π^μ gives a basis to the line $\pi^K \otimes \wedge^r \left(W_\pi'^{\mathrm{Fr}=q}\right)$.

(ii) $\mathrm{ord}_{s=1/2} L(\pi_{F'}, s) = 1$ *if and only if* $\dim W_\pi'^{\mathrm{Fr}=q} = 1$. In particular, if $\mathrm{ord}_{s=1/2} L(\pi_{F'}, s) = 3$, then $\dim W_\pi'^{\mathrm{Fr}=q} = 3$.

5 Relative trace formula

5.1 An overview of RTF. A natural tool to study automorphic period integrals is the *relative trace formula* (RTF) introduced by Jacquet. For the reader's convenience, we give a very brief overview of the relative trace formula (cf. the survey articles Jacquet [2005], Lapid [2006, 2010], and Offen [2009]).

We start with a triple $(\mathrm{G}, \mathrm{H}_1, \mathrm{H}_2)$ consisting of a reductive group G and two subgroups $\mathrm{H}_1, \mathrm{H}_2$ defined over F. Known examples suggest that we may further assume that the pairs $(\mathrm{H}_i, \mathrm{G})$ are spherical (cf. Section 2.1.3), although this is not essential to our informal discussion here.

To a test function $f \in \mathcal{C}_c^\infty(\mathrm{G}(\mathbb{A}))$ we associate an automorphic kernel function,

$$K_f(x, y) := \sum_{\gamma \in \mathrm{G}(F)} f(x^{-1}\gamma y), \quad x, y \in \mathrm{G}(\mathbb{A}),$$

which is invariant under $\mathrm{G}(F)$ for both variables x and y. This defines an integral operator representing $R(f)$ for the action R of $\mathrm{G}(\mathbb{A})$ on the Hilbert space $L^2([\mathrm{G}])$. Therefore the kernel function has a spectral decomposition, and the contribution of a cuspidal automorphic representation π to the kernel function is given by

$$K_{\pi,f}(x, y) = \sum_{\varphi \in \mathrm{OB}(\pi)} \big(\pi(f)\varphi\big)(x)\, \overline{\varphi(y)}, \tag{5-1}$$

where the sum runs over an orthonormal basis $\mathrm{OB}(\pi)$ of π (with respect to the Petersson inner product).

Then we consider a linear functional on $\mathcal{C}_c^\infty(\mathrm{G}(\mathbb{A}))$,

$$\mathbb{I}(f) = \int_{[\mathrm{H}_1]} \int_{[\mathrm{H}_2]} K_f(h_1, h_2)\, dh_1\, dh_2. \tag{5-2}$$

The spectral contribution (5-1) from an automorphic representation π is the (global) *spherical character* (relative to $(\mathrm{H}_1, \mathrm{H}_2)$), denoted by $\mathbb{I}_\pi(f)$. Similar to (2-8), this is equal to

$$\mathbb{I}_\pi(f) = \sum_{\phi \in \mathrm{OB}(\pi)} \mathcal{P}_{\mathrm{H}_1}(\pi(f)\phi)\overline{\mathcal{P}_{\mathrm{H}_2}(\phi)}.$$

Let $\mathrm{H}_{1,2} := \mathrm{H}_1 \times \mathrm{H}_2$. Then $\mathrm{H}_{1,2}$ acts on G by $(h_1, h_2)\colon \gamma \mapsto h_1^{-1}\gamma h_2$. For certain nice orbits $\gamma \in \mathrm{G}(F)/\mathrm{H}_{1,2}(F)$, we can define orbital integrals (relative to $\mathrm{H}_{1,2}$):

$$\mathrm{Orb}(\gamma, f) := \mathrm{vol}([\mathrm{H}_{1,2,\gamma}]) \int_{\mathrm{H}_{1,2}(\mathbb{A})/\mathrm{H}_{1,2,\gamma}(\mathbb{A})} f(h_1^{-1}\gamma h_2)\, dh_1\, dh_2, \tag{5-3}$$

where $\mathrm{H}_{1,2,\gamma}$ denotes the stabilizer of γ, and vol stands for "volume".

The relative trace formula attached to the triple $(\mathrm{G}, \mathrm{H}_1, \mathrm{H}_2)$ is then the identity between the spectral expansion and the geometric expansion of $\mathbb{I}(f)$:

$$\sum_\pi \mathbb{I}_\pi(f) + \cdots = \sum_\gamma \mathrm{Orb}(\gamma, f) + \cdots,$$

where the $\cdots$ parts need more care (in fact saying so is oversimplifying). We will use $\mathrm{RTF}_{(\mathrm{G},\mathrm{H}_1,\mathrm{H}_2)}$ to stand for the above relative trace formula identity. This is only a very coarse form, and depending on the triple $(\mathrm{G}, \mathrm{H}_1, \mathrm{H}_2)$ the identity may need further refinements such as stabilization, as experience with the Arthur–Selberg trace formula suggests.

Remark 5.1. When we take the triple $(\mathrm{H} \times \mathrm{H}, \Delta_\mathrm{H}, \Delta_\mathrm{H})$, where $\Delta_\mathrm{H} \subset \mathrm{H} \times \mathrm{H}$ is the diagonal embedding of H, the associated relative trace formula is essentially equivalent to the Arthur–Selberg trace formula associated to H. Therefore the RTF can be viewed as a generalization of the Arthur–Selberg trace formula.

In application to questions such as the Gan–Gross–Prasad conjecture, we need to compare two RTFs that are close to each other,

$$\mathrm{RTF}_{(\mathrm{G},\mathrm{H}_1,\mathrm{H}_2)} \longleftrightarrow \mathrm{RTF}_{(\mathrm{G}',\mathrm{H}_1',\mathrm{H}_2')}.$$

The comparison allows us to connect the automorphic periods on G to those on G′. There are many successful examples, although it is a subtle question how to seek comparable RTFs in general.

5.2 Jacquet–Rallis RTFs.

5.2.1 . We recall the two RTFs constructed by Jacquet and Rallis [2011] to attack the Gan–Gross–Prasad conjecture in the Hermitian case (cf. Section 2.2.2).

The first RTF deals with the automorphic H-period integral on G and is associated to the triple $(\mathrm{G}, \mathrm{H}, \mathrm{H})$. The second one is associated to the triple $(\mathrm{G}', \mathrm{H}_1', \mathrm{H}_2')$ where

$$\mathrm{G}' = \mathrm{R}_{F'/F}(\mathrm{GL}_{n-1} \times \mathrm{GL}_n),$$

and

$$\mathrm{H}_1' = \mathrm{R}_{F'/F}\mathrm{GL}_{n-1}, \quad \mathrm{H}_2' = \mathrm{GL}_{n-1} \times \mathrm{GL}_n,$$

where $(\mathrm{H}_1', \mathrm{G}')$ is the Rankin–Selberg pair, and $(\mathrm{H}_2', \mathrm{G}')$ the Flicker–Rallis pair, cf. Section 2.1.3. Moreover it is necessary to insert a quadratic character of $\mathrm{H}_2'(\mathbb{A})$:

$$\eta = \eta_{n-1,n} : (h_{n-1}, h_n) \in \mathrm{H}_2'(\mathbb{A}) \longmapsto \eta_{F'/F}^{n-2}(\det(h_{n-1}))\eta_{F'/F}^{n-1}(\det(h_n)),$$

where $\eta_{F'/F} : F^\times\backslash\mathbb{A}^\times \to \{\pm 1\}$ is the quadratic character associated to F'/F by class field theory.

For the later application to the arithmetic Gan–Gross–Prasad conjecture, we introduce (cf. W. Zhang [2012b, §3.1]) the global distribution on $\mathrm{G}'(\mathbb{A})$ parameterized by a complex variable $s \in \mathbb{C}$,

(5-4)
$$\mathbb{J}(f', s) = \int_{[\mathrm{H}_1']}\int_{[\mathrm{H}_2']} K_{f'}(h_1, h_2)\,\left|\det(h_1)\right|^s \eta(h_2)\, dh_1\, dh_2, \quad f' \in \mathcal{C}_c^\infty(\mathrm{G}'(\mathbb{A})).$$

We set

$$\mathbb{J}(f') = \mathbb{J}(f', 0).$$

Remark 5.2. Due to the presence of the Flicker–Rallis pair $(\mathrm{H}_2', \mathrm{G}')$, the cuspidal part of the spectral side in $\mathrm{RTF}_{(\mathrm{G}',\mathrm{H}_1',\mathrm{H}_2')}$ only contains those automorphic representations that are in the image of the quadratic base change from unitary groups. This gives the hope that the spectral sides of the two RTFs should match.

Remark 5.3. In Gan, Gross, and Prasad [2012], Gan, Gross, and Prasad also made global conjectures for $\mathrm{SO}_n \times \mathrm{SO}_m$ and $\mathrm{U}_n \times \mathrm{U}_m$ when $|n-m| > 1$. Towards them in the Hermitian cases, Y. Liu in Liu [2014, 2016] has generalized the construction of Jacquet and Rallis.

5.2.2 Geometric terms: orbital integrals. In the comparison of geometric sides of two RTFs, we need to match orbits and orbital integrals. We review the comparison in the Jacquet–Rallis case.

We call an element $\gamma \in \mathrm{G}(F)$ *regular semi-simple* (relative to the action of $\mathrm{H}_{1,2} = \mathrm{H}_1 \times \mathrm{H}_2$) if its orbit under $\mathrm{H}_{1,2}$ is Zariski closed and its stabilizer is of minimal dimension. The regular semi-simple orbits will be the nice ones for the study of orbital integrals. For the triples $(\mathrm{G}, \mathrm{H}, \mathrm{H})$ and $(\mathrm{G}', \mathrm{H}'_1, \mathrm{H}'_2)$ in the Jacquet–Rallis RTFs, the condition is equivalent to γ having Zariski closed orbit and trivial stabilizer. In particular, for such γ the orbital integral (5-3) simplifies. We denote by $\mathrm{G}(F)_{\mathrm{rs}}$ (resp. $\mathrm{G}'(F)_{\mathrm{rs}}$) the set of regular semi-simple elements in $\mathrm{G}(F)$ (resp. $\mathrm{G}'(F)$). We denote by $[\mathrm{G}(F)_{\mathrm{rs}}]$ and $[\mathrm{G}'(F)_{\mathrm{rs}}]$ the respective sets of orbits.

Depending on the pair of Hermitian spaces $W := (W_{n-1}, W_n)$, we denote the triple $(\mathrm{G}, \mathrm{H}, \mathrm{H})$ by $(\mathrm{G}_W, \mathrm{H}_W, \mathrm{H}_W)$. We consider the equivalence relation $(W_{n-1}, W_n) \sim (W'_{n-1}, W'_n)$ if there is a scalar $\lambda \in F^\times$ such that we have isometries $W'_{n-1} \simeq {}^\lambda W_{n-1}$ and $W'_n \simeq {}^\lambda W_n$, where the left superscript changes the Hermitian form by a multiple λ. There is a natural bijection (cf. W. Zhang [2012b, §2], Rapoport, Smithling, and W. Zhang [2017a, §2])

$$\coprod_W [\mathrm{G}_W(F)_{\mathrm{rs}}] \xrightarrow{\sim} [\mathrm{G}'(F)_{\mathrm{rs}}], \tag{5-5}$$

where the left hand side runs over all pairs $W = (W_{n-1}, W_n)$ up to equivalence. This bijection holds for any quadratic extension of fields F'/F of characteristic not equal to 2.

Now we let F'/F be a quadratic extension of *local fields*. For $g \in \mathrm{G}_W(F)_{\mathrm{rs}}$ and $f \in \mathcal{C}_c^\infty(\mathrm{G}_W(F))$ we introduce the orbital integral

$$\mathrm{Orb}(g, f) = \int_{\mathrm{H}_{1,2}(F)} f(h_1^{-1} g h_2)\, dh_1\, dh_2. \tag{5-6}$$

For $\gamma \in \mathrm{G}'(F)_{\mathrm{rs}}$, $f' \in \mathcal{C}_c^\infty(\mathrm{G}'(F))$, and $s \in \mathbb{C}$, we introduce the (weighted) orbital integral

$$\mathrm{Orb}(\gamma, f', s) = \int_{\mathrm{H}'_{1,2}(F)} f(h_1^{-1} \gamma h_2) \lvert \det(h_1) \rvert^s \eta(h_2)\, dh_1\, dh_2. \tag{5-7}$$

We set

$$\mathrm{Orb}(\gamma, f') := \mathrm{Orb}(\gamma, f', 0) \quad \text{and} \quad \partial\mathrm{Orb}(\gamma, f') := \frac{d}{ds}\Big|_{s=0} \mathrm{Orb}(\gamma, f', s). \tag{5-8}$$

Definition 5.4. (i) We say that $g \in \mathrm{G}_W(F)_{\mathrm{rs}}$ and $\gamma \in \mathrm{G}'(F)_{\mathrm{rs}}$ *match* if their orbits correspond to each other under (5-5).

(ii) Dually, we say that a function $f' \in \mathcal{C}_c^\infty(\mathrm{G}'(F))$ and a tuple $\{f_W \in \mathcal{C}_c^\infty(\mathrm{G}_W(F))\}$ indexed by W (up to equivalence) are *transfers* of each other if for each W and each $g \in \mathrm{G}_W(F)_{\mathrm{rs}}$,

$$\mathrm{Orb}(g, f_W) = \omega(\gamma)\,\mathrm{Orb}(\gamma, f')$$

whenever $\gamma \in \mathrm{G}'(F)_{\mathrm{rs}}$ matches g. Here $\omega(\gamma)$ is a certain explicit transfer factor W. Zhang [2014b] and Rapoport, Smithling, and W. Zhang [2018].

(iii) We say that a component f_W in the tuple is a *transfer* of f' if the remaining components of the tuple are all zero.

In W. Zhang [2014b] we prove the following.

Theorem 5.5. *Let F'/F be a quadratic extension of p-adic local fields (then there are two equivalence classes of pairs of Hermitian spaces denoted by $W, W^\flat$ respectively). Then for any $f' \in \mathcal{C}_c^\infty(\mathrm{G}'(F))$ there exists a transfer $(f_0, f_1) \in \mathcal{C}_c^\infty(\mathrm{G}_W(F)) \times \mathcal{C}_c^\infty(\mathrm{G}_{W^\flat}(F))$, and for any pair $(f_0, f_1) \in \mathcal{C}_c^\infty(\mathrm{G}_W(F)) \times \mathcal{C}_c^\infty(\mathrm{G}_{W^\flat}(F))$ there exists a transfer $f' \in \mathcal{C}_c^\infty(\mathrm{G}'(F))$.*

This was conjectured by Jacquet and Rallis [2011]. For archimedean local fields F'/F, an "approximate transfer" is proved by Xue [n.d.].

5.2.3 Spectral terms: spherical characters. We are now back to F being a number field. For the triple $(\mathrm{G}, \mathrm{H}_1, \mathrm{H}_2)$ we have defined the global (resp. local) spherical characters by (2-8) (resp. by (2-10)). For the triple $(\mathrm{G}', \mathrm{H}_1', \mathrm{H}_2')$, we define the global spherical character associated to a cuspidal automorphic representation Π of $\mathrm{G}'(\mathbb{A})$,

$$\mathbb{J}_\Pi(f', s) = \sum_{\phi \in \mathrm{OB}(\Pi)} \mathcal{P}_{\mathrm{H}_1', s}(\Pi(f)\phi)\overline{\mathcal{P}_{\mathrm{H}_2', \eta}(\phi)}, \quad f' \in \mathcal{C}_c^\infty(\mathrm{G}'(\mathbb{A})), \quad s \in \mathbb{C},$$

where $\mathcal{P}_{\mathrm{H}_1', s}$ is the automorphic period integral $\mathcal{P}_{\mathrm{H}_1', \chi_s}$ for the character χ_s of $\mathrm{H}_1(\mathbb{A}) \in \mathrm{GL}_{n-1}(\mathbb{A}_{F'})$ defined by $h \mapsto |\det(h)|_{F'}^s$. We set $\mathbb{J}_\Pi(f') = \mathbb{J}_\Pi(f', 0)$. We expect to have a global character identity W. Zhang [2014a, Conj. 4.2]:

Conjecture 5.6. *Let π be a tempered cuspidal automorphic representation of $\mathrm{G}(\mathbb{A})$ such that $\mathrm{Hom}_{\mathrm{H}(\mathbb{A})}(\pi, \mathbb{C}) \neq 0$. Let $\Pi = \mathrm{BC}(\pi)$ be its base change which we assume is cuspidal. Then for $f' \in \mathcal{C}_c^\infty(\mathrm{G}'(\mathbb{A}))$ and any transfer $f \in \mathcal{C}_c^\infty(\mathrm{G}(\mathbb{A}))$,*

$$\mathbb{I}_\pi(f) = 2^{-\beta_\pi}\,\mathbb{J}_\Pi(f').$$

Remark 5.7. In fact here we have $\beta_\pi = 2$ due to the cuspidality of $\Pi = \mathrm{BC}(\pi)$. Conjecture 5.6 is known when π_v is supercuspidal at a place v split in F'/F, cf. W. Zhang

[2014b]. In general it should follow from a full spectral decomposition of the Jacquet–Rallis relative trace formulas, and perhaps along the way one will discover the correct definition of the global spherical character $\mathbb{J}_\Pi(f')$ when $\Pi = \mathrm{BC}(\pi)$ is not cuspidal.

In W. Zhang [2014a, §3.4], we defined a local spherical character $\mathbb{J}_{\Pi_v}(f'_v, s)$ for any tempered Π_v (depending on some auxiliary data). Then, for pure tensors $f' = \otimes_v f'_v$, the global spherical character decomposes naturally as an Euler product for $\Pi = \mathrm{BC}(\pi)$,

$$\mathbb{J}_\Pi(f', s) = 2^{-\beta_\pi} \mathscr{L}(s + 1/2, \pi) \prod_v \mathbb{J}_{\Pi_v}(f'_v, s). \tag{5-9}$$

We set $\mathbb{J}_{\Pi_v}(f'_v) = \mathbb{J}_{\Pi_v}(f'_v, 0)$. We expect to have a local character identity W. Zhang [ibid., Conj. 4.4]:

Conjecture 5.8. *Let π_v be a tempered representation of $\mathrm{G}(F_v)$ such that $\mathrm{Hom}_{\mathrm{H}(F_v)}(\pi, \mathbb{C}) \neq 0$. Let $\Pi_v = \mathrm{BC}(\pi_v)$ be its base change. Then for $f'_v \in \mathscr{C}_c^\infty(\mathrm{G}'(F_v))$ and any transfer $f_v \in \mathscr{C}_c^\infty(\mathrm{G}(F_v))$,*

$$\mathbb{J}_{\Pi_v}(f'_v) = \kappa_{\pi_v}\, \mathbb{I}_{\pi_v}(f_v),$$

where κ_{π_v} is an explicit constant.

By a theorem of Harish-Chandra, the character of an admissible representation of $\mathrm{G}(F_v)$ for any reductive group G over a p-adic local field F_v admits a local expansion around the identity of $\mathrm{G}(F_v)$ as a sum of Fourier transforms of unipotent orbital integrals. We have a partial analog for the local spherical character $\mathbb{J}_{\Pi_v}$.

Theorem 5.9. *Let v be a non-archimedean place. Let $\Pi_v = \mathrm{BC}(\pi_v)$ be the base change of a tempered representation π_v of $\mathrm{G}(F_v)$. For any small neighborhood of the identity element of $\mathrm{G}'(F_v)$, there exists an admissible (in the sense of W. Zhang [ibid., §8.1]) function $f'_v \in \mathscr{C}_c^\infty(\mathrm{G}'(F_v))$ such that*

$$\mathbb{J}_{\Pi_v}(f'_v) = c_\Pi \cdot \widehat{\mu}_{\mathrm{reg}}(f'_v),$$

where $\widehat{\mu}_{\mathrm{reg}}$ is the Fourier transform of the (relative) regular unipotent orbital integral, cf. W. Zhang [ibid., §6.3, §8.2], and c_{Π_v} is an explicit constant depending on Π_v.

We have the following.

Theorem 5.10. *Conjecture 5.8 holds if v is split in F'/F, or F_v is a p-adic local field.*

The case of a split v is rather easy W. Zhang [ibid.]. The case of a supercuspidal representation π_v was proved in W. Zhang [ibid.]. For the general p-adic case, the result is proved by Beuzart-Plessis in Beuzart-Plessis [2016] using Theorem 5.9, a local relative trace formula for Lie algebras in W. Zhang [2014b, §4.1], and a group analog in Beuzart-Plessis [2015b].

Remark 5.11. If $\Pi = \mathrm{BC}(\pi)$ is cuspidal, then Conjecture 5.6 and Conjecture 5.8 together imply Conjecture 2.11.

5.3 Arithmetic RTF. In W. Zhang [2012b], the author introduced a relative trace formula approach to the arithmetic Gan–Gross–Prasad conjecture. Let

$$\partial\mathbb{J}(f') = \frac{d}{ds}\Big|_{s=0}\mathbb{J}(f', s),$$

cf. (5-4). Then the idea is that, in analogy to the usual comparison of two RTFs, we hope to compare the height pairing $\mathrm{Int}(f)$ in (3-4) and $\partial\mathbb{J}(f')$ for $f \in \mathcal{H}(\widetilde{\mathrm{G}}, K^{\circ}_{\widetilde{\mathrm{G}}})$ and ay transfer $f' \in \mathcal{C}_c^{\infty}(\mathrm{G}'(\mathbb{A}))$.

Remark 5.12. Here we note that there is no archimedean component in the test function f on the unitary group side. Implicitly we demand that $f' = \otimes_v f'_v \in \mathcal{C}_c^{\infty}(\mathrm{G}'(\mathbb{A}))$, where f'_∞ is a *Gaussian* test function in the sense of Rapoport, Smithling, and W. Zhang [2017b, §7.3] (equivalently, we complete f by tensoring a distinguished archimedean component f_∞ as in W. Zhang [2012b, §3.2, (3.5)]). We also note that, by the isomorphisms (3-2), the orbits on $\widetilde{\mathrm{G}}(F)_{\mathrm{rs}}$ are in natural bijection with those on $\mathrm{G}(F)_{\mathrm{rs}}$, and all geometric terms related to G in Section 5.2.2 transport to $\widetilde{\mathrm{G}}$. We will not repeat the definitions.

To be able to work in a greater generality than the case the height pairing (3-1) is defined, in Rapoport, Smithling, and W. Zhang [2017b], Rapoport, Smithling, and the author turn to the arithmetic intersection theory $(\ ,\ )_{\mathrm{GS}}$ of Arakelov and Gillet–Soulé Gillet and Soulé [1990, §4.2.10] on the arithmetic Chow group $\widehat{\mathrm{Ch}}^*(\mathfrak{X})$ of a regular proper flat scheme (or DM stack) $\mathfrak{X}$ over $\mathrm{Spec}(O_{F'})$. For certain more general levels $K_{\widetilde{\mathrm{G}}} \subset K^{\circ}_{\widetilde{\mathrm{G}}}$, we construct regular integral models $\mathcal{M}_{K_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}})$ of $\mathrm{Sh}_{K_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}})$ (essentially by adding Drinfeld level structures at split primes to the moduli space $\mathcal{M}_{K^{\circ}_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}})$, cf. Rapoport, Smithling, and W. Zhang [2017b, §4, §5]). We enhance the arithmetic diagonal cycle to an element $\widehat{z}_K$ in $\widehat{\mathrm{Ch}}^{n-1}(\mathcal{M}_{K_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}}))$, and we extend the action R of a smaller Hecke algebra $\mathcal{H}^{\mathrm{spl}}(\widetilde{\mathrm{G}}, K_{\widetilde{\mathrm{G}}}) \subset \mathcal{H}(\widetilde{\mathrm{G}}, K_{\widetilde{\mathrm{G}}})$ on the Chow group of $\mathrm{Sh}_{K_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}})$ to an action $\widehat{R}$ on the arithmetic Chow group. We define

$$\mathrm{Int}(f) = \left(\widehat{R}(f)\widehat{z}_K, \widehat{z}_K\right)_{\mathrm{GS}}, \quad f \in \mathcal{H}^{\mathrm{spl}}(\widetilde{\mathrm{G}}, K_{\widetilde{\mathrm{G}}}). \tag{5-10}$$

We can then state an arithmetic intersection conjecture for the arithmetic diagonal cycle on the global integral model $\mathcal{M}_{K_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}})$ Rapoport, Smithling, and W. Zhang [ibid., §8.1, §8.2].

Conjecture 5.13. *Let* $f \in \mathcal{H}^{\mathrm{spl}}(\widetilde{\mathrm{G}}, K_{\widetilde{\mathrm{G}}})$*, and let* $f' \in \mathcal{C}_c^\infty(\mathrm{G}'(\mathbb{A}))$ *be a transfer of* f*. Then*

$$\mathrm{Int}(f) = -\partial\mathbb{J}(f') - \mathbb{J}(f'_{\mathrm{corr}}),$$

where $f'_{\mathrm{corr}} \in \mathcal{C}_c^\infty(\mathrm{G}'(\mathbb{A}))$ *is a correction function. Furthermore, we may choose* f' *such that* $f'_{\mathrm{corr}} = 0$.

Remark 5.14. A deeper understanding of the local spherical character $\mathbb{J}_{\Pi_v}(f'_v, s)$ (or rather, its derivative) in (5-9), together with the spectral decomposition of $\mathbb{J}(f', s)$, should allow us to deduce Conjecture 3.5 from Conjecture 5.13. We hope to return to this point in the future.

The comparison can be localized for a (large) class of test functions f and f'. Let $f = \otimes_v f_v$ be a pure tensor such that there is a place u_0 of F where f_{u_0} has support in the regular semisimple locus $\widetilde{\mathrm{G}}(F_{u_0})_{\mathrm{rs}}$. Then the cycles $\widehat{R}(f)\widehat{z}_K$ and $\widehat{z}_K$ do not meet in the generic fiber $\mathrm{Sh}_{K_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}})$. The arithmetic intersection pairing then localizes as a sum over all places w of F' (note that $F = \mathbb{Q}$)

$$\mathrm{Int}(f) = \sum_w \mathrm{Int}_w(f).$$

Here for a non-archimedean place w, the local intersection pairing $\mathrm{Int}_w(f)$ is defined through the Euler–Poincaré characteristic of a derived tensor product on $\mathcal{M}_{K_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}}) \otimes_{O_F} O_{F,w}$, cf. Gillet and Soulé [1990, 4.3.8(iv)].

Similarly, let $f' = \otimes_v f'_v$ be a pure tensor such that there is a place u_0 of F where f'_{u_0} has support in the regular semi-simple locus $\mathrm{G}'(F_{u_0})_{\mathrm{rs}}$. Then we have a decomposition

$$\mathbb{J}(f', s) = \sum_{\gamma \in [\mathrm{G}'(F)_{\mathrm{rs}}]} \mathrm{Orb}(\gamma, f', s),$$

where each term is a product of local orbital integrals (5-6),

$$\mathrm{Orb}(\gamma, f', s) = \prod_v \mathrm{Orb}(\gamma, f'_v, s).$$

The first derivative $\partial\mathbb{J}(f')$ then localizes as a sum over places v of F,

$$\partial\mathbb{J}(f') = \sum_v \partial\mathbb{J}_v(f'),$$

where the summand $\partial\mathbb{J}_v(f')$ takes the derivative of the local orbital integral (cf. (5-8)) at the place v,

$$\partial\mathbb{J}_v(f') = \sum_{\gamma \in [\mathrm{G}'(F)_{\mathrm{rs}}]} \partial\mathrm{Orb}(\gamma, f'_v) \cdot \prod_{u \neq v} \mathrm{Orb}(\gamma, f'_u).$$

It is then natural to expect a place-by-place comparison between

$$\mathrm{Int}_v(f) = \sum_{w|v} \mathrm{Int}_w(f) \qquad \text{and} \qquad \partial\mathbb{J}_v(f')$$

If a place v_0 of F splits into two places $w_0, \overline{w}_0$ of F' (and under the above regularity condition on the support of f and of f'), we have Rapoport, Smithling, and W. Zhang [2017b, Thm. 1.3]

$$\mathrm{Int}_{w_0}(f) = \mathrm{Int}_{\overline{w}_0}(f) = \partial\mathbb{J}_{v_0}(f') = 0.$$

For a place w_0 of F' above a non-split place v_0 of $F = \mathbb{Q}$, we have a smooth integral model $\mathfrak{M}_{K_{\widetilde{\mathrm{G}}}}(\widetilde{\mathrm{G}}) \otimes_{O_F} O_{F,w_0}$ when $K_{\widetilde{\mathrm{G}},v_0}$ is a hyperspecial compact open subgroup $\widetilde{\mathrm{G}}(O_{F,v_0})$ (resp. a special parahoric subgroup $K^{\circ}_{\widetilde{\mathrm{G}},v_0}$) for inert v_0 (resp. ramified v_0).

For an inert v_0, the comparison between $\mathrm{Int}_{v_0}(f)$ and $\partial\mathbb{J}_{v_0}(f')$ is then reduced to a local conjecture that we will consider in the next section, the *arithmetic fundamental lemma* conjecture. Let $W^\flat[v_0]$ be the pair of nearby Hermitian spaces, i.e., the Hermitian space (with respect to F'/F) that is totally negative at archimedean places, and is not equivalent to W at v_0. Let $\widetilde{\mathrm{G}}^\flat[v_0]$ be the corresponding group, an inner form of $\widetilde{\mathrm{G}}$.

Theorem 5.15. *Let $f = \otimes_v f_v$ be a pure tensor such that*

(i) $f_{v_0} = \mathbf{1}_{\widetilde{\mathrm{G}}(O_{F,v_0})}$, *and*

(ii) *there is a place u_0 of F where f_{u_0} has support in the regular semisimple locus* $\widetilde{\mathrm{G}}(F_{v_0})_{\mathrm{rs}}$.

Then

$$\mathrm{Int}_{v_0}(f) = \sum_{g \in \widetilde{\mathrm{G}}^\flat[v_0](F)_{\mathrm{rs}}} \mathrm{Int}_{v_0}(g) \cdot \prod_{u \neq v_0} \mathrm{Orb}(g, f_u), \tag{5-11}$$

where the local intersection number $\mathrm{Int}_{v_0}(g)$ *is defined by* (6-2) *in the next section.*

For $F = \mathbb{Q}$, this is W. Zhang [2012b, Thm. 3.9]. The general case is established in (the proof of) Rapoport, Smithling, and W. Zhang [2017b, Thm. 8.15].

The expansion (5-11) resembles the geometric side of a usual RTF, and hence we call the expansion (the geometric side of) an *arithmetic RTF*.

Finally, for a ramified place v_0, the analogous question is reduced to the local *arithmetic transfer* conjecture formulated by Rapoport, Smithling and the author in Rapoport, Smithling, and W. Zhang [2017a] and Rapoport, Smithling, and W. Zhang [2018]. We have a result similar to Theorem 5.15, Rapoport, Smithling, and W. Zhang [2017b, Thm. 8.15].

5.4 Geometric RTF (over function fields). In the last part of this section, let us briefly recall the strategy to prove the higher Gross–Zagier formula in Section 4 over function fields.

To continue from Section 4, let f be an element in the spherical Hecke algebra $\mathscr{H}$ (with $\mathbb{Q}$-coefficient). Let

$$\mathrm{Int}_r(f) := \Big(R(f) * \theta_*^{\mu}[\mathrm{Sht}_T^{\mu}], \quad \theta_*^{\mu}[\mathrm{Sht}_T^{\mu}]\Big)_{\mathrm{Sht}_G'^{\mu}}$$

be the intersection number of the Heegner–Drinfeld cycle with its translation by a Hecke correspondence $R(f)$. Here the right hand side does not depend on μ but only on the number r of modifications of the Shtukas.

Next, consider the triple $(\mathrm{G}', \mathrm{H}_1', \mathrm{H}_2')$ where $\mathrm{G}' = \mathrm{G} = \mathrm{PGL}_2$ and $\mathrm{H}_1' = \mathrm{H}_2'$ are the diagonal torus A of PGL_2. Similarly to 5-4, we define a distribution by a (regularized) integral

$$\mathbb{J}(f,s) = \int_{[\mathrm{H}_1']} \int_{[\mathrm{H}_2']} K_f(h_1,h_2)\, |h_1 h_2|^s\, \eta(h_2)\, dh_1\, dh_2,$$

where, for $h = \mathrm{diag}(a,d) \in A(\mathbb{A})$, we write $|h| = |a/d|$ and $\eta(h) = \eta_{F'/F}(a/d)$. Let

$$\mathbb{J}_r(f) = \frac{d^r}{ds^r}\Big|_{s=0} \mathbb{J}(f,s).$$

Then Yun and the author proved in Yun and W. Zhang [2017] the following *key identity*, which we may call a *geometric RTF*, in contrast to the arithmetic intersection numbers in the number field case.

Theorem 5.16. *Let $f \in \mathscr{H}$. Then*

$$\mathbb{I}_r(f) = (\log q)^{-r} \mathbb{J}_r(f). \tag{5-12}$$

In this situation of geometric intersection, our proof of the key identity (5-12) is entirely global, in the sense that we do *not* reduce the identity to the comparison of local orbital integrals. In fact, our proof of (5-12) gives a term-by-term identity of the orbital integrals. This strategy is explained in the forthcoming work of Yun on the function field analog of the arithmetic fundamental lemma Yun [n.d.(b)].

For a more detailed exposition on the geometric construction related to the proof of Equation (5-12), see Yun's survey Yun [n.d.(a)].

6 The arithmetic fundamental lemma conjecture

We now consider the local version of special cycles on Shimura varieties, i.e., (formal) cycles on Rapoport–Zink formal moduli spaces of p-divisible groups. The theorem of

Rapoport–Zink on the uniformization of Shimura varieties Rapoport and Zink [1996] relates the local cycles to the global ones, and this allows us to relate the local height of the global cycles (the *semi-global* situation in Rapoport, Smithling, and W. Zhang [2017b]) to intersection numbers of local cycles, cf. Theorem 5.15.

6.1 The fundamental lemma of Jacquet and Rallis, and a theorem of Yun. Now let F be a finite extension of $\mathbb{Q}_p$ for an *odd* prime p. Let O_F be the ring of integers in F, and denote by q the number of elements in the residue field of O_F. Let $\breve{F}$ be the completion of a maximal unramified extension of F. Let F'/F be an *unramified* quadratic extension.

Recall from Section 5.2.2 that there are two equivalence classes of pairs of Hermitian spaces, denoted by $W, W^\flat$ respectively, such that, for $W = (W_{n-1}, W_n)$, both W_{n-1} and W_n contain self-dual lattices. We rename the respective groups as G and $\mathrm{G}^\flat$ respectively, and we rewrite the bijection of orbits (5-5):

$$\left[\mathrm{G}(F)_{\mathrm{rs}}\right] \sqcup \left[\mathrm{G}^\flat(F)_{\mathrm{rs}}\right] \xrightarrow{\sim} \left[\mathrm{G}'(F)_{\mathrm{rs}}\right]. \tag{6-1}$$

Let $\mathrm{G}(O_F)$ be the hyperspecial compact open subgroup of $\mathrm{G}(F)$ defined by a self-dual lattice.

Theorem 6.1 (Fundamental Lemma (FL)). *For a prime p sufficiently large, the characteristic function $\mathbf{1}_{\mathrm{G}'(O_{F_0})} \in \mathcal{C}_c^\infty(\mathrm{G}'(F))$ transfers to the pair of functions $(\mathbf{1}_{\mathrm{G}(O_F)}, 0) \in \mathcal{C}_c^\infty(\mathrm{G}(F)) \times \mathcal{C}_c^\infty(\mathrm{G}^\flat(F))$.*

Jacquet and Rallis conjecture that the same is always true for any *odd* p Jacquet and Rallis [2011]. Yun proved the equal characteristic analog of their conjecture for $p > n$; Gordon deduced the p-adic case for p large (but unspecified), cf. Yun [2011].

6.2 The arithmetic fundamental lemma conjecture. Next, we let $\mathcal{N}_n$ be the unitary Rapoport–Zink formal moduli space over $\operatorname{Spf} O_{\breve{F}}$ parameterizing *Hermitian supersingular formal $O_{F'}$-modules of signature* $(1, n-1)$, cf. S. Kudla and Rapoport [2011] and Rapoport, Smithling, and W. Zhang [2018]. Let $\mathcal{N}_{n-1,n} = \mathcal{N}_{n-1} \times_{\operatorname{Spf} O_{\breve{F}}} \mathcal{N}_n$. Then $\mathcal{N}_{n-1,n}$ admits an action by $\mathrm{G}^\flat(F)$.

There is a natural closed embedding $\delta \colon \mathcal{N}_{n-1} \to \mathcal{N}_n$ (a local analog of the closed embedding (3-3)). Let

$$\Delta \colon \mathcal{N}_{n-1} \longrightarrow \mathcal{N}_{n-1,n}$$

be the graph morphism of δ. We denote by $\Delta_{\mathcal{N}_{n-1}}$ the image of Δ. For $g \in \mathrm{G}^\flat(F)_{\mathrm{rs}}$, we consider the intersection product on $\mathcal{N}_{n-1,n}$ of $\Delta_{\mathcal{N}_{n-1}}$ with its translate $g\Delta_{\mathcal{N}_{n-1}}$, defined through the derived tensor product of the structure sheaves,

$$\operatorname{Int}(g) := (\Delta_{\mathcal{N}_{n-1}}, g \cdot \Delta_{\mathcal{N}_{n-1}})_{\mathcal{N}_{n-1,n}} := \chi\left(\mathcal{N}_{n-1,n}, \mathcal{O}_{\Delta_{\mathcal{N}_{n-1}}} \otimes^{\mathbb{L}} \mathcal{O}_{g\cdot\Delta_{\mathcal{N}_{n-1}}}\right). \tag{6-2}$$

We have defined the derivative of the orbital integral (5-8).

Conjecture 6.2 (Arithmetic Fundamental Lemma (AFL), W. Zhang [2012b]). *Let* $\gamma \in \mathrm{G}'(F)_{\mathrm{rs}}$ *match an element* $g \in \mathrm{G}^{\flat}(F)_{\mathrm{rs}}$. *Then*

$$\omega(\gamma)\, \partial\mathrm{Orb}\left(\gamma, \mathbf{1}_{\mathrm{G}'(O_F)}\right) = -2\,\mathrm{Int}(g) \cdot \log q.$$

Remark 6.3. (i) We may interpret the orbital integrals in terms of "counting lattices", cf. Rapoport, Terstiege, and W. Zhang [2013, §7].

(ii) See Rapoport, Smithling, and W. Zhang [2018, §4] for some other equivalent formulations of the AFL conjecture.

Theorem 6.4. (i) *The AFL Conjecture 6.2 holds when* $n = 2, 3$.

(ii) *When* $p \geq \frac{n}{2} + 1$, *the AFL Conjecture 6.2 holds for* minuscule *elements* $g \in \mathrm{G}^{\flat}(F)$ *in the sense of Rapoport, Terstiege, and W. Zhang [2013].*

Part (i) was proved in W. Zhang [2012b]; a simplified proof when $p \geq 5$ is given by Mihatsch in Mihatsch [2017]. Part (ii) was proved by Rapoport, Terstiege, and the author in Rapoport, Terstiege, and W. Zhang [2013]; a simplified proof is given by Li and Zhu in Li and Y. Zhu [2017]. Mihatsch in Mihatsch [2016] proved more cases of the AFL for arbitrary n but under restrictive conditions on g.

Remark 6.5. (i) Yun has announced a proof of the function field analog of the AFL conjecture Yun [n.d.(a),(b)].

(ii) Let F'/F be a *ramified* quadratic extension of p-adic fields. In Rapoport, Smithling, and W. Zhang [2017a] and Rapoport, Smithling, and W. Zhang [2018], Rapoport, Smithling, and the author propose an *arithmetic transfer* (AT) conjecture. This conjecture can be viewed as the counterpart of the existence of transfer (cf. Theorem 5.5) in the arithmetic context over a p-adic field. We proved the conjecture for $n = 2, 3$.

(iii) The analogous question on archimedean local fields remains a challenge, involving Green currents in the complex geometric setting and relative orbital integrals on real Lie groups.

RESOLUTION OF SINGULARITIES OF COMPLEX ALGEBRAIC VARIETIES AND THEIR FAMILIES

DAN ABRAMOVICH

Abstract

We discuss Hironaka's theorem on resolution of singularities in charactetistic 0 as well as more recent progress, both on simplifying and improving Hironaka's method of proof and on new results and directions on families of varieties, leading to joint work on toroidal orbifolds with Michael Temkin and Jarosław Włodarczyk.

Contents

1 Introduction

1.1 Varieties and singularities. An affine complex algebraic variety X is the zero set in $\mathbb{C}^n$ of a collection of polynomials $f_i \in \mathbb{C}[x_1, \ldots, x_n]$, and a general complex algebraic

New research reported here is supported by BSF grant 2014365, which is held jointly with J. Włodarczyk (Purdue) and M. Temkin (Jerusalem).

MSC2010: primary 14E15; secondary 14M25, 14A20.

variety is patched together from such affine varieties much as a differentiable manifold is patched together from euclidean balls.

But unlike differentiable manifolds, which locally are all the same (given the dimension), a complex algebraic variety can have an interesting structure locally at a point $p \in X$: the point is *regular* or *simple* if the f_i form the defining equations of a differentiable submanifold, and otherwise it is *singular*, hiding a whole world within it. In the case of one equation, a point $p = (a_1, \ldots, a_n)$ is regular precisely when the defining equation f_1 has a non-vanishing derivative at p, and in general one needs to look at the Jacobian matrix of the defining equations, just like when studying submanifolds. The set of regular points $X^{reg} \subset X$ is always open. The variety X is itself *regular* if $X^{reg} = X$.[1]

1.2 What is resolution of singularities? A look at a few singularities[2] quickly reveals that they are quite beautiful, but complicated - really they are not *simple*. How can we understand them? *Resolution of singularities* provides one approach. For simplicity we restrict to *irreducible* varieties, namely those which cannot be written as a union $X_1 \cup X_2$ of two closed nonempty subvarieties. A resolution of singularities of a variety X is a surgery operation, a morphism $X' \to X$ which takes out the singular points and replaces them by regular points. Formally:

Definition 1.2.1. *A* resolution of singularities *of an irreducible variety X is a* proper morphism $f : X' \to X$, *where X' is regular and irreducible, and f restricts to an isomorphism $f^{-1}(X^{reg}) \longrightarrow X^{reg}$.*

The irreducibility assumption is not serious — for instance one can resolve each irreducible component separately.

I need to explain the terms. A *morphism* $f : X' \to X$ is a mapping which locally on affine patches is defined by polynomials of the coordinates. It is an isomorphism if it is invertible as such. It is *proper* if it is proper as a mapping of topological spaces in the usual Euclidean topology: the image of a compact subset is compact. This is a way to say that we are missing no points: it would be cheating - and useless - to define X' to be just X^{reg}: the idea is to *parametrize* X in a way that reveals the depths of its singularities - not to erase them! One way $X' \to X$ can be guaranteed to be proper is if it is *projective*, namely X' embeds as a closed subvariety of $X \times \mathbb{P}^n$ for some n, where $\mathbb{P}^n$ stands for the complex projective space.

1.3 Hironaka's theorem. In 1964 Hironaka published the following, see Hironaka [1964, Main Theorem 1]:

[1] I am taking the scheme theoretic approach here: the vanishing locus of $f(x) = x^2$ is singular.

[2] I cannot improve on these:
https://imaginary.org/gallery/herwig-hauser-classic

Theorem 1.3.1 (Hironaka). *Let X be a complex algebraic variety. Then there is a projective resolution of singularities $X' \to X$.*

Hironaka's theorem is an end of an era, but also a beginning: in the half century since, people, including Hironaka, have continued to work with renewed vigor on resolution of singularities. Why is that?

I see two reasons. One reason can be seen in Grothendieck's address, Grothendieck [1971]:

> Du point de vue technique, la démonstration du théorème de Hironaka constitue une prouesse peu commune. Le rapporteur avoue n'en avoir pas fait entièrement le tour. Aboutissement d'années d'efforts concentrés, elle est sans doute l'une des démonstrations les plus «dures» et les plus monumentales qu'on connaisse en mathématique.

Consider, for instance, that Hironaka developed much of the theory now known as *Gröbner bases* (at roughly the same time as Buchberger [1965]) for the purpose of resolution of singularities!

There has been a monumental effort indeed to simplify Hironaka's proof, and to break it down to more basic elements, so that the techniques involved come naturally and the ideas flow without undue effort. I think this has been a resounding success and Grothendieck himself would have approved of the current versions of the proof - he certainly would no longer have trouble going through it. In my exposition I attempt to broadly describe the results of this effort.

A few points in this effort are marked by the following:

- The theory of maximal contact: Giraud [1974] and Aroca, Hironaka, and Vicente [1977].
- Constructive resolution using an invariant: Villamayor [1989], Bierstone and Milman [1997], and Encinas and Villamayor [1998].
- The optimal version of canonical resolution: Bierstone and Milman [1997].
- Simplification using order of ideal: Encinas and Villamayor [2003].
- Functoriality as a proof technique and guiding principle: Włodarczyk [2005] and Bierstone and Milman [2008].
- Dissemination to the masses: Cutkosky [2004], Hauser [2006], and Kollár [2007].

The other reason is generalizations and refinements of the resolution theorem. First and foremost, algebraic geometers want to resolve singularities in positive and mixed characteristics, as the implications would be immense. In addition, one is interested in simplifying families of varieties, simplifying algebraic differential equations, making the resolution process as effective and as canonical as possible, and preserving structure one is provided with at the outset. Below I will discuss *resolution in families* while preserving *toroidal* structures, focussing on joint work with Michael Temkin of Jerusalem and Jarosław Włodarczyk of Purdue.

2 Hironaka's method: from resolution to order reduction

The purpose of this section is to indicate how Hironaka's resolution of singularities can be reduced to an algebraic problem, namely *order reduction* of an ideal.

2.1 Blowing up. The key tool for Hironaka's resolution of singularities is an operation called *blowing up* of a regular subvariety Z of a regular variety Y, see Hartshorne [1977, Definition p. 163]

2.1.1 Blowing up a point. A good idea can be gleaned from the special case where $Y = \mathbb{A}^n$, affine n-space, and Z is the origin, as explained in Hartshorne [ibid., Example 7.12.1] and depicted on the cover of Shafarevich [2013]. Think about $\mathbb{P}^{n-1}$ as the set of lines in $\mathbb{A}^n$ through the origin. The blowing up $Y' \to Y$ is then given as the *incidence variety*

$$Y' = \{(x, \ell) \in \mathbb{A}^n \times \mathbb{P}^{n-1} \mid x \in \ell\},$$

with its natural projection to $\mathbb{A}^n$.

This can be described in equations as follows:

$$Y' = \{((x_1, \dots, x_n), (Y_1 : \dots : Y_n)) \in \mathbb{A}^n \times \mathbb{P}^{n-1} \mid x_i Y_j = x_j Y_i \ \forall i, j\}.$$

Since $\mathbb{P}^n$ is covered by affine charts, this can further be simplified. For instance on the chart where $Y_n \neq 0$ with coordinates $y_1, \dots, y_{n-1}$, this translates to

$$\{((x_1, \dots, x_n), (y_1, \dots, y_{n-1})) \in \mathbb{A}^n \times \mathbb{A}^{n-1} \mid x_j = x_n y_j,\ 1 \leq j \leq n-1\}.$$

In other words, the coordinates $x_1, \dots, x_{n-1}$ are redundant and this is just affine space with coordinates $y_1, \dots, y_{n-1}, x_n$. In terms of coordinates on Y we have $y_j = x_j / x_n$.

The fibers of $Y' \to Y$ are easy to describe: away from the origin $x_1 = \dots = x_n = 0$ the map is invertible, as the line ℓ is uniquely determined by $(x_1, \dots, x_n)$. Over the origin all possible lines occur, so the fiber is $\mathbb{P}^{n-1}$, naturally identified as the space of lines through the origin.

2.1.2 Blowing up a regular subvariety. In general the process is similar: given regular subvariety Z of Y, then $f : Y' \to Y$ replaces each point $z \in Z$ by the projective space of normal directions to Z at z. If Z is locally defined by equations $x_1 = \ldots = x_k = 0$ and if $x_{k+1}, \ldots, x_n$ form coordinates along Z, then Y' has local patches, one corresponding to each x_i, with coordinates

$$\frac{x_1}{x_i}, \ldots, \frac{x_{i-1}}{x_i}, \; x_i, \; \frac{x_{i+1}}{x_i}, \ldots, \frac{x_k}{x_i}, \; x_{k+1}, \ldots, x_n.$$

Thus the blowing up $Y' \to Y$ of a regular subvariety Z of a regular variety Y always results in a regular variety.

We often say that Z is the *center* of the blowing up $Y' \to Y$, or that the blowing up $Y' \to Y$ is *centered* at Z.

2.1.3 The Proj **construction.** Grothendieck gave a more conceptual construction, which applies to an arbitrary subscheme Z defined by an ideal sheaf $\mathcal{I}$ in an arbitrary scheme Y:

$$Y' = \operatorname{Proj}_Y \bigoplus_{k=0}^{\infty} \mathcal{I}^k / \mathcal{I}^{k+1}.$$

The map $f^{-1}(Y \setminus Z) \to (Y \setminus Z)$ is always an isomorphism, so we identify $Y \setminus Z$ with its preimage.

What the reader may want to take from this is that the blowings up we introduced in particularly nice cases are part of a flexible array of transformations.

The complement E of $Y \setminus Z$ in Y' is called the *exceptional locus*. It is *a Cartier divisor*, a subvariety of codimension 1 locally defined by one equation. If Z is nowhere dense in Y, then $Y' \to Y$ is birational. If moreover Y and Z are regular, then E is regular.

2.1.4 The strict transform. Blowing up serves in the resolution of singularities of a subvariety $X \subset Y$ through the *strict transform* $X' \subset Y'$: this is the closure of $X \setminus Z$ in Y'. Grothendieck showed that X' is the same as the blowing up of $X \cap Z$ in X, using the Proj construction above.

From the point of view of resolution of singularities, the challenge is to make X' less singular than X by an appropriate choice of Z.

Consider for instance the cuspidal plane curve X given by $y^2 - x^3 = 0$ in the affine plane $Y = \mathbb{A}^2$ with coordinates x, y. Blowing up the origin and focusing on the chart with coordinates $x, z = y/x$, we obtain the equation $z^2x^2 - x^3 = 0$, which we rewrite as $x^2(z^2 - x) = 0$. The locus $x = 0$ describes the exceptional line, and X' is given by $z^2 - x = 0$, a regular curve.

2.2 Embedded resolution. Theorem 1.3.1 is proven by way of the following theorem:

Theorem 2.2.1 (Embedded resolution)**.** *Suppose $X \subset Y$ is a closed subvariety of a regular variety Y. There is a sequence of blowings up $Y_n \to Y_{n-1} \to \cdots \to Y_0 = Y$, with regular centers $Z_i \subset Y_i$ and strict transforms $X_i \subset Y_i$, such that Z_i does not contain any irreducible component of X_i and such that X_n is regular.*

In other words, the final strict transform of X in a suitably chosen sequence of blowings up of Y is regular.

In the example of the cuspidal curve $X \subset Y = \mathbb{A}^2$, the single blowing up $Y_1 \to Y$ centered at the origin $Z = \{(0,0)\}$ provides an embedded resolution $X' \to X$ of X.

If X is embedded inside a regular variety Y, then Theorem 2.2.1 immediately gives a resolution of singularities $X_n \to X$. What if X is not embedded? There are a number of viable approaches, but the best is to strengthen Theorem 2.2.1: one makes the blowing up procedure independent of re-embedding X and compatible with local patching. This is what is done in practice. I describe the underlying principles in Sections 3.8 and 3.10 below. The upshot is that "good embedded resolution implies resolution".

From here on we pursue a good embedded resolution.

2.3 Normal crossings. To go further one needs to describe a desirable property of the exceptional divisor E_i and its interaction with the center Z_i.

Definition 2.3.1. *We say that a closed subset $E \subset Y$ of a regular variety Y is a* simple normal crossings divisor *if in its decomposition $E = \cup E_j$ into irreducible components, each component E_j is regular, and these components intersect transversally: locally at a point $p \in E$ there are local parameters $x_1, \ldots, x_m$ such that E is the zero locus of a reduced monomial $x_1 \cdots x_k$.*

We further say that E and a regular subvariety Z have normal crossings *if such coordinates can be chosen so that $Z = V(x_{j_1}, \ldots, x_{j_l})$ is the zero set of a subset of these coordinates.*

When the set of coordinates $x_{j_1}, \ldots, x_{j_l}$ is disjoint from $x_1, \ldots, x_k$ the strata of E meet Z transversely, but the definition above allows quite a bit more flexibility.

This definition works well with blowing up: If E is a simple normal crossings divisor, E and Z have normal crossings, $f : Y' \to Y$ is the blowing up of the regular center Z with exceptional divisor E_Z, and $E' = f^{-1}E \cup E_Z$ then E' is a simple normal crossings divisor.

2.4 Principalization. Embedded resolution is proven by way of the following algebraic result:

Theorem 2.4.1 (Principalization)**.** *Let Y be a regular variety and $\mathcal{I}$ an ideal sheaf. There is a sequence of blowings up $Y_n \to Y_{n-1} \to \cdots \to Y_0 = Y$, regular subvarieties $Z_i \subset Y_i, i = 0, \ldots, n-1$ and simple normal crossings divisors $E_i \subset Y_i, i = 1, \ldots, n$ such that*

- *$f_i : Y_{i+1} \to Y_i$ is the blowing up of Z_i for $i = 0, \ldots, n-1$,*
- *E_i and Z_i have normal crossings for $i = 1, \ldots, n-1$,*
- *$\mathcal{I}\mathcal{O}_{Y_i}$ vanishes on Z_i for $i = 0, \ldots, n-1$,*
- *E_{i+1} is the union of $f_i^{-1} E_i$ with the exceptional locus of f_i for $i = 0, \ldots, n-1$*

and such that the resulting ideal sheaf $\mathcal{I}_n = \mathcal{I}\mathcal{O}_{Y_n}$ is an invertible ideal with zero set $V(\mathcal{I}_n)$ supported in E_n.

In local coordinates $x_1, \ldots, x_m$ on Y_n as above, this means that $\mathcal{I}_n = (x_1^{a_1} \cdots x_m^{a_k})$ is locally principal and monomial, hence the name “principalization”. The condition that Z_i have normal crossings with E_i guarantees that E_{i+1} is a simple normal crossings divisor.

2.4.2 Principalization implies embedded resolution. Quoting Kollár [2007, p. 137], principalization implies embedded resolution seemingly “by accident”: suppose for simplicity that X is irreducible, and let the ideal of $X \subset Y$ be $\mathcal{I}$. Since $\mathcal{I}_n$ is the ideal of a divisor supported in the exceptional locus, at some point in the sequence the center Z_i must contain the strict transform X_i of X. Since $\mathcal{I}$ vanishes on Z_i, it follows that Z_i coincides with X_i at least near X_i. In particular X_i is regular!

2.4.3 Are we working too hard? Principalization seems to require “too much” for resolution: why should we care about exceptional divisors which lie outside X? Are we trying too hard?

In the example of the cuspidal curve $X \subset Y = \mathbb{A}^2$ above, the single blowing up $Y_1 \to Y$ at the origin does *not* suffice for principalization: the resulting equation $x^2(z^2 - x) = 0$ with exceptional $\{x = 0\}$ is *not* monomial. One needs no less that *three* more blowings up! I’ll describe just one key affine patch of each:

- Blowing up $x = z = 0$ one gets, in one affine patch where $x = zw$, the equation $z^3w^2(z - w) = 0$, strict transform $X_2 = \{z = w\}$ and exceptional $\{wz = 0\}$.
- Blowing up $z = w = 0$ one gets, in one affine patch where $z = wv$, the equation $v^3w^6(v - 1) = 0$. The exceptional in this patch is $\{wv = 0\}$, with one component (the old $\{z = 0\}$) appearing only in the other patch. The strict transform is $X_3 = \{v = 1\}$.

- In the open set $\{v \neq 0\}$ we blow up $\{v = 1\}$. This actually does nothing, except turning the function $u = v - 1$ into a monomial along $v = 1$, so the equation $v^3 w^6 (v-1) = 0$ at these points can be written as $(u+1)^3 w^6 u = 0$, which in this patch is equivalent to $w^6 u = 0$, a monomial in the exceptional parameters u, w.

The fact that we could blow up $\{v = 1\}$ means that X_3 is regular, giving rather late evidence that we obtained resolution of singularities for X. These "redundant" steps add to the sense that this method works "by accident". It turns out that principalization itself is quite useful in the study of singularities. Also the fact that it provides the prize of resolution is seen as sufficient justification. The discussion in Section 6 will put it in the natural general framework of toroidal structures.

Accident or not, we will continue to pursue principalization.

2.5 Order reduction. Finally, principalization of an ideal is proven by way of *order reduction*.

The *order* $\mathrm{ord}_p(\mathcal{I})$ of an ideal $\mathcal{I}$ at a point p of a regular variety Y is the maximum integer d such that $\mathfrak{m}_p^d \supseteq \mathcal{I}$; here $\mathfrak{m}_p$ is the maximal ideal of p. It tells us "how many times every element of $\mathcal{I}_p$ vanishes at p."

In particular we have $\mathrm{ord}_p(\mathcal{I}) \geq 1$ precisely if $\mathcal{I}$ vanishes at p.

We write $\mathrm{maxord}(\mathcal{I}) = \max\{\mathrm{ord}_p(\mathcal{I}) | p \in X\}$. For instance we have $\mathrm{maxord}(\mathcal{I}) = 0$ if and only if $\mathcal{I}$ is the unit ideal, which vanishes nowhere. Another exceptional case is $\mathrm{maxord}(\mathcal{I}) = \infty$ which happens if $\mathcal{I}$ vanishes on a whole component of Y. We'll ignore that case for now.

Given an integer a, we write $V(\mathcal{I}, a)$ for the locus of points p where $\mathrm{ord}_p(\mathcal{I}) \geq a$. A regular closed subvariety $Z \subset Y$ is said to be $(\mathcal{I}, a)$-*admissible* if and only if $Z \subset V(\mathcal{I}, a)$, in other words, the order of $\mathcal{I}$ at every point of Z is at least a. Admissibility is related to blowings up: if $\mathrm{maxord}(\mathcal{I}) = a$, and if $Y' \to Y$ is the blowing up of an $(\mathcal{I}, a)$-admissible $Z \subset Y$, with exceptional divisor E having ideal $\mathcal{I}_E$, then $\mathcal{I}\mathcal{O}_{Y'} = (\mathcal{I}_E)^a\, \mathcal{I}'$, with $\mathrm{maxord}(\mathcal{I}') \leq a$.

Order reduction is the following statement:

Theorem 2.5.1 (Order reduction)**.** *Let Y be a regular variety, $E_0 \subset Y$ a simple normal crossings divisor, and $\mathcal{I}$ an ideal sheaf, with*

$$\mathrm{maxord}(\mathcal{I}) = a.$$

There is a sequence of $(\mathcal{I}, a)$-admissible blowings up $Y_n \to Y_{n-1} \to \cdots \to Y_0 = Y$, with regular centers $Z_i \subset Y_i$ having normal crossings with E_i such that $\mathcal{I}\mathcal{O}_{X_n} = \mathcal{I}_n \mathcal{I}'_n$with $\mathcal{I}_n$ an invertible ideal supported on E_n and such that

$$\mathrm{maxord}(\mathcal{I}'_n) < a.$$

Order reduction implies principalization simply by induction on the maximal order $\mathrm{maxord}(\mathcal{I}) = a$: once $\mathrm{maxord}(\mathcal{I}'_n) = 0$ we have $\mathcal{I}\mathcal{O}_{X_n} = \mathcal{I}_n$ so only the exceptional part remains, which is supported on a simple normal crossings divisor by induction.

Hironaka himself used the *Hilbert–Samuel function*, an invariant much more refined than the order. It is a surprising phenomenon that resolution becomes easier to explain when one uses just the order, thus less information, see Encinas and Villamayor [2003].

It remains to prove order reduction.

3 Hironaka's method: order reduction

3.1 Differential operators. Nothing so far was particularly sensitive to the fact that we were working over $\mathbb{C}$, or even a field of characteristic 0. That starts changing now.

Since Y is regular, it has a *tangent bundle* T_Y. Local sections ∂ of T_Y are first order differential operators $\partial : \mathcal{O}_Y \to \mathcal{O}_Y$. As usual we denote the sheaf of sections of the tangent bundle with the same symbol T_Y, hoping the confusion can be overcome.

3.1.1 The characteristic 0 case. In characteristic 0, the sheaf of rings generated over $\mathcal{O}_Y$ by the operators in T_Y is the *sheaf of differential operators* $\mathfrak{D}_Y$. As a sheaf of $\mathcal{O}_Y$ modules it looks locally like the symmetric algebra $\mathrm{Sym}^\bullet(T_Y) = \oplus_{n\geq 0}\mathrm{Sym}^n(T_Y)$, but its ring structure is very different, as $\mathfrak{D}_Y$ is non-commutative. Still for any integer a there is a subsheaf $\mathfrak{D}_Y^{\leq a} \subset \mathfrak{D}_Y$ of differential operators of order $\leq a$, those sections which can be written in terms of monomials of order at most a in sections of T_Y. As a special case, one always has a splitting $\mathfrak{D}_Y^{\leq 1} = \mathcal{O}_Y \oplus T_Y$, the projection $\mathfrak{D}_Y^{\leq 1} \to \mathcal{O}_Y$ given by applying $\nabla \mapsto \nabla(1)$.

3.1.2 The general case. Things are quite different in characteristic $p > 0$: one can use the same definition, but in some sense it is deficient, because these differential operators do not detect pth powers. There is a natural and sophisticated replacement, which coincides with $\mathfrak{D}_Y$ in characteristic 0, and defined as follows:

On $Y \times Y$ consider the diagonal $\Delta \subset Y \times Y$. It is a closed subvariety, and one can consider its ideal $\mathcal{I}_\Delta$. The *sheaf of principal parts of order a of Y* is defined as $\mathcal{P}\mathcal{P}_Y^a = \mathcal{O}_{Y\times Y}/\mathcal{I}_\Delta^{a+1}$ - it is a sheaf of $\mathcal{O}_Y$-modules via either projection; its fiber at $p \in Y$ describes functions on Y up to order a at p. Its dual sheaf is $\mathfrak{D}^{\leq a} := (\mathcal{P}\mathcal{P}_Y^a)^\vee$, which *in characteristic 0* admits the concrete description given earlier. The natural projection $\mathcal{P}\mathcal{P}_Y^a \to \mathcal{P}\mathcal{P}_Y^{a-1}$ gives rise to an inclusion $\mathfrak{D}_Y^{\leq a-1} \subset \mathfrak{D}_Y^{\leq a}$, and one defines in general $\mathfrak{D}_Y = \cup_a \mathfrak{D}_Y^{\leq a}$.

This is nice enough, but the fact that in positive characteristics sections of $\mathfrak{D}_Y$ are not written as polynomials in sections of T_Y is the source of much trouble.

3.2 Derivatives and order. Let $\mathcal{I}$ be an ideal sheaf on Y and $y \in Y$ a point. Write $\mathcal{D}_Y^{\leq a}\mathcal{I}$ for the ideal generated by elements $\nabla(f)$, where ∇ an operator in $\mathcal{D}_Y^{\leq a}$ and f a section of $\mathcal{I}$. We have the following characterization:

$$\operatorname{ord}_y(\mathcal{I}) = \min\{a : (\mathcal{D}^{\leq a}\mathcal{I})_y = \mathcal{O}_{Y,y}\}.$$

In other words, the order of $\mathcal{I}$ at y is the minimum order of a differential operator ∇ such that for some $f \in \mathcal{I}_y$ the element $\nabla(f)$ does not vanish at y.

We define $\mathcal{T}(\mathcal{I}, a) := \mathcal{D}^{\leq a-1}\mathcal{I}$. In these terms, the set $V(\mathcal{I}, a)$ can be promoted to a *scheme*, the zero locus of an ideal: $V(\mathcal{I}, a) := V(\mathcal{T}(\mathcal{I}, a))$.[3]

This is not too surprising in characteristic 0 since we all learned calculus, but it may seem strange in characteristic $p > 0$. For instance, the order of (x^p) is p, since there is always an operator ∇ of order p such that $\nabla(x^p) = 1$. In characteristic 0 we can write

$$\nabla = \frac{1}{p!}\left(\frac{\partial}{\partial x}\right)^p,$$

but in characteristic p we have no such expression!

3.3 Induction and maximal contact hypersurfaces. We return to working over $\mathbb{C}$, in particular in characteristic 0, so we can use the letter p for a point of Y.

Remember that we want to prove order reduction of an ideal $\mathcal{I}$ of maximal order a. Hironaka's next idea was to use induction on dimension by restricting attention to a hypersurface H, in such a way that a suitable order reduction on H results, *by blowing up the same centers,* in order reduction of $\mathcal{I}$ on Y.

I am not being historically correct here, since Hironaka used invariants much more refined than order. I depart from history further, and use Giraud's concept of *maximal contact hypersurfaces*, adapted to orders rather than other invariants.

Definition 3.3.1. *Let $\mathcal{I}$ be an ideal of maximal order a.* A maximal contact hypersurface for $(\mathcal{I}, a)$ at p *is a hypersurface H* regular at p*, such that, in some neighborhood Y^0 of p we have $H \supseteq V(\mathcal{I}, a) = V(\mathcal{T}(\mathcal{I}, a))$, namely H contains the* scheme *of points where $\mathcal{I}$ has order a.*

3.4 Derivatives and existence in characteristic 0. It is not too difficult to show that *in characteristic 0*, a maximal contact hypersurface for $(\mathcal{I}, a)$ at p exists. Since $\mathcal{I}$ has maximal order a, we have $\mathcal{D}^{\leq a}(\mathcal{I}) = (1)$. Consider the ideal $\mathcal{T}(\mathcal{I}, a) = \mathcal{D}^{\leq a-1}(\mathcal{I})$. Since we are in characteristic 0, it must contain an antiderivative of 1, so $\operatorname{ord}_p(\mathcal{T}(\mathcal{I}, a)) \leq$

---

[3] This is the *right* scheme structure, as it satisfies an appropriate universal property.

1. Any local section x of $\mathcal{T}(\mathcal{I}, a)$ with order ≤ 1 gives a maximal contact hypersurface $\{x = 0\}$ at p.

Here is an example: suppose $\mathcal{I} = (f)$ where

$$f(x, y) = y^a + g_1(x)y^{a-1} + \cdots + g_{a-1}(x)y + g_a(x).$$

Then $\mathrm{ord}_{(0,0)}(f) = a$ exactly when $\mathrm{ord}_0(g_i) \geq i$ for all i. In characteristic 0 we may replace y by $y + g_1(x)/a$, so we may assume $g_1(x) = 0$. In this case $\partial^{a-1} f/\partial y^{a-1} = a! \cdot y$, so $\{y = 0\}$ is a maximal contact hypersurface at $(0, 0)$.

The definition I gave is pointwise. It is easy to see that if H is a maximal contact hypersurface for $(\mathcal{I}, a)$ at p then the same holds at any nearby p', so the concept is local. Unfortunately it is also not hard to cook up examples where there is no *global* maximal contact hypersurface which works everywhere. We will tackle this problem in Section 3.8 below.

3.4.1 Positive characteristics. Alas, there are fairly simple examples in charactersitic $p > 0$ where maximal contact hypersurfaces do not exist, see Narasimhan [1983] and Hauser [2010]. The whole discussion from here on simply does not work in characteristic > 0.

3.5 What should we resolve on H? For induction to work we need to decide what exactly we want to do on the hypersurface H. The example $\mathcal{I} = (f)$ above is instructive: just restricting $\mathcal{I}$ to H does not work!

Assume

$$f(x, y) = y^a + g_2(x)y^{a-2} + \cdots + g_{a-1}(x)y + g_a(x),$$

with $\mathrm{ord}_0(g_i) \geq i$ for all i. The restriction of $\mathcal{I}$ to the hypersurface $H = \{y = 0\}$ is the ideal $(g_a(x))$. Now clearly this ideal does not retain enough information from the original ideal. This is manifest with the notion of admissibility introduced in Section 2.5, as $(g_a(x), a)$-admissible centers in H will not always give $(\mathcal{I}, a)$-admissible centers in Y. For instance it might happen that $g_a = 0$, so every center on H is $(g_a(x), a)$-admissible, but $g_{a-1} \neq 0$, so not every center on H is $(\mathcal{I}, a)$-admissible on Y!

The collection of elements $g_2(x), \ldots, g_a(x)$ surely hold all the necessary information. However each comes with its own requirements: in order to reduce the order of $\mathcal{I}$ below a, we need to reduce the order of at least one of $g_i(x)$ below i.

We now generalize this discussion to arbitrary ideals.

3.5.1 Coefficient ideals and the induction scheme. In order to generalize this, we need to identify an analogue of these "elements" $g_i(x)$, and derivatives come to the rescue again. Let $\mathcal{I}$ be an ideal of maximal order a on a variety Y and H a maximal contact hypersurface. Then for any $i < a$ the ideals $\mathfrak{D}_Y^{\le i}\mathcal{I}$ have maximal order precisely $a-i$. It follows that the restricted ideals $(\mathfrak{D}_Y^{\le i}\mathcal{I})_{|H}$ have maximal order $\ge a-i$. These restrictions are the analogues of $g_{a-i}(x)$.

The following is at the technical core of the proof. I am aware of several proofs of this proposition, but they all seem to go a bit beyond the level of discussion I wish to maintain here. For reference, see Kollár [2007, Section 3.9].

Proposition 3.5.2. *Any sequence of $(\mathcal{I}, a)$-admissible blowings up has centers lying in H and its successive strict transforms. The resulting sequence of blowings up on H is $((\mathfrak{D}_Y^{\le i}\mathcal{I})_{|H}, a-i)$-admissible for every $i < a$.*

Conversely, every sequence of blowings up on H which is $((\mathfrak{D}_Y^{\le i}\mathcal{I})_{|H}, a-i)$-admissible for every $i < a$ gives rise, by blowing up the same centers on Y, to a sequence of $(\mathcal{I}, a)$-admissible blowings up.

Such an admissible sequence on H may be called an *order reduction* for the collection $((\mathfrak{D}_Y^{\le i}\mathcal{I})_{|H}, a-i)$ if it forms an order reduction for at least one of these pairs. It is a formal consequence of the proposition that an order reduction for $(\mathcal{I}, a)$ is the same as an order reduction for the collection $((\mathfrak{D}_Y^{\le i}\mathcal{I})_{|H}, a-i), i = 0, \dots, a$.

This may appear as troublesome: we wanted to prove order reduction for one ideal, and the induction requires us to prove order reduction for a collection of ideals. But there is a simple trick that allows one to replace this collection of ideals by a single ideal, in such a way that the notions of order reduction coincide:

Definition 3.5.3. *For an ideal $\mathcal{I}$ of maximal order a define its* coefficient ideal *to be the ideal sum $C(\mathcal{I}, a) := \sum(\mathfrak{D}_Y^{\le i}\mathcal{I})^{a!/(a-i)}$.*

Proposition 3.5.4 (Włodarczyk [2005, §3.4])**.** *Order reduction for $(C(\mathcal{I}, a)_{|H}, a!)$ is the same as order reduction for the collection $((\mathfrak{D}_Y^{\le i}\mathcal{I})_{|H}, a-i), i = 0, \dots, a$.*

We obtain:

Corollary 3.5.5 (Kollár [2007, Corollary 3.85])**.** *A sequence of blowings up is an order reduction for $(\mathcal{I}, a)$ if and only if it is an order reduction for $(C(\mathcal{I}, a)_{|H}, a!)$.*

3.6 A trouble of exceptional loci. I have been deliberately ignoring a subtle point. Theorem 2.5.1 about order reduction takes the additional datum of a divisor $E_0 \subset Y$. This is important for principalization, since once we reduce the order of $\mathcal{I}$ from a to $a-1$ with exceptional divisor say E_0, we want any further centers of blowing up used in further order reduction of $\mathcal{I}$ to have normal crossings with E_0.

For instance, in the example of a cuspidal curve above, the ideal $\mathcal{I} = x^2(z^2 - x)$ is of the form $\mathcal{I}_E^2 \mathcal{I}'$. The unique maximal contact hypersurface for $(\mathcal{I}', 1)$ is precisely X', the vanishing locus of $\mathcal{I}'$, but since it is tangent to E it does not have normal crossings with E.

The standard way to treat this is via a trick: one separates the relevant part of the ideal $\mathcal{I}'$ from the monomial part $\mathcal{I}_E$ by applying a suitable principalization for an ideal of the form $\mathcal{I}_E^\alpha + \mathcal{I}'^\beta$ describing the intersection of their loci. This is somewhat subtle and a bit disappointing. One feels that monomial ideals should only serve for good, as they are the goal.

I'll totally ignore this issue here, referring to Kollár [ibid., Section 3.13]. I have an excuse: in the procedure described below in my work with Temkin and Włodarczyk, this is not an issue at all, as monomial ideals become our best friends.

3.7 The problem of gluing. I postponed two important issues. Resolution of singularities requires *good* embedded resolution, *good* principalization, *good* order reduction: the process must be compatible with patching of open sets and independent of the embedding. A related issue is the fact that maximal contact hypersurfaces are not global, so patching open sets where maximal contact hypersurfaces do not overlap is required!

The classical approach has several ideas involved and has several levels of complexity. First, one devises a more elaborate *resolution invariant*, which records behavior of a given ideal on a sequence of nested maximal contact hypersurfaces. Second, one devises a class of transformations, called *test transformations*, which include admissible blowings up, restrictions to open sets, but also other operations, such as projections from a product.

One shows that ideals with the same invariant admit the same sequences of test transformations. It is a more subtle fact that the opposite is true - the invariant can be read off the test transformation. Once the dust settles it becomes clear that the order reduction one produces is independent of choices and is local, hence it can be patched along open sets. Also, the issue of the choice of embedding for resolution of singularities becomes local, hence it reduces to a simple principle I call *the re-embedding principle* in Section 3.10 below.

Some subset of this approach, in particular the fact that invariants can be read from the class of test transformations, is known as *Hironaka's trick*.

I have to admit that I never quite understood this approach until I read Włodarczyk's paper Włodarczyk [2005], which uses a completely different approach. After that transformative event I was able to read Bierstone and Milman [2008], and suddenly the classical approach was illuminated. I therefore prefer to present Włodarczyk's approach here, as perhaps others will experience the same transformation and subsequent illumination.

3.8 Włodarczyk's functoriality principle. Already Hironaka was interested in functorial properties of resolution of singularities. For instance, if X is a singular variety with a group G acting, ideally one would want the resolution to be G equivariant. Also if $X^0 \subset X$ is open, the resolution of X^0 should ideally be the restriction of that of X. This is stated explicitly in Bierstone and Milman [1997, §13].

Włodarczyk's great idea in Włodarczyk [2005] was that

> *functoriality is a powerful tool in the very proof of resolution of singularities.*

Moreover,

> *functoriality leads one to discover an order reduction algorithm.*

Włodarcyk requires one to take this very seriously. Indeed, for his principle to succeed one needs to use hidden symmetries, which are revealed only after $\mathcal{I}$ is tuned appropriately.

3.8.1 Smooth pullbacks. Let us first define the terms. Let $Y_n \to \cdots \to Y_0 = Y$ be an order reduction of $(\mathcal{I}, a)$ compatible with simple normal crossings divisor E. Let $Y' \to Y$ be a *smooth* morphism, what geometers call a *submersion*, such as an open embedding or a product with a regular variety. One can write $\mathcal{I}' = \mathcal{I}\mathcal{O}_Y$, $E' = E \times_Y Y'$ and $Y_i' = Y_i \times_Y Y'$, and then automatically $Y_n' \to \cdots \to Y_0' = Y'$ is an order reduction for $(\mathcal{I}', a)$, compatible with E', the *smooth pullback* order reduction. Some of the resulting steps might become trivial, in which case we drop them from the order reduction sequence.

Definition 3.8.2. *A* functorial order reduction *is a rule assigning to an ideal $\mathcal{I}$ on a regular variety Y with simple normal crossings divisor E and integer a such that* $\operatorname{maxord}(\mathcal{I}) \leq a$, *an order reduction $Y_n \to \cdots \to Y$, in such a way that for any smooth morphism $Y' \to Y$, the corresponding order reduction $Y_n' \to \cdots \to Y'$ is the smooth pullback order reduction of $Y_n \to \cdots \to Y$.*

To prove order reduction it suffices to produce functorial *order reduction on open patches, because then they automatically glue together.*

What about maximal contact hypersurfaces? Let us say we have produced functorial order reduction in dimension $\dim(Y) - 1$ and we wish to prove it for Y. We can choose a local maximal contact hypersurface $H \subset Y$ and reduce the order of the coefficient ideal $C(\mathcal{I}, a)_{|H}$. By Corollary 3.5.5 this results in *local* order reduction for $(\mathcal{I}, a)$, but *a priori* this depends on the choice of H. We claim that in fact there is no such dependence, and that the resulting order reduction is functorial on Y. For this we use $(\mathcal{I}, a)$-special automorphisms.

3.8.3 Special automorphisms. Let $Y_m \to \cdots \to Y_0$ be an $(\mathcal{I}, a)$-admissible sequence with centers $Z_i \subset Y_i$. Recall that this gives in particular a sequence of ideals $\mathcal{I}_i \subset \mathcal{O}_{Y_i}$

such that $Z_i \subset V(\mathcal{I}_i, a)$ and $\mathcal{I}_i \mathcal{O}_{Y_{i+1}} = \mathcal{I}_{E_{i+1}}^a \mathcal{I}_{i+1}$. An automorphism ϕ of Y is *special* if it *fixes* every $(\mathcal{I}, a)$-admissible sequence. This means that ϕ fixes $V(\mathcal{I}, a)$, in particular it fixes Z_0, hence it lifts to an automorphism ϕ_1 of Y_1, *which fixes* $V(\mathcal{I}_1, a)$, and inductively we obtain automorphisms ϕ_i of Y_i fixing $V(\mathcal{I}_i, a)$.

This is a very strong assumption on an automorphism, but Włodarczyk proved the following powerful result:

Proposition 3.8.4 (Włodarczyk [ibid.]). *Let $H_1, H_2 \subset Y$ be two local maximal contact hypersurfaces at $p \in V(\mathcal{I}, a)$. Then, after replacing Y by an étale neighborhood of p, there is a special automorphism ϕ of Y fixing p and sending H_1 to H_2.*

In particular, the functorial order reductions for $C(\mathcal{I}, a)_{|H_i}$ induce the same order reduction for $\mathcal{I}$, which is automatically functorial!

I deliberately did not require the automorphism ϕ to send $\mathcal{I}_i$ to itself, which would make the statement easier to grasp. Indeed, the following example shows that in general *it is impossible for ϕ to send $\mathcal{I}_i$ to itself,* and suggests that Proposition 3.8.4 is quite surprising and should require an ingenious idea.

Consider the ideal (xy) in the affine plane Y, with maximal order 2 attained at $V(\mathcal{I}, 2) = (0, 0)$, the origin. We have $\mathcal{D}^{\leq 2-1}\mathcal{I} = \mathcal{D}^{\leq 1}\mathcal{I} = (x, y)$, and so the lines $H_1 = \{x = 0\}$ and $H_2 = \{x + y = 0\}$ are both maximal contact hypersurfaces. Clearly any automorphism of Y sending H_1 to H_2 must change $\mathcal{I}$, since $\mathcal{I}_{|H_1} = 0$ and $\mathcal{I}_{|H_2} \neq 0$.

In this particular case the coefficient ideal is (x^2, xy, y^2), and the automorphism $(x, y) \mapsto (x + y, y)$ does send H_1 to H_2 fixing this ideal, so whatever procedure we apply using H_1 - in this case necessarily blowing up the origin - coincides with the process we apply using H_2.

3.8.5 Homogenization. The general case is slightly more subtle than the example: in general there is no automorphism carrying H_1 to H_2 fixing the coefficient ideal either. Searching for a natural replacement which is fixed under a special automorphism, Włodarcyk discovered the *homogenization* $\mathcal{H}(\mathcal{I}, a)$ described below.[4]

Definition 3.8.6. *Recall the notation $\mathcal{T}(\mathcal{I}, a) = \mathcal{D}_Y^{\leq a-1}\mathcal{I}$. The* homogenization *of $(\mathcal{I}, a)$ is the ideal*

$$\mathcal{H}(\mathcal{I}, a) := \sum_{i=0}^{a} \mathcal{D}^i(\mathcal{I})\, \mathcal{T}(\mathcal{I}, a)^i.$$

[4]A Different variant is used in Kollár [2007]; the treatment in Bravo, Garcia-Escamilla, and Villamayor U. [2012] in terms of differential Rees algebras provides a natural structure subsuming homogenization and coefficient ideals.

Włodarczyk's idea is that $\mathcal{I}$ lacks symmetries because it is not sufficiently tuned. In contrast, the ideal $\mathcal{H}(\mathcal{I}, a)$ is tuned to reveal the hidden symmetry ϕ.[5]

The ideal $\mathcal{H}(\mathcal{I}, a)$ is designed to contain all terms of Taylor expansions of elements of $\mathcal{I}$ in terms of any variable h in $\mathcal{T}(\mathcal{I}, a)$. If $H_1 = \{x = 0\}$, $H_2 = \{x + h = 0\}$ and $x = x_1, x_2, \ldots, x_m$ are local parameters of Y and p, chosen so that $x_1+h, x_2, \ldots, x_m$ also form local parameters, then the transformation $\phi(x_1, x_2, \ldots, x_m) = (x_1 + h, x_2, \ldots, x_m)$ is a local automorphism of Y formally sending $f(x_1, x_2, \ldots, x_m)$ to

$$\sum \frac{\partial^i f}{\partial x_1^i} h^i.$$

Note that $\frac{\partial^i f}{\partial x_1^i} h^i \in \mathcal{D}^i(\mathcal{I})\,\mathcal{T}(\mathcal{I}, a)^i$. Thus on formal completions this sends an element of $\mathcal{H}(\mathcal{I}, a)$ to an element of $\mathcal{H}(\mathcal{I}, a)$, and a bit of reflection shows that ϕ is a special automorphism with respect to $\mathcal{H}(\mathcal{I}, a)$. A standard argument allows to pass from completion to étale neighborhoods, hence ϕ defines a special automorphism with respect to $\mathcal{H}(\mathcal{I}, a)$ on a suitable étale neighborhood.

A simple computation shows:

Proposition 3.8.7. *Order reduction for $(\mathcal{I}, a)$ is equivalent to order reduction for $\mathcal{H}(\mathcal{I}, a)$.*

Thus ϕ is a special automorphism with respect to $(\mathcal{I}, a)$ as well!

3.9 A sketch of the algorithm. Let us summarize how one *functorially* reduces the order of a nonzero ideal $\mathcal{I}$ of maximal order $a > 0$ on a regular variety Y.

If $\dim(Y) = 0$ there is nothing to prove, since $\mathcal{I}$ is trivial hence of order 0. We assume proven order reduction in dimension $< \dim(Y)$.

We cover $V(\mathcal{I}, a)$ with open patches U possessing maximal contact hypersurfaces H_U. The coefficient ideal $C(\mathcal{I}, a)_{|H_U}$ has order $\geq a!$.

If this order is infinite, it means that $\mathcal{I}_{|U} = \mathcal{I}^a_{H_U}$, we simply blow up H_U and automatically the order of $\mathcal{I}$ is reduced on U.

Otherwise we can inductively reduce the order of this ideal by a functorial sequence of transformations $H_k \to \cdots \to H$ until the order drops below $a!$. By Corollary 3.5.5 these provide a local order reduction for $(\mathcal{I}, a)$ which patches together to a functorial order reduction by Proposition 3.8.4.

[5] In Bierstone and Milman [2008], Bierstone and Milman replace $(\mathcal{I}, a)$ by its equivalence class with respect to test transformation. With the "blurred vision" of equivalence classes of ideals, a hidden symmetry is again revealed. This is related to Hironaka's approach using the concept of *infinitely near points*.

3.10 The re-embedding principle. I still need to explain why a suitable embedded resolution of singularities implies resolution in general. If X is covered by open subsets X_i embedded in regular varieties Y_i, we want to claim that the resolutions $X_i' \to X_i$ agree on intersections $X_i \cap X_j$. Said another way, no matter how $X_i \cap X_j$ is embedded, the resolutions agree[6]. Since our procedures are functorial for étale maps and Y_i are regular, we may as well assume $Y_i = \mathbb{A}^{n_i}$. Finally affine spaces differ by iterated projections, so we are reduced to the following statement, which seems to follow from our procedures "by accident", see Kollár [2007, Claim 3.71.2]:

Proposition 3.10.1 (The re-embedding principle)**.** *Suppose $\mathcal{I}$ is an ideal on a regular variety Y. Consider the embedding $Y \subset Y_1 := Y \times \mathbb{A}^1$ sending $y \mapsto (y, 0)$. Let $\mathcal{I}_1 = \mathcal{I}\mathcal{O}_{Y_1} + (z)$, where z is the coordinate on $\mathbb{A}^1$. Then the principalization described above of $\mathcal{I}_1$ on Y_1 is obtained by taking the principalization of $\mathcal{I}$ on Y and blowing up the same centers, embedded in Y_1 and is transforms.*

I would very much like to say that this follows from functoriality, but this is not so simple (see Kollár's treatment). Instead, we look under the hood of principalization. To principalize $\mathcal{I}_1$ we need to reduce the order of $\mathcal{I}_1$ below 1. The order of $\mathcal{I}_1$ is 1, since z has order 1, and then z defines a maximal contact hypersurface, which is, seemingly by accident, precisely Y with the coefficient ideal $\mathcal{I}$, so the statement follows for the first blowing up. The local product structure persists after blowing up, so the statement holds for the entire order reduction procedure.

4 Toric varieties and toroidal embeddings

To proceed further it is useful to introduce a nice class of variety with "fairly simple" singularities.

4.1 Toric varieties. A *toric variety* is a *normal* variety X with a dense embedding $T = (\mathbb{C}^*)^n \hookrightarrow X$ such that the action of T on itself by translations extends to X. Here *normal* means that the local rings are integrally closed, a condition which guarantees that X is regular in codimension 1.

Toric varieties are a simple playing ground for algebraic geometers, as many aspects of a toric variety can be translated to combinatorics. To a toric variety X one associates a *fan* Σ_X, a collection of rational polyhedral cones in the lattice $N_T := \mathrm{Hom}(\mathbb{C}^*, T)$ which intersect similarly to cells of a CW complex. One makes toric varieties into a category on which arrows are torus equivariant morphisms which are surjective on the tori. Similarly

[6] There is a subtle issue of synchronization by codimension I will ignore. See Bierstone, Milman, and Temkin [2011, §5.3], Temkin [2011, §2.5.10]

fans form a category: a map of fans $\Sigma_1 \to \Sigma_2$ is induced by a map of lattices $N_1 \to N_2$ with finite cokernel, such that a cone of Σ_1 maps into a cone in Σ_2. There is an equivalence of categories

$$\{\text{toric varieties}\} \leftrightarrow \{\text{fans}\}.$$

A toric variety X is regular if and only if its fan Σ_X is regular: every cone is simplicial, and generators of its edges span a saturated lattice in N_T. Toric birational maps correspond to subdivisions of fans, and so toric resolution of singularities can be done by finding a regular subdivision, a fairly simple task.

There are great sources to learn the theory. See Kempf, Knudsen, Mumford, and Saint-Donat [1973], Oda [1988], and Fulton [1993].

4.2 Toroidal embeddings. All toric varieties are rational, so they have a limited chance to help with resolution of singularities. A *toroidal embedding* is an open embedding $U \subset X$ which locally analytically in the euclidean topology looks like a toric variety: for a point $p \in X$ there is a patch $V_p \subset X$ and a corresponding open set $W_p \subset Y$, where $T \subset Y$ is a toric variety, and an analytic isomorphism $V_p \to W_p$ carrying $V_p \cap U$ onto $W_p \cap T$.

One can speak of *toroidal morphisms* $X_1 \to X_2$ between toroidal embeddings: these are those morphisms which locally on the source look like toric morphisms of toric varieties.

As toroidal embeddings look locally like toric varieties their singularities are toric. It comes as no surprise that toric resolution of singularities extends quite easily to toroidal embeddings. In fact, one associates to a toroidal embedding $U \subset X$ a combinatorial gadget - a rational polyhedral cone complex - in a functorial manner. This is not an equivalence of categories, but it is still true that subdivisions correspond to toroidal birational morphisms, and the resolution procedure for fans extends to polyhedral cone complexes.

This is developed in Kempf, Knudsen, Mumford, and Saint-Donat [1973].

5 Resolution in families

I briefly recall known results on resolution in families, all relying on de Jong's *alteration method.*

5.1 The alteration theorem. In de Jong [1996], Johan de Jong discovered a method to replace a variety X by a regular variety X' with a morphism $X' \to X$ which is not necessarily birational, but is *proper, surjective and generically finite*. Such maps he called *alterations*, which differ from birational *modifications* in that the extension of function fields $K(X) \subset K(X')$ may be nontrivial.

Theorem 5.1.1 (de Jong [ibid.]). *Let X be a variety over a field of arbitrary characteristic and Z a subvariety. There is an alteration $f : X' \to X$ such that X' is smooth and $f^{-1}Z$ a simple normal crossings divisor.*

5.1.2 Sketch of proof. Here is the basic idea: assume for simplicity X is projective; blowing up makes Z into a divisor. One can choose a rational projection $X \dashrightarrow \mathbb{P}^{n-1}$, which becomes a morphism after replacing X by a modification, so that the generic fiber X_η over the generic point $\eta \in \mathbb{P}^n$ is a smooth curve, of some genus g, and Z can be viewed as a collection of k marked points on X_η. This corresponds to a morphism $\{\eta\} \to \overline{\mathfrak{M}}_{g,k}(X,d)$, the Kontsevich space of stable maps, where d is the degree of X_η with respect to some projective embedding. Properness of this moduli space provides us an alteration $B \to \mathbb{P}^n$ over which this extends to a family of stable maps $Y_0 \to X$ parametrized by B. Induction on the dimension allows us to assume that B is smooth and the degeneracy locus of Y_0/B is a simple normal crossings divisor. An inspection of Y_0 shows that it has the structure of toroidal embedding, hence admits a combinatorial resolution of singularities $Y \to Y_0$. The composite morphism $Y \to X$ is the required alteration.

5.2 Toroidalization. In the introduction, we stated resolution of singularities as the problem of making points of X *simple*. If instead we have a family of varieties $X \to B$ parametrized by a variety B, what should a resolution of singularities of the *family* mean? That is, when are the singularities of the family *simple*?

It is not hard to see that making all the fibers regular is impossible. Since we agree that toroidal singularities are rather simple, one might consider a toroidal morphism to represent a family with simple singlarities. Here are two solutions based on this idea:

Theorem 5.2.1 (Altered toroidalization, de Jong [ibid.]). *Let $X \to B$ be a dominant morphism of varieties. There are alterations $B_1 \to B$ and $X_1 \to X \times_B B_1$, with regular toroidal embedding structures $U_B \subset B_1$ and $U_X \subset X_1$, and a* toroidal *morphism $X_1 \to B_1$ making the following diagram commutative.*

(1)
$$\begin{array}{ccc} X_1 & \longrightarrow & X \\ \downarrow & & \downarrow \\ B_1 & \longrightarrow & B \end{array}$$

See improvement on this in Theorem 5.3.1 below. This is proven in much the same way as one proves de Jong's alteration theorem, Theorem 5.1.1. One needs to simply replace the projection $X \dashrightarrow \mathbb{P}^n$ by a relative projection $X \dashrightarrow \mathbb{P}^{d-1} \times B$, where d is the relative dimension of X over B.

In characteristic 0 one can inprove the situation, using *modifications* instead of *alterations*:

Theorem 5.2.2 (Toroidalization, Abramovich and Karu [2000, Theorem 2.1]). *Let $X \to B$ be a dominant morphism of complex projective varieties. There is a modification $B' \to B$, a modification $X' \to X$, and regular toroidal embedding structures $U_B \subset B'$ and $U_X \subset X'$, such that the map $X' \dashrightarrow B'$ is a* toroidal *morphism.*

Theorem 5.2.2 is proven using the following addition to de Jong's method, introduced in Abramovich and de Jong [1997]: in essence, one brings oneself to a situation as in equation (1), where the Galois group $Gal(K(X_1)/K(X))$ of the function field extension acts on the whole diagram. In characteristic 0 it turns out that the singularities of the quotients X_1/G and B_1/G can be resolved by toroidal methods - this is a feature of *tame* group actions in general. This sketch is only true in essense: in practice the Galois structure is intertwined with the inductive structure of the proof of Theorem 5.2.1.

Theorems 5.2.1 and 5.2.2 have two major disadvantages: they are by no means functorial, and they necessarily change the general fiber of $X \to B$ even if it is already regular.

5.3 Semistable reduction. We have already pointed out that toroidal embeddings can be resolved. The same is true to some extent for families as well. This means that the singularities in Theorems 5.2.1 and 5.2.2 can still be improved.

Let $X \to B$ be a toroidal morphism between toroidal embeddings. Assume X and B are regular. We say that $X \to B$ is *semistable* if locally at any point $x \in X$ there are distinct monomial variables $y_1, \ldots, y_k$ on B and $x_1, \ldots, x_m$ on X such that X is described by the following equations:

$$\begin{aligned} x_1 \cdots x_{l_1} &= y_1, \\ x_{l_1+1} \cdots x_{l_2} &= y_2, \\ \vdots \quad & \quad \vdots \\ x_{l_{k-1}+1} \cdots x_{l_k} &= y_k. \end{aligned}$$

This means that locally X is a product of families of the form $x_1 \cdots x_l = y$. This is truly the best one can hope for. A somewhat weaker and more flexible version would replace y_i by monomials m_i without common factors.

De Jong actually proved:

Theorem 5.3.1 (Altered semistable reduction, de Jong [1996]). *Let $X \to B$ be a dominant morphism of varieties over a field. There are alterations $B_1 \to B$ and $X_1 \to X \times_B B_1$,* *and regular toroidal embedding structures* $U_B \subset B_1$ *and* $U_X \subset X_1$*, with semistable morphism* $X_1 \to B_1$.

In characteristic 0 a somewhat weaker result was proven in Abramovich and Karu [2000, Theorem 0.3] where the generic fiber is modified but not altered. The strongest form is given in Karu [2000] for families of surfaces and threefolds:

Theorem 5.3.2 (Semistable reduction, Karu [ibid.]). *Let* $X \to B$ *be a dominant morphism of complex projective varieties with* $\dim(X) - \dim(B) \leq 3$*. There is an alteration* $B' \to B$*, a modification* $X' \to X \times_B B'$*, and regular toroidal embedding structures* $U_B \subset B'$ *and* $U_X \subset X'$*, such that the map* $X' \dashrightarrow B'$ *is semistable.*

The case of arbitrary relative dimension is conjectured in Abramovich and Karu [2000, Conjecture 0.2], and reduced to a completely combinatorial problem in Abramovich and Karu [ibid., Conjecture 8.4]. This remains open.

6 Resolution in toroidal orbifolds

6.1 Towards functorial resolution of families. All the toroidalization and semistable reduction theorems above suffer from severe non-functoriality, and most importantly they change the generic fiber even if it is smooth. This is a major drawback in application. For example, one would like to take a smooth family of varieties over an open base and compactify it with as simple fibers as possible. One envisions compactifying by closure in some projective space and applying toroidalization or semistable reduction. The theorems above do not provide this, as the original family is necessarily changed.

The approach I present here is to start from scratch and use Hironaka's method instead of de Jong's. People have thought of this for a while, notably Cutkosky, see Cutkosky [2005], though his goals are different.

6.2 Temkin's functoriality principle. Consider the family $X \to B$ where X is a regular surface with coordinates x, y and B a curve with coordinate t, and where the map is given by $xy = t$. This is a semistable family.

Now take the base change $B_1 \to B$ given by $s^2 = t$. The pullback family $X_1 \to B_1$ is given by equation $xy = s^2$, which is semistable in the weaker sense, as s^2 is a monomial. If we are to allow semistable families to be compatible with base change this additional flexibility is a must. From the point of view of resolution of singularities in families, both families are good, even though X_1 is singular.

An important point in this example is that $B_1 \to B$ and $X_1 \to X$ are *toroidal* morphisms. If we are to prove a functorial procedure for resolving singularities in families, the procedure must not modify families which are already semistable, so both $X \to B$ and $X_1 \to B_1$ must stay intact.

In Hironaka's resolution, the best way to ensure that regular varieties stay intact is to require the resolution to be functorial for smooth morphisms. Indeed if X is regular then $X \to \operatorname{Spec} \mathbb{C}$ is a smooth morphism, so the resolution of X must be the pullback of the resolution of $\operatorname{Spec} \mathbb{C}$, which is necessarily trivial.

In the semistable reduction problem, the best way to ensure that a toroidal $X \to B$ stays intact is to require functoriality for *toroidal* morphisms. For instance, if already $B = \operatorname{Spec} \mathbb{C}$ is just a point and X is toroidal, then the morphism $X \to \operatorname{Spec} \mathbb{C}$ is toroidal, so the procedure we produce for $X \to \operatorname{Spec} \mathbb{C}$ must be the pullback of the procedure we produce for the identity $\operatorname{Spec} \mathbb{C} \to \operatorname{Spec} \mathbb{C}$, which is necessarily trivial.

Temkin's functoriality principle is thus:

> *Toroidal morphisms form the smallest reasonable class of morphisms under which semistable reduction should be functorial.*

And, in view of Włodarczyk's philosophy,

> *functoriality for toroidal morphisms should lead one to discover a semistable reduction procedure.*

As a necessary prerequisite, *we must produce a resolution procedure, built on Hironaka's procedure, which is functorial for toroidal morphisms.*

6.3 Enter toroidal orbifolds. Having accepted Temkin's functoriality principle and agreed that we must produce a resolution procedure, built on Hironaka's procedure, which is functorial for toroidal morphisms, there is another surprising conclusion coming our way.

Temkin's principle forces us to take a departure from previous algorithms:

1. We can no longer work with a smooth ambient variety Y - *we must allow Y to have toroidal singularities.*

2. We cannot use only blowings up of smooth centers as our basic operations. Instead we use a class of modifications, called *Kummer blowings up*, which are stable under toroidal base change. These involve taking roots of monomials, in particular:

3. We can no longer work only with varieties Y - *we must allow Y to be a Deligne–Mumford stack.*

In essence, we are using "weighted blowings up on steroids". The stacks we need are as follows:

Definition 6.3.1. *A* toroidal orbifold (Y, U) *is a Deligne–mumford stack Y with diagonalizable inertia with a toroidal embedding $U \subset Y$.*

Item (3) may be hard to accept but it is absolutely essential for functoriality under toroidal morphisms.

Consider the affine plane Y, with coordinates x, u, where we endow the plane with a toroidal structure by declaring $U = Y \setminus \{u = 0\}$, so x is a parameter and u is a *monomial*. Say we want to principalize the ideal $\mathcal{I} := (x^2, u^2)$. Functoriality under smooth morphisms suggests that we must blow up the ideal (x, u). This indeed works and principalizes $\mathcal{I}$ in one step.

Now consider the affine plane Y_0, with coordinates x, v, similar to the above, but say we want to principalize the ideal $\mathcal{I}_0 := (x^2, v)$. Note that we have a toroidal morphism $Y \to Y_0$ given by $u^2 = v$, and $\mathcal{I} = \mathcal{I}_0 \mathcal{O}_Y$. Temkin's functoriality tells us that there should be a center on Y_0 whose pullback is (x, u). This center must therefore be defined by $(x, \sqrt{v})$!

There is only one way to deal with it, and that is to work systematically in a setup where one is allowed, when necessary, to take roots of monomials. This is possible precisely when working with toroidal orbifolds, as indicated above.

6.4 Principalization in toroidal orbifolds. In the joint work Abramovich, Temkin, and Włodarczyk [2017a] with Temkin and Włodarczyk we prove

Theorem 6.4.1 (Toroidal principalization)**.** *Let (Y, U) be a toroidal orbifold and $\mathcal{I}$ an ideal sheaf. There is a sequence $Y_n \to Y_{n-1} \to \cdots \to Y_0 = Y$ of Kummer blowings up, all supported over the vanishing locus $V(\mathcal{I})$, such that $\mathcal{I}\mathcal{O}_{Y_n}$ is an invertible monomial ideal.* The process is functorial for toroidal base change morphisms $Y' \to Y$.

6.5 Logarithmic derivatives and logarithmic orders. Temkin's functoriality principle suggests a natural replacement for derivatives.

In the toroidal world, the natural replacement for derivatives is provided by *logarithmic derivatives*: if u is a *monomial* function on a toroidal Y, then we use the operator $u\frac{\partial}{\partial u}$, which sends u to itself, but not $\frac{\partial}{\partial u}$. One then defines the sheaf $\mathcal{D}^{\leq a}_{Y,U}$ of *logarithmic* differential operators of order $\leq a$.

Given an ideal $\mathcal{I}$ on a toroidal (Y, U), one defines its *logarithmic order* at $p \in Y$ to be $\operatorname{logord}_p(\mathcal{I}) = \min\{a : \mathcal{D}^{\leq a}_{Y,U}(\mathcal{I}) = (1)\}$. This can take the value ∞ when the *monomial part* $\mathfrak{M}(\mathcal{I}) := \mathcal{D}^{\infty}_{Y,U}\mathcal{I}$ is nontrivial.

Then a miracle happens: using Temkin's functoriality and logarithmic derivatives, the broad outlines of principalization described above, as laid out in detail in Włodarczyk [2005], work in this new context once one has a stable formalism of toroidal orbifolds.

The formalism is developed in Abramovich, Temkin, and Włodarczyk [2017b] and the proof of the theorem is written out in Abramovich, Temkin, and Włodarczyk [2017a].

Our next task is to return to work on families of varieties. We hope to report on that in the near future.

Abstract

The theory of holomorphic foliations has its origins in the study of differential equations on the complex plane, and has turned into a powerful tool in algebraic geometry. One of the fundamental problems in the theory is to find conditions that guarantee that the leaves of a holomorphic foliation are algebraic. These correspond to algebraic solutions of differential equations. In this paper we discuss algebraic integrability criteria for holomorphic foliations in terms of positivity of its tangent sheaf, and survey the theory of Fano foliations, developed in a series of papers in collaboration with Stéphane Druel. We end by classifying all possible leaves of del Pezzo foliations.

1 Introduction

The theory of holomorphic foliations has its origins in the study of differential equations on the complex plane $\mathbb{C}^2$. A central problem in this theory consists in finding conditions that guarantee the existence of algebraic solutions (Darboux [1878], Painlevé [1894], Poincaré [1891]). Consider for instance the following algebraic differential equations:

$$\frac{dy}{dx} = \frac{y}{x}, \tag{1-1}$$

$$\frac{dy}{dx} = y. \tag{1-2}$$

While the solutions to equation (1-1) are algebraic, namely $y = cx$, the solutions to equation (1-2) are mostly transcendental, namely $y = ce^x$. In both cases, the algebraic differential equation defines a saturated subsheaf $\mathcal{F} \subset T_{\mathbb{C}^2}$. By saturated we mean that $T_{\mathbb{C}^2}/\mathcal{F}$ is torsion free. We call this subsheaf a *foliation* of the plane. Curves that are everywhere

MSC2010: primary 37F75; secondary 14E30, 14M22.

tangent to $\mathscr{F}$ correspond to solutions of the equation, and are called *leaves of the foliation*. We remark that classically the word foliation refers to the partition of the plane into leaves. If we extend to $\mathbb{P}^2$ the foliations $\mathscr{F} \subset T_{\mathbb{C}^2}$ defined by the equations above, we obtain the saturated subsheaves $\mathscr{O}_{\mathbb{P}^2}(1) \subset T_{\mathbb{P}^2}$ in (1-1) and $\mathscr{O}_{\mathbb{P}^2} \subset T_{\mathbb{P}^2}$ in (1-2). As we shall see, the ampleness of $\mathscr{O}_{\mathbb{P}^2}(1)$ forces the solutions of equation (1-1) to be algebraic. This is the simplest manifestation of a series of results relating properties of positivity and algebraicity of holomorphic foliations.

In general, a *foliation* on a normal variety X is a saturated nonzero coherent subsheaf $\mathscr{F} \subsetneq T_X$ that satisfies the Frobenius integrability condition: $\mathscr{F}$ is closed under the Lie bracket. The Frobenius condition guarantees that a dense open subset of X is covered by analytic submanifolds whose tangent bundles are restrictions of $\mathscr{F}$. When these submanifolds are connected and maximal, we say that they are *leaves* of $\mathscr{F}$. We refer to Section 2 for definitions and generalities about holomorphic foliations on complex varieties, including notions of singularity for foliations.

In the last decades, foliations have proved to be a powerful tool in algebraic geometry. For instance, they play an important role in the proof of Green–Griffiths conjecture for surfaces of general type with positive Segre class (F. A. Bogomolov [1977], McQuillan [1998]). In many applications, a key problem is to find conditions that guarantee that a foliation has algebraic leaves, in which case we say that it is *algebraically integrable*, and to describe the structure of these algebraic subvarieties. We briefly mention two important instances of this.

1.1 (Miyaoka's criterion of uniruledness)**.** In Miyaoka [1987], Miyaoka proved a remarkable criterion of uniruledness in terms of numerical properties of the tangent sheaf. Namely, if X is a non-uniruled normal projective variety, then its cotangent sheaf Ω^1_X is generically semi-positive. This last condition means that for a sufficiently general complete intersection curve C on X, the restriction $(\Omega^1_X)_{|C}$ is semi-positive. This criterion in one of the main ingredients in the proof of abundance for threefolds (see Shepherd-Barron [1992]). Algebraic integrability of foliations plays a key role in Miyaoka's proof, which involves reduction to positive characteristic. Namely, if Ω^1_X is not generically semi-positive, then, using Harder–Narasimhan filtrations, one can construct a special foliation on X, whose restriction to a sufficiently general complete intersection curve C is ample. This foliation is shown to be algebraically integrable and covered by rational curves.

Miyaoka's algebraicity criterion has been extensively generalized. We mention Bost's arithmetic geometric counterpart (Bost [2001]), Bogomolov and McQuillan's criterion, which gives rationally connectedness of general leaves (see F. Bogomolov and McQuillan [2016] and also Kebekus, Solá Conde, and Toma [2007]), and most recently the extension by Campana and Paŭn, which considers positivity of the tangent sheaf with respect to more general movable curve classes (Campana and Păun [2015]). These criteria will be further discussed in Section 2.

1.2 (The structure of singular varieties with numerically trivial canonical class)**.** The Beauville–Bogomolov decomposition theorem asserts that, after étale cover, any compact Kähler manifold with numerically trivial canonical class is a product of a torus, Calabi–Yau and irreducible symplectic manifolds (Beauville [1983]). This structure result has been recently generalized to the singular setting in Druel [2017] and Höring and Peternell [2017]. Algebraic integrability of foliations plays a key role in the proof of this structure theorem. Namely, Greb, Kebekus, and Peternell [2016b] gives a decomposition of the tangent sheaf of a singular complex projective variety X with trivial canonical class into a direct sum of foliations with strong stability properties. Druel provides in Druel [2017] an algebraic integrability criterion to show that this decomposition of the tangent sheaf is induced by a product structure on a quasi-étale cover of X.

A common idea behind the algebraic integrability results for foliations discussed above is that positivity properties of foliations tend to increase algebraicity properties of the leaves. In a series of papers in collaboration with Stéphane Druel (Araujo and Druel [2013], Araujo and Druel [2014], Araujo and Druel [2016], Araujo and Druel [2017] and Araujo and Druel [2018]), we have investigated foliations with positive anticanonical class, which we call *Fano foliations*. For Fano foliations, a rough measure of positivity is the *index*. The index $\iota_{\mathcal{F}}$ of a Fano foliation $\mathcal{F}$ on a complex projective manifold X is the largest integer dividing $-K_{\mathcal{F}}$ in $\mathrm{Pic}(X)$. One special property of Fano foliations is that their leaves are always covered by rational curves, even when these leaves are not algebraic. Our works on Fano foliations with high index indicated that the higher is the index, the closer it is to being algebraically integrable. First of all, we have the following general bound on the index, in analogy with Kobayachi–Ochiai's theorem on the index of Fano manifolds:

Theorem 1.3 (Araujo, Druel, and Kovács [2008, Theorem 1.1])**.** *Let $\mathcal{F} \subsetneq T_X$ be a Fano foliation of rank r on a complex projective manifold X. Then $\iota_{\mathcal{F}} \leqslant r$, and equality holds only if $X \cong \mathbb{P}^n$.*

Foliations on $\mathbb{P}^n$ attaining the bound of Theorem 1.3 are induced by linear projections $\mathbb{P}^n \dashrightarrow \mathbb{P}^{n-r}$ (Déserti and Cerveau [2005, Théorème 3.8]). These results have been generalized to the singular setting in Araujo and Druel [2014] and Höring [2014].

Next we consider Fano foliations $\mathcal{F} \subsetneq T_X$ of rank r on complex projective manifolds X with index $\iota_{\mathcal{F}} = r - 1$. In analogy with the theory of Fano manifolds, we call them *del Pezzo foliations*. In contrast with the case of maximal index $\iota_{\mathcal{F}} = r$, there are examples of del Pezzo foliations on $\mathbb{P}^n$ with non-algebraic leaves. In fact, del Pezzo foliations on $\mathbb{P}^n$ were classified in Loray, Pereira, and Touzet [2013]. They are the following.

- A foliation induced by a dominant rational map $\mathbb{P}^n \dashrightarrow \mathbb{P}(1^{n-r}, 2)$, defined by $n-r$ linear forms and one quadric form, where $\mathbb{P}(1^{n-r}, 2)$ denotes the weighted projective space with weights $\underbrace{1, \dots, 1}_{r \text{ times}}, 2$.

- The linear pullback of a foliation $\mathscr{C}$ on $\mathbb{P}^{n-r+1}$ induced by a global vector field.

In the second case, if the vector field is general, then the leaves of $\mathscr{C}$ are transcendental, as the solutions to equation (1-2) above illustrates. Hence, the leaves of the del Pezzo foliation are not algebraic either. The following algebraic integrability result asserts that these are the only transcendental del Pezzo foliations on complex projective manifolds.

Theorem 1.4 (Araujo and Druel [2013, Theorem 1.1]). *Let $\mathscr{F}$ be a del Pezzo foliation on a complex projective manifold $X \not\cong \mathbb{P}^n$. Then $\mathscr{F}$ is algebraically integrable, and its general leaves are rationally connected.*

In the classical setting, del Pezzo manifolds were classified by Fujita in the 1980's. Most of them are complete intersections on weighted projective spaces. One may also expect a classification of del Pezzo foliations. For example, the only del Pezzo foliations on smooth quadric hypersurfaces are those induced by the restriction of linear projections from the ambient projective space (Araujo and Druel [2016, Proposition 3.18]). Moreover, quadrics are the only hypersurfaces that admit del Pezzo foliations (Araujo and Druel [2013, Corollary 4.8.]). We also know examples of del Pezzo foliations on certain Grassmannians and projective space bundles over projective spaces (Araujo and Druel [ibid., Sections 4 and 9]). In Section 3 we discuss the classification of del Pezzo foliations, under restrictions on the rank or on the singularities of the foliation. A complete classification of del Pezzo foliations seems to be a difficult problem. A step in this direction is a classification of all possible leaves of del Pezzo foliations, which is given in Proposition 3.3.

We remark that codimension 1 Fano foliations of large index on complex projective spaces have been classically studied. The *degree* d of a foliation $\mathscr{F}$ of rank r on $\mathbb{P}^n$ is defined as the degree of the locus of tangency of $\mathscr{F}$ with a general linear subspace $\mathbb{P}^{n-r} \subset \mathbb{P}^n$. It satisfies $d = r - \iota_{\mathscr{F}}$. So Fano foliations of large index on $\mathbb{P}^n$ are precisely those with small degree. Codimension 1 foliations on $\mathbb{P}^n$ of degree 0 and 1 were classified in Jouanolou [1979]. Those of degree 2 were classified in Cerveau and Lins Neto [1996].

Theorem 1.4 is in fact a special case of a more general result that gives a lower bound for the *algebraic rank* of a Fano foliation in terms of the index. The algebraic rank $r^a_{\mathscr{F}}$ of a foliation $\mathscr{F}$ on an algebraic variety X is the maximum dimension of an algebraic subvariety through a general point of X that is everywhere tangent to $\mathscr{F}$. A foliation is said to be *purely transcendental* if its algebraic rank is 0.

Theorem 1.5 (Araujo and Druel [2018, Corollary 1.6.]). *Let $\mathcal{F}$ be a Fano foliation of index $\iota_{\mathcal{F}}$ on a complex projective manifold X. Then $r^a_{\mathcal{F}} \geqslant \iota_{\mathcal{F}}$, and equality holds if and only if $X \cong \mathbb{P}^n$ and $\mathcal{F}$ is the pullback under a linear projection of a purely transcendental foliation on $\mathbb{P}^{n-r^a_{\mathcal{F}}}$ with trivial canonical class.*

Fano foliations may also play a distinguished role in the emerging theory of birational geometry of foliations. Higher dimensional algebraic geometry has had a strong influence in the study of holomorphic foliations. Techniques from the minimal model program have been successfully applied to the study of global properties of holomorphic foliations, leading to the birational classification of foliations by curves on surfaces (Brunella [1999], Mendes [2000], Brunella [2004]). In higher dimensions, very little is known and difficulties abound: Kawamata–Viehweg vanishing, abundance and resolution of singularities all fail in general for foliations. Positive results, mostly in dimension 3, include a reduction of singularities for foliations on threefolds (Cano [2004], McQuillan and Panazzolo [2013]) and a cone theorem for rank 2 foliations on threefolds (Spicer [2017]). We also mention that there are structure results for foliations with numerically trivial canonical class (Touzet [2008], Loray, Pereira, and Touzet [2013], Loray, Pereira, and Touzet [2011], Pereira and Touzet [2013]).

In the context of birational geometry of foliations, it is important to develop the theory of foliations on mildly singular varieties. In Section 2 we survey some aspects of the theory of foliations in this more general setup. In Section 3 discuss the classification of del Pezzo foliations on projective manifolds.

Notation and conventions. We always work over the field $\mathbb{C}$ of complex numbers. Varieties are always assumed to be irreducible. We denote by X_{ns} the nonsingular locus of a variety X. Given a sheaf $\mathcal{F}$ of $\mathcal{O}_X$-modules of generic rank r on a variety X, we denote by $\det(\mathcal{F})$ the sheaf $(\wedge^r \mathcal{F})^{**}$. If $\mathcal{G}$ is another sheaf of $\mathcal{O}_X$-modules on X, then we denote by $\mathcal{F}[\otimes]\mathcal{G}$ the sheaf $(\mathcal{F} \otimes \mathcal{G})^{**}$. When X is a normal variety, we denote by T_X the tangent sheaf $(\Omega^1_X)^*$.

Acknowledgments. I am deeply grateful to Stéphane Druel for the collaboration throughout the years and for his comments on earlier versions of this paper. I also thank Jorge Vitório Pereira for inspiring conversations about holomorphic foliations.

2 Foliations

In this section we define foliations on algebraic varieties, their canonical class and notions of singularities. We then discuss criteria of algebraic integrability and special properties of Fano foliations.

Definition 2.1. A *foliation* on a normal variety X is a saturated nonzero coherent subsheaf $\mathcal{F} \subsetneq T_X$ that is closed under the Lie bracket.

The *rank* r of $\mathcal{F}$ is the generic rank of $\mathcal{F}$.

The *canonical class* $K_{\mathcal{F}}$ of $\mathcal{F}$ is any Weil divisor on X such that $\mathcal{O}_X(-K_{\mathcal{F}}) \simeq \det(\mathcal{F})$.

We say that $\mathcal{F}$ is *Gorenstein* if $K_{\mathcal{F}}$ is Cartier.

We say that $\mathcal{F}$ is $\mathbb{Q}$-*Gorenstein* if $K_{\mathcal{F}}$ is $\mathbb{Q}$-Cartier.

Definition 2.2. Let $\mathcal{F}$ be a $\mathbb{Q}$-Gorenstein foliation of rank r on a normal variety X, and consider the induced map

$$\eta : \Omega_X^r = \wedge^r(\Omega_X^1) \to \wedge^r(T_X^*) \to \wedge^r(\mathcal{F}^*) \to \det(\mathcal{F}^*) \simeq \mathcal{O}_X(K_{\mathcal{F}}).$$

This is called a *Pfaff field* of rank r on X (Araujo and Druel [2014, Definition 3.4]). The *singular locus* S of $\mathcal{F}$ is the closed subscheme of X whose ideal sheaf $\mathcal{I}_S$ is the image of the associated map $\Omega_X^r[\otimes]\mathcal{O}_X(-K_{\mathcal{F}}) \to \mathcal{O}_X$. On the nonsingular locus X_{ns} of X, S_{red} consists of the points at which $\mathcal{F}_{|X_{\mathrm{ns}}}$ is not a subbundle of $T_{X_{\mathrm{ns}}}$. When $S = \varnothing$, we say that $\mathcal{F}$ is a *regular* foliation.

An analytic subvariety $Y \subset X$ is *invariant* under $\mathcal{F}$ if it is not contained in the singular locus of $\mathcal{F}$, and the restriction $\eta_{|Y_{\mathrm{ns}}} : \Omega^r_{X\,|Y_{\mathrm{ns}}} \to \mathcal{O}_X(K_{\mathcal{F}})_{|Y_{\mathrm{ns}}}$ factors through the natural map $\Omega^r_{X\,|Y_{\mathrm{ns}}} \to \Omega^r_{Y\,|Y_{\mathrm{ns}}}$.

A maximal invariant subvariety of dimension r is called a *leaf* of $\mathcal{F}$.

There are several notions of singularities for foliations. The notion of *reduced* foliations has been used in the birational classification of foliations by curves on surfaces (see Brunella [2004]). More recently, notions of singularities coming from the minimal model program have shown very useful when studying birational geometry of foliations. We introduce the notions of *canonical* and *log canonical* foliations following McQuillan [2008, Definition I.1.2]. Terminal and log terminal singularities can be defined analogously.

Definition 2.3. Let $\mathcal{F}$ be a $\mathbb{Q}$-Gorenstein foliation on a normal variety X. Let $\varphi : \tilde{X} \to X$ be a projective birational morphism. There is a unique foliation $\tilde{\mathcal{F}}$ on $\tilde{X}$ that agrees with $\varphi^*\mathcal{F}$ on the open subset of $\tilde{X}$ where φ is an isomorphism, and uniquely defined rational numbers $a(E, X, \mathcal{F})$'s such that

$$K_{\tilde{\mathcal{F}}} = \varphi^* K_{\mathcal{F}} + \sum_E a(E, X, \mathcal{F})E,$$

where E runs through all exceptional prime divisors for φ. As usual, the discrepancies $a(E, X, \mathcal{F})$'s do not depend on the birational morphism φ, but only on the valuations associated to the E's. We say that $\mathcal{F}$ is *canonical* if $a(E, X, \mathcal{F}) \geqslant 0$ for all E exceptional over X. We say that $\mathcal{F}$ is *log canonical* if $a(E, X, \mathcal{F}) \geqslant -\epsilon(E)$ for all E exceptional over X, where

$$\epsilon(E) = \begin{cases} 0 & \text{if } E \text{ is invariant by the foliation,} \\ 1 & \text{if } E \text{ is not invariant by the foliation.} \end{cases}$$

If a Gorenstein foliation is regular, then it is canonical (Araujo and Druel [2013, Lemma 3.10]).

Definition 2.4. Let X be a normal projective variety, and $\mathscr{F}$ a $\mathbb{Q}$-Gorenstein foliation on X. We say that $\mathscr{F}$ is a $\mathbb{Q}$-*Fano foliation* if $-K_{\mathscr{F}}$ is ample. In this case, the *index* of $\mathscr{F}$ is the largest positive rational number $\iota_{\mathscr{F}}$ such that $-K_{\mathscr{F}} \sim_{\mathbb{Q}} \iota_{\mathscr{F}} H$ for a Cartier divisor H on X.

If $\mathscr{F}$ is a $\mathbb{Q}$-Fano foliation of rank r on a normal projective variety X, then, by Höring [2014, Corollary 1.2], $\iota_{\mathscr{F}} \leqslant r$. Moreover, equality holds if and only if X is a generalized normal cone over a normal projective variety Z, and $\mathscr{F}$ is induced by the natural rational map $X \dashrightarrow Z$ (see also Araujo, Druel, and Kovács [2008, Theorem 1.1], and Araujo and Druel [2014, Theorem 4.11]). In Section 3 below we discuss Fano foliations of rank r and index $\iota_{\mathscr{F}} = r - 1$. We call these *del Pezzo* foliations.

Definition 2.5. Let $\mathscr{F}$ be a foliation on a normal variety X. We say that $\mathscr{F}$ is *algebraically integrable* if it is induced by a dominant rational map $\varphi\colon X \dashrightarrow Y$ with connected fibers into a normal variety. This means that, over the smooth locus $X^\circ \subset X$ of φ, we have $\mathscr{F}_{|X^\circ} = T_{X^\circ/Y}$.

In the setting of Definition 2.5, the general leaf of $\mathscr{F}$ is a general fiber of $\varphi_{|X^\circ}\colon X^\circ \dashrightarrow Y$. The map $\varphi\colon X \dashrightarrow Y$ is unique up to birational equivalence. It is often useful to take the variety Y to be the normalization of the unique proper subvariety of the Chow variety of X whose general point parametrizes the closure of a general leaf of $\mathscr{F}$ (viewed as a reduced and irreducible cycle in X). It comes with a universal cycle and induced morphisms:

(2-1)
$$\begin{array}{ccc} Z & \xrightarrow{\ \nu\ } & X \\ {\scriptstyle\pi}\downarrow & \swarrow{\scriptstyle \varphi}\ (\text{dashed}) & \\ Y. & & \end{array}$$

Here Z is normal, $\nu\colon Z \to X$ is birational and, for a general point $y \in Y$, $\nu\big(\pi^{-1}(y)\big) \subset X$ is the closure of a leaf of $\mathscr{F}$. We refer to the diagram (2-1) as the *family of leaves* of $\mathscr{F}$.

In our investigations of $\mathbb{Q}$-Gorenstein algebraically integrable foliations, it proved to be very useful to work with their *log leaves*, rather than with their leaves.

Definition 2.6 (Araujo and Druel [2014, Definition 3.11 and Remark 3.12])**.** Let $\mathscr{F}$ be a $\mathbb{Q}$-Gorenstein algebraically integrable foliation on a normal projective variety X. Let $i: F \to X$ be the normalization of the closure of a general leaf of $\mathscr{F}$. There is a canonically defined effective $\mathbb{Q}$-divisor Δ on F such that $K_F + \Delta \sim_{\mathbb{Q}} i^* K_{\mathscr{F}}$. If $\mathscr{F}$ is Gorenstein, then Δ is integral. The pair (F, Δ) is called a *general log leaf* of $\mathscr{F}$. Consider the family of leaves of $\mathscr{F}$ as in diagram (2-1). If $y \in Y$ is a general point, then $F \cong Z_y = \pi^{-1}(y)$. Over the smooth locus of X, we have $\operatorname{Supp}(\Delta) = \operatorname{Exc}(\nu) \cap Z_y$ under this identification, where $\operatorname{Exc}(\nu)$ denotes the exceptional locus of $\nu: Z \to X$ (Araujo and Druel [2018, Lemma 2.12]). In particular, over the smooth locus of X, $F \setminus \Delta$ is smooth.

For a Cartier divisor L on X, we write $L_{|F}$ for the pullback i^*L of L.

Proposition 2.7 (Araujo and Druel [ibid., Corollary 2.13])**.** *Let X be a smooth projective variety, and $\mathscr{F} \subsetneq T_X$ an algebraically integrable foliation on X, with general log leaf (F, Δ). Suppose that either $\rho(X) = 1$, or $\mathscr{F}$ is a Fano foliation. Then $\Delta \neq 0$.*

The following notion of log canonicity for algebraically integrable foliations is weaker than the notion introduced in Definition 2.3 (see Araujo and Druel [2013, Proposition 3.11]).

Definition 2.8. Let X be a normal projective variety, $\mathscr{F}$ a $\mathbb{Q}$-Gorenstein algebraically integrable foliation on X, and (F, Δ) its general log leaf. We say that $\mathscr{F}$ has *log canonical singularities along a general leaf* if (F, Δ) is log canonical.

The following is a special geometric property of algebraically integrable $\mathbb{Q}$-Fano foliation with log canonical singularities along a general leaf. It implies in particular that there is a common point in the closure of every general leaf.

Proposition 2.9 (Araujo and Druel [2016, Proposition 3.13])**.** *Let $\mathscr{F}$ be an algebraically integrable $\mathbb{Q}$-Fano foliation on a normal projective variety X, having log canonical singularities along a general leaf. Then there is a log canonical center of the general log leaf (F, Δ) whose image in X does not vary with the log leaf.*

Remark 2.10. The log canonicity assumption in Proposition 2.9 is necessary to guarantee the existence of a common point in the closure of a general leaf. For instance, consider the Grassmannian $\mathbb{G}(1, m)$ of lines on $\mathbb{P}^m$ for $m \geqslant 3$, and the rational map $\mathbb{G}(1, m) \dashrightarrow \mathbb{G}(1, m-1)$ induced by the projection $\mathbb{P}^m \dashrightarrow \mathbb{P}^{m-1}$ from a fixed point $P \in \mathbb{P}^m$. It induces a del Pezzo foliation $\mathscr{F}$ of rank 2 on $\mathbb{G}(1, m)$ whose general log leaf (F, Δ) is isomorphic to $(\mathbb{P}^2, 2\ell)$, where ℓ is a line in $\mathbb{P}^2$ (see Araujo and Druel [2013, Example 4.3]). More precisely, F is the $\mathbb{P}^2$ of lines contained in a plane $\Pi \cong \mathbb{P}^2$ of $\mathbb{P}^m$ that contains P, and ℓ is the line consisting of lines on Π through P. This log leaf is not log canonical, and there is no common point in the closure of a general leaf. Also, Araujo and Druel [ibid., Construction 9.10] produces del Pezzo foliations on projective space bundles over positive dimensional smooth projective varieties, which are contained in the relative tangent bundle of the fibration. Clearly there is no common point in the closure of a general leaf. The general log leaf in this case is isomorphic to a cone over $(C, 2P)$, where C is a rational normal curve and $P \in C$ is a point. Again, it is not log canonical.

It is useful to have effective algebraic integrability criteria for foliations. We recall Bogomolov and McQuillan's criterion (see also Bost [2001] and Kebekus, Solá Conde, and Toma [2007]).

Theorem 2.11 (F. Bogomolov and McQuillan [2016, Theorem 0.1])**.** *Let X be a normal projective variety, and $\mathcal{F}$ a foliation on X. Let $C \subset X$ be a complete curve disjoint from the singular loci of X and $\mathcal{F}$. Suppose that the restriction $\mathcal{F}_{|C}$ is an ample vector bundle on C. Then the leaf of $\mathcal{F}$ through any point of C is an algebraic variety, and the leaf of $\mathcal{F}$ through a general point of C is moreover rationally connected.*

This criterion can be applied to describe special properties of $\mathbb{Q}$-Fano foliations. Let X be a normal projective variety and $\mathcal{A}$ any ample line bundle on X. Consider the usual notions of slope and semi-stability with respect to $\mathcal{A}$ for torsion-free sheaves on X. Given a $\mathbb{Q}$-Fano foliation $\mathcal{F}$ of rank r on X, we have $\mu_{\mathcal{A}}(\mathcal{F}) = \frac{-K_{\mathcal{F}} \cdot \mathcal{A}^{n-1}}{r} > 0$. Let

$$0 = \mathcal{F}_0 \subset \mathcal{F}_1 \subset \cdots \subset \mathcal{F}_k = \mathcal{F} \tag{2-2}$$

be the Harder–Narasimhan filtration of $\mathcal{F}$ with respect to $\mathcal{A}$, with quotients $\mathcal{Q}_i = \mathcal{E}_i/\mathcal{E}_{i-1}$ satisfying $\mu_{\mathcal{A}}(\mathcal{Q}_1) > \mu_{\mathcal{A}}(\mathcal{Q}_2) > \ldots > \mu_{\mathcal{A}}(\mathcal{Q}_k)$. By the Mehta–Ramanathan Theorem, the Harder–Narasimhan filtration of $\mathcal{F}$ with respect to $\mathcal{A}$ commutes with restriction to a general complete intersection curve C. This generality conditions means that $C = H_1 \cap \cdots \cap H_{\dim(X)-1}$, where the H_i's are general members of linear systems $|m_i \mathcal{A}|$ for $m_i \in \mathbb{N}$ sufficiently large. It implies that each $\mathcal{F}_i$ is locally free along C. Set $s = \max\{i \geqslant 1 \mid \mu_{\mathcal{A}}(\mathcal{F}_i/\mathcal{F}_{i-1}) > 0\} \geqslant 1$. From the properties of the Harder–Narasimhan filtrations, it follows that $\mathcal{F}_i \subset T_X$ is a foliation for $1 \leqslant i \leqslant s$. From the slope conditions and properties of vector bundles on smooth curves (Hartshorne [1971, Theorem 2.4]), it follows that each restriction $(\mathcal{F}_i)_{|C}$ is ample. By Theorem 2.11, for $1 \leqslant i \leqslant s$, $\mathcal{F}_i \subset T_X$ is an algebraically integrable foliation, and the closure of a general leaf is rationally connected. This gives the following property of $\mathbb{Q}$-Fano foliations.

Corollary 2.12. *Let $\mathcal{F}$ be a $\mathbb{Q}$-Fano foliation on a normal projective variety X. Then $\mathcal{F}$ contains an algebraically integrable subfoliation whose general leaves are rationally connected.*

Remark 2.13. Let X be a Fano manifold with $\rho(X) = 1$ and consider the Harder–Narasimhan filtration of the tangent bundle T_X as in (2-2). Since $\rho(X) = 1$, any ample line bundle $\mathcal{A}$ gives the same notion of stability. A conjecture due to Iskovskikh predicts that T_X is (semi-)stable. If T_X is not semi-stable, the first nonzero subsheaf $\mathcal{F}_1$ in its Harder–Narasimhan filtration is called the maximal destabilizing subsheaf of T_X. Arguing as before, we see that $\mathcal{F}_1$ is an algebraically integrable Fano foliation on X. The slope inequality $\mu_{\mathcal{A}}(\mathcal{F}_1) > \mu_{\mathcal{A}}(T_X)$ is equivalent to the index inequality $\frac{\iota_{\mathcal{F}_1}}{\mathrm{rank}(\mathcal{F}_1)} > \frac{\iota_X}{\dim(X)}$. So in order to prove Iskovskikh's conjecture, one must rule out the existence of Fano foliations with large index on X.

More generally, one defines the *algebraic rank* $r^a_{\mathcal{F}}$ of a foliation $\mathcal{F}$ as the maximum dimension of an algebraic subvariety through a general point of X that is everywhere tangent to $\mathcal{F}$. If $\mathcal{F}$ has rank r, then $0 \leqslant r^a_{\mathcal{F}} \leqslant r$, and $r^a_{\mathcal{F}} = r$ if and only if $\mathcal{F}$ is algebraically integrable. When $r^a_{\mathcal{F}} = 0$, we say that the foliation $\mathcal{F}$ is *purely transcendental*. Suppose that $\mathcal{F}$ is not algebraically integrable. Then there exist a normal variety Y, unique up to birational equivalence, a dominant rational map with connected fibers $\varphi\colon X \dashrightarrow Y$, and a purely transcendental foliation $\mathcal{G}$ on Y such that $\mathcal{F}$ is the pullback of $\mathcal{G}$ via φ. This means that $\mathcal{F}_{|X^\circ} = (d\varphi^\circ)^{-1}(\mathcal{G}_{|Y^\circ})$, where $X^\circ \subset X$ and $Y^\circ \subset Y$ are smooth open subsets over which φ restricts to a smooth morphism $\varphi^\circ\colon X^\circ \to Y^\circ$.

We end this section by mentioning an algebraic integrability criterion of Campana and Păun, which generalizes Theorem 2.11. The classical notion of slope-stability with respect to an ample line bundle has been extended to allow stability conditions given by movable curve classes on $\mathbb{Q}$-factorial normal projective varieties (Campana and Peternell [2011], Greb, Kebekus, and Peternell [2016a], Campana and Păun [2015]). In this more general setting, one still has Harder–Narasimhan filtrations as in (2-2), although the analogous of the Mehta–Ramanathan Theorem fails in general. Let $\mathcal{F}$ be a foliation on a $\mathbb{Q}$-factorial normal projective variety X, and suppose that it has positive slope with respect to movable curve class $\alpha \in \mathrm{N}_1(X)_{\mathbb{R}}$. Consider the Harder–Narasimhan filtration of $\mathcal{F}$ with respect to α as in (2-2), and set $s = \max\{i \geqslant 1 \mid \mu_\alpha(\mathcal{F}_i/\mathcal{F}_{i-1}) > 0\} \geqslant 1$. Then the algebraic integrability criterion of Campana and Păun (Campana and Păun [ibid., Theorem 4.2]) implies that, for $1 \leqslant i \leqslant s$, $\mathcal{F}_i \subset T_X$ is an algebraically integrable foliation, and the closure of a general leaf is rationally connected. In particular, if $\mathcal{F}$ is a purely transcendental foliation, then $K_{\mathcal{F}}$ is pseudo-effective.

3 Classification of del Pezzo foliations

In this section we discuss classification results for del Pezzo foliations on projective manifolds.

Definition 3.1. A *del Pezzo foliation* is a Fano foliation $\mathcal{F}$ of rank $r \geqslant 2$ and index $\iota_{\mathcal{F}} = r - 1$.

In the Introduction we described all del Pezzo foliations on projective spaces and quadric hypersurfaces. We have the following classification of codimension 1 del Pezzo foliations on projective manifolds. See Araujo and Druel [2014, Theorem 1.3] for a more general statement.

Theorem 3.2. *Let $\mathcal{F} \subset T_X$ be a codimension 1 del Pezzo foliation on a smooth projective variety X. Then one of the following holds.*

1. *$X \cong \mathbb{P}^n$.*

2. *X is isomorphic to a quadric hypersurface in $\mathbb{P}^{n+1}$.*

3. *There is an inclusion of vector bundles $\mathcal{K} \subset \mathcal{E}$ on $\mathbb{P}^1$, inducing a relative linear projection*

$$\begin{array}{ccc} \mathbb{P}(\mathcal{E}) & \overset{\varphi}{\dashrightarrow} & \mathbb{P}(\mathcal{K}) \,, \\ & \searrow \quad \swarrow_{q} & \\ & \mathbb{P}^1 & \end{array}$$

such that $X \cong \mathbb{P}(\mathcal{E})$ and $\mathcal{F}$ is the pullback via φ of a foliation

$$q^*\Big(\det\big(\mathcal{E}/\mathcal{K}\big)\Big) \hookrightarrow T_{\mathbb{P}(\mathcal{K})} \,.$$

Moreover, one of the following holds.

- $(\mathcal{E}, \mathcal{K}) \cong \big(\mathcal{O}_{\mathbb{P}^1}(2) \oplus \mathcal{O}_{\mathbb{P}^1}(a)^{\oplus 2}, \mathcal{O}_{p^1}(a)^{\oplus 2}\big)$ *for some positive integer a.*
- $(\mathcal{E}, \mathcal{K}) \cong \big(\mathcal{O}_{\mathbb{P}^1}(1)^{\oplus 2} \oplus \mathcal{O}_{\mathbb{P}^1}(a)^{\oplus 2}, \mathcal{O}_{\mathbb{P}^1}(a)^{\oplus 2}\big)$ *for some positive integer a.*
- $(\mathcal{E}, \mathcal{K}) \cong \big(\mathcal{O}_{\mathbb{P}^1}(1) \oplus \mathcal{O}_{\mathbb{P}^1}(a) \oplus \mathcal{O}_{\mathbb{P}^1}(b), \mathcal{O}_{\mathbb{P}^1}(a) \oplus \mathcal{O}_{\mathbb{P}^1}(b)\big)$ *for distinct positive integers a and b.*

Theorem 3.2 is the first instance of classification of del Pezzo foliations, when the ambient space is smooth and the codimension is 1. The classification problem can move in different directions. One may be interested in del Pezzo foliations on mildly singular varieties. In this direction, Araujo and Druel [ibid., Theorem 1.3] allows X to be factorial and canonical. The conclusion is the same as in Theorem 3.2, with the additional possibility of X being a cone over certain surfaces of Picard rank 1. One may be interested in classifying codimension 1 Fano foliations of slightly smaller index. Fano foliations $\mathcal{F}$ of rank $r \geq 3$ and index $\iota_{\mathcal{F}} = r - 2$ are called *Mukai foliations*. In Araujo and Druel [2017], we have classified codimension 1 Mukai foliations on projective manifolds. Finally, one is often interested in del Pezzo foliations of arbitrary rank. For the rest of this paper, we consider del Pezzo foliations of arbitrary rank on projective manifolds. Recall from Theorem 1.4

that, except when the ambient space is $\mathbb{P}^n$, del Pezzo foliations are always algebraically integrable. As a step in the classification problem, we give a classification of all possible general log leaves of del Pezzo foliations.

Proposition 3.3. *Let $\mathscr{F}$ be an algebraically integrable del Pezzo foliation of rank $r \geqslant 2$ on a smooth projective variety X, with general log leaf (F, Δ). Let L be an ample divisor on X such that $-K_{\mathscr{F}} \sim (r-1)L$. Then $\big(F, \Delta, L_{|F}\big)$ satisfies one of the following conditions.*

1. $\big(F, \mathscr{O}_F(\Delta), \mathscr{O}_F(L_{|F})\big) \cong (\mathbb{P}^r, \mathscr{O}_{\mathbb{P}^r}(2), \mathscr{O}_{\mathbb{P}^r}(1))$.
2. *(F, Δ) is a cone over (Q^m, H), where Q^m is a smooth quadric hypersurface in $\mathbb{P}^{m+1}$ for some $2 \leqslant m \leqslant r$, $H \in \big|\mathscr{O}_{Q^m}(1)\big|$, and $L_{|F}$ is a hyperplane under this embedding.*
3. $\big(F, \mathscr{O}_F(\Delta), \mathscr{O}_F(L_{|F})\big) \cong (\mathbb{P}^2, \mathscr{O}_{\mathbb{P}^2}(1), \mathscr{O}_{\mathbb{P}^2}(2))$.
4. *$\big(F, \mathscr{O}_F(L_{|F})\big) \cong (\mathbb{P}_{\mathbb{P}^1}(\mathscr{E}), \mathscr{O}_{\mathbb{P}(\mathscr{E})}(1))$, and one of the following holds:*
   - *(a) $\mathscr{E} = \mathscr{O}_{\mathbb{P}^1}(1) \oplus \mathscr{O}_{\mathbb{P}^1}(d)$ for some $d \geqslant 2$, and $\Delta \sim_{\mathbb{Z}} \sigma + f$, where σ is the minimal section and f a fiber of $\mathbb{P}(\mathscr{E}) \to \mathbb{P}^1$.*
   - *(b) $\mathscr{E} = \mathscr{O}_{\mathbb{P}^1}(2) \oplus \mathscr{O}_{\mathbb{P}^1}(d)$ for some $d \geqslant 2$, and Δ is a minimal section.*
   - *(c) $\mathscr{E} = \mathscr{O}_{\mathbb{P}^1}(1) \oplus \mathscr{O}_{\mathbb{P}^1}(1) \oplus \mathscr{O}_{\mathbb{P}^1}(d)$ for some $d \geqslant 1$, and $\Delta = \mathbb{P}_{\mathbb{P}^1}(\mathscr{O}_{\mathbb{P}^1}(1) \oplus \mathscr{O}_{\mathbb{P}^1}(1))$.*
5. *(F, Δ) is a cone over (C_d, B), where C_d is rational normal curve of degree d in $\mathbb{P}^d$ for some $d \geqslant 2$, $B \in \big|\mathscr{O}_{\mathbb{P}^1}(2)\big|$, and $L_{|F}$ is a hyperplane under this embedding.*
6. *(F, Δ) is a cone over the pair (4a) above, and $L_{|F}$ is a hyperplane section of the cone.*

Proof. By Proposition 2.7, $\Delta \neq 0$, and so $K_F + (r-1)L_{|F} \sim -\Delta$ is not pseudo-effective.

Let $\nu\colon \tilde{F} \to F$ be a resolution of singularities, and set $\tilde{L} = \nu^* L_{|F}$. Then $\tilde{L}$ is nef and big. In the language of Andreatta [2013], $(\tilde{F}, \tilde{L})$ is a quasi-polarized variety. Moreover, $K_{\tilde{F}} + (r-1)\tilde{L}$ is not pseudo-effective. As in the proof of Höring [2014, Lemma 2.5], we run a $(K_{\tilde{F}} + (r-1)\tilde{L})$-MMP, $\varphi : \tilde{F} \dashrightarrow F'$. Since $K_{\tilde{F}} + (r-1)\tilde{L}$ is not pseudo-effective, it ends with a Mori fiber space $F' \to Z$:

$$\begin{array}{ccccc} (\tilde{F}, \tilde{L}) & \dashrightarrow & (F_i, L_i) & \dashrightarrow & (F', L'). \\ \big\downarrow{\scriptstyle \nu} & & & & \\ F & & & & \end{array}$$

By Andreatta [2013, Proposition 3.6], if (F_i, L_i) is an r-dimensional terminal $\mathbb{Q}$-factorial quasi-polarized variety, and $\mathbb{R}_{\geqslant 0}[C]$ is a $(K_{F_i} + (r-1)L_i)$-negative extremal ray of birational type, then $L_i \cdot C = 0$. Therefore, $\varphi : \tilde{F} \dashrightarrow F'$ is an MMP relative to F, and there exists a morphism $\nu' \colon F' \to F$ such that $\nu = \nu' \circ \varphi$. In particular, $L' = (\nu')^* L_{|F}$ is nef and big. Quasi-polarized varieties (F', L') with a Mori fiber space structure induced by a $(K_{F'} + (r-1)L')$-negative extremal ray were classified in Andreatta [ibid., Proposition 3.5]. They are the following:

(a) $(\mathbb{P}^r, \mathcal{O}_{\mathbb{P}^r}(1))$.

(b) $(Q^r, \mathcal{O}_{Q^r}(1))$, where Q^r is a quadric hypersurface in $\mathbb{P}^{r+1}$.

(c) A cone over $(\mathbb{P}^2, \mathcal{O}_{\mathbb{P}^2}(2))$ (where the vertex is allowed to be empty).

(d) $(\mathbb{P}_B(\mathscr{E}), \mathcal{O}_{\mathbb{P}_B(\mathscr{E})}(1))$, where $\mathscr{E}$ is a nef and big vector bundle of rank r over a smooth curve B.

In case (a) we have $F' \cong F$ and $\Delta \in \left|\mathcal{O}_{\mathbb{P}^r}(2)\right|$.

In case (b) we have $F' \cong F$ and $\Delta \in \left|\mathcal{O}_{Q^r}(1)\right|$. Moreover, since $F \setminus \Delta$ is smooth, (F, Δ) is a cone over (Q^m, H), where Q^m is a smooth quadric hypersurface in $\mathbb{P}^{m+1}$ and $H \in \left|\mathcal{O}_{Q^m}(1)\right|$, for some $1 \leqslant m \leqslant r$. When $m = 1$, F is isomorphic to a cone over a conic curve, and this case will be covered under case (d) below.

In case (c), we have $F' \cong F$, (F, Δ) is a cone over the Veronese embedding of $(\mathbb{P}^2, \ell)$ in $\mathbb{P}^5$. Here ℓ is a line in $\mathbb{P}^2$ and thus Δ is a cone over a smooth conic. In particular, (F, Δ) is log canonical and Δ is its only log canonical center. By Proposition 2.9, the image of Δ does not vary with the log leaf. Suppose that the vertex V of (F, Δ) is nonempty. Then the image of V does not vary with the log leaf either. Therefore any point of X can be connected to any point in the image of V in X by a rational curve of L-degree 1. This implies that $X \cong \mathbb{P}^n$. From the classification of del Pezzo foliations on $\mathbb{P}^n$, we see that this is not possible. We conclude that $V = \varnothing$ and $\big(F, \mathcal{O}_F(\Delta), \mathcal{O}_F(L_{|F})\big) \cong (\mathbb{P}^2, \mathcal{O}_{\mathbb{P}^2}(1), \mathcal{O}_{\mathbb{P}^2}(2))$.

We now consider case (d). Denote by g is the genus of B and by f a fiber of the natural morphism $\pi : F' \to B$. Write ξ for a divisor on F' such that $\mathcal{O}_{\mathbb{P}(\mathscr{E})}(1) \cong \mathcal{O}_{F'}(\xi)$, and e for a divisor on B such that $\mathcal{O}_B(e) \cong \det \mathscr{E}$. Then $-K_{F'} = r\xi + \pi^*(-e - K_B)$.

We consider the following possibilities:

(d-1) $F' \cong F$.

(d-2) $\nu' \colon F' \to F$ is the divisorial contraction induced by ξ.

(d-3) $\nu'\colon F' \to F$ is the small contraction induced by ξ.

In case (d-1), since F is rationally connected, we must have $B \cong \mathbb{P}^1$ and $\mathcal{E}$ is an ample vector bundle on $\mathbb{P}^1$. Write

$$\mathcal{E} = \mathcal{O}_{\mathbb{P}^1}(a_1) \oplus \cdots \oplus \mathcal{O}_{\mathbb{P}^1}(a_r),$$

with $1 \leqslant a_1 \leqslant \cdots \leqslant a_r$. We have $0 \neq \Delta \in \left|\xi + (-\sum a_i + 2) f\right|$, and so

$$1 \leqslant h^0\big(\mathbb{P}(\mathcal{E}), \mathcal{O}_{\mathbb{P}(\mathcal{E})}(1) \otimes \pi^*\mathcal{O}_{\mathbb{P}^1}(-\textstyle\sum a_i + 2)\big) = h^0\big(\mathbb{P}^1, \mathcal{E}(-\textstyle\sum a_i + 2)\big).$$

This implies that $(r; a_1, \ldots, a_{r-1}) \in \big\{(2;1), (2;2), (3;1,1)\big\}$. When $\mathcal{E} = \mathcal{O}_{\mathbb{P}^1}(1) \oplus \mathcal{O}_{\mathbb{P}^1}(1)$, F is a smooth quadric surface, and has already been consider. So we have one of the possibilities described in (4).

In case (d-2), F is $\mathbb{Q}$-factorial and $(\nu')^*\Delta \in \left|\mathcal{O}_{\mathbb{P}(\mathcal{E})}(1) \otimes \pi^*(\det \mathcal{E}^\vee \otimes \omega_B^\vee)\right|$, and so

$$1 \leqslant h^0\big(\mathbb{P}(\mathcal{E}), \mathcal{O}_{\mathbb{P}(\mathcal{E})}(1) \otimes \pi^*(\det \mathcal{E}^\vee \otimes \omega_B^\vee)\big) = h^0\big(B, \mathcal{E} \otimes \det \mathcal{E}^\vee \otimes \omega_B^\vee\big).$$

By Hartshorne's theorem (Hartshorne [1971, Theorem 2.4]), $\mathcal{E}$ is nef if and only if it has no quotient with negative slope. So we must have $g \in \{0, 1\}$. Moreover, if $g = 1$, then $\det \mathcal{E}$ is the first nonzero piece of the Harder–Narasimhan filtration of $\mathcal{E}$, and $\mathcal{Q} = \mathcal{E}/\det \mathcal{E}$ is a vector bundle on B. The only member of $\left|\mathcal{O}_{\mathbb{P}(\mathcal{E})}(1) \otimes \pi^*(\det \mathcal{E}^\vee)\right|$ is precisely the projectivization of $\mathcal{Q}$. It is the exceptional divisor of ν', which is impossible. So we conclude that $B \cong \mathbb{P}^1$, F is a cone over a rational normal curve of degree d for some $d \geqslant 1$, and $L_{|F}$ is a hyperplane under this embedding. When $d = 1$, we have $F \cong \mathbb{P}^r$. So we may assume that $d \geqslant 2$. A straightforward computation shows that Δ is linearly equivalent to two times a ruling of the cone.

In case (d-3), $\mathcal{O}_F(L_{|F})$ pulls back to $\mathcal{O}_{\mathbb{P}(\mathcal{E})}(1)$, and Δ is the image under the small contraction of a nonzero effective divisor $\Delta' \in \left|\mathcal{O}_{\mathbb{P}(\mathcal{E})}(1) \otimes \pi^*(\det \mathcal{E}^\vee \otimes \omega_B^\vee)\right|$. As before, $g \in \{0, 1\}$. Moreover, if $g = 1$, then $\det \mathcal{E}$ is the first nonzero piece of the Harder–Narasimhan filtration of $\mathcal{E}$, $\mathcal{Q} = \mathcal{E}/\det \mathcal{E}$ is a vector bundle on B, and $\Delta' \cong \mathbb{P}(\mathcal{Q})$ is the only member of $\left|\mathcal{O}_{\mathbb{P}(\mathcal{E})}(1) \otimes \pi^*(\det \mathcal{E}^\vee)\right|$. In particular, (F, Δ) is log canonical and Δ is its only log canonical center. By Proposition 2.9, the image of Δ does not vary with the log leaf, and so the image of its singular locus V does not vary with the log leaf either. Note that V is the image of the exceptional locus of ν'. Therefore any point of X can be connected to any point of V by a rational curve of L-degree 1, and thus $X \cong \mathbb{P}^n$. From the classification of del Pezzo foliations on $\mathbb{P}^n$, we see that this is not possible. So we conclude that $B \cong \mathbb{P}^1$. As in (d-1), we see that one of the following holds:

- $\mathcal{E} = \mathcal{O}_{\mathbb{P}^1}^{\oplus r-2} \oplus \mathcal{O}_{\mathbb{P}^1}(1) \oplus \mathcal{O}_{\mathbb{P}^1}(d)$ for some $d \geqslant 2$, $r > 2$, and $\Delta' \sim_{\mathbb{Z}} \sigma + f$, where $\sigma = \mathbb{P}_{\mathbb{P}^1}\big(\mathcal{O}_{\mathbb{P}^1}^{\oplus r-2} \oplus \mathcal{O}_{\mathbb{P}^1}(1)\big)$, and f a fiber of $\mathbb{P}_{\mathbb{P}^1}(\mathcal{E}) \to \mathbb{P}^1$.
- $\mathcal{E} = \mathcal{O}_{\mathbb{P}^1}^{\oplus r-2} \oplus \mathcal{O}_{\mathbb{P}^1}(2) \oplus \mathcal{O}_{\mathbb{P}^1}(d)$ for some $d \geqslant 2$, $r > 2$, and $\Delta = \mathbb{P}_{\mathbb{P}^1}\big(\mathcal{O}_{\mathbb{P}^1}^{\oplus r-2} \oplus \mathcal{O}_{\mathbb{P}^1}(2)\big)$.
- $\mathcal{E} = \mathcal{O}_{\mathbb{P}^1}^{\oplus r-3} \oplus \mathcal{O}_{\mathbb{P}^1}(1) \oplus \mathcal{O}_{\mathbb{P}^1}(1) \oplus \mathcal{O}_{\mathbb{P}^1}(d)$ for some $d \geqslant 1$, $r > 3$, and $\Delta = \mathbb{P}_{\mathbb{P}^1}(\mathcal{O}_{\mathbb{P}^1}^{\oplus r-3} \oplus \mathcal{O}_{\mathbb{P}^1}(1) \oplus \mathcal{O}_{\mathbb{P}^1}(1))$.

The first case can also be described as a cone over the pair (4a) above, yielding (6). The latter two cases can be described as cones over the pairs (4b) and (4c) above, respectively. In these cases, (F, Δ) is log canonical and Δ is its only log canonical center. Moreover, Δ is a cone with vertex $V \neq \varnothing$ over a conic and a smooth quadric surface, respectively. By Proposition 2.9, the image of Δ does not vary with the log leaf, and so the image of V does not vary with the log leaf either. Therefore any point of X can be connected to any point in the image of V in X by a rational curve of L-degree 1, and thus $X \cong \mathbb{P}^n$. From the classification of del Pezzo foliations on $\mathbb{P}^n$, we see that this is not possible. □

We do not know examples of del Pezzo foliations with log leaves of type (3) and (6) described in Proposition 3.3. When the general log leaf of $\mathcal{F}$ is log canonical, Proposition 2.9 may be used to recover the ambient space X. For example, consider case (1), when $\big(F, \mathcal{O}_F(\Delta), \mathcal{O}_F(L_{|F})\big) \cong (\mathbb{P}^r, \mathcal{O}_{\mathbb{P}^r}(2), \mathcal{O}_{\mathbb{P}^r}(1))$. If (F, Δ) is log canonical, then Proposition 2.9 yields a common point $x \in X$ in the closure of a general leaf. Therefore any point of X can be connected to x by a rational curve of L-degree 1. This implies that $X \cong \mathbb{P}^n$. On the other hand, there are del Pezzo foliations with general log leaf of type (1) and not log canonical (see Remark 2.10).

We end this paper by reviewing a classification of del Pezzo foliations on projective manifolds under restrictions on the singularities of the foliation $\mathcal{F}$. Namely, we assume that $\mathcal{F}$ has log canonical singularities and is locally free along a general leaf. Recall from Theorem 1.4 that, if $X \ncong \mathbb{P}^n$, then del Pezzo foliations on X are always algebraically integrable. If we remove the log canonicity assumption, we know more examples of del Pezzo foliations, as discussed in Remark 2.10. One may be able to remove the locally freeness assumption using the classification of log leaves in Proposition 3.3.

Theorem 3.4. *[Araujo and Druel [2013, 9.1 and Theorems 1.3, 9.2, 9.6] and Araujo and Druel [2016, Theorem 1.3]] Let $\mathcal{F}$ be an algebraically integrable del Pezzo foliation of rank r on a projective manifold X. Suppose that $\mathcal{F}$ has log canonical singularities and is locally free along a general leaf. Then one of the following holds.*

1. *$r = 2$ and $\rho(X) = 1$.*

2. *$X \cong \mathbb{P}^n$.*

3. *X is isomorphic to a quadric hypersurface in $\mathbb{P}^{n+1}$.*

4. *$X \cong \mathbb{P}^1 \times \mathbb{P}^k$, $r \in \{2,3\}$ and $\mathcal{F}$ is the pullback via the second projection of a foliation on $\mathbb{P}^k$ induced by a linear projection.*

5. *There is an inclusion of vector bundles $\mathcal{K} \subset \mathcal{E}$ on $\mathbb{P}^1$, inducing a relative linear projection*

$$\begin{array}{ccc} \mathbb{P}(\mathcal{E}) & \overset{\varphi}{\dashrightarrow} & \mathbb{P}(\mathcal{K}) \,, \\ & \searrow \quad \swarrow_{q} & \\ & \mathbb{P}^1 & \end{array}$$

such that $X \cong \mathbb{P}(\mathcal{E})$ and $\mathcal{F}$ is the pullback via φ of a foliation

$$q^*\Big(\det\big(\mathcal{E}/\mathcal{K}\big)\Big) \hookrightarrow T_{\mathbb{P}(\mathcal{K})} \,.$$

Moreover, one of the following holds.

- *$(\mathcal{E},\mathcal{K}) \cong \big(\mathcal{O}_{\mathbb{P}^1}(2) \oplus \mathcal{O}_{\mathbb{P}^1}(a)^{\oplus m}, \mathcal{O}_{\mathbb{P}^1}(a)^{\oplus m}\big)$ for some $a \geqslant 1$ and $m \geqslant 2$ ($r = 2$).*
- *$(\mathcal{E},\mathcal{K}) \cong \big(\mathcal{O}_{\mathbb{P}^1}(1)^{\oplus 2} \oplus \mathcal{O}_{\mathbb{P}^1}(a)^{\oplus m}, \mathcal{O}_{\mathbb{P}^1}(a)^{\oplus m}\big)$ for some $a \geqslant 1$ and $m \geqslant 2$ ($r = 3$).*
- *$\mathcal{E} \cong \mathcal{O}_{\mathbb{P}^1}(1) \oplus \mathcal{K}$, where $\mathcal{K}$ is an ample vector bundle not isomorphic to $\mathcal{O}_{\mathbb{P}^1}(a)^{\oplus m}$ for any integer a ($r = 2$).*

6. *There is an inclusion of vector bundles $\mathcal{K} \subset \mathcal{E}$ on $\mathbb{P}^k$, with $k \geqslant 2$ and $\mathcal{E}/\mathcal{K} \cong \mathcal{O}_{\mathbb{P}^k}(1)$, inducing a relative linear projection*

$$\begin{array}{ccc} \mathbb{P}(\mathcal{E}) & \overset{\varphi}{\dashrightarrow} & \mathbb{P}(\mathcal{K}) \,, \\ & \searrow \quad \swarrow_{q} & \\ & \mathbb{P}^k & \end{array}$$

such that $X \cong \mathbb{P}(\mathcal{E})$ and $\mathcal{F}$ is the pullback via φ of a foliation $q^*\mathcal{O}_{\mathbb{P}^k}(1) \hookrightarrow T_{\mathbb{P}(\mathcal{K})}$ ($r = 2$).

BIRATIONAL GEOMETRY OF ALGEBRAIC VARIETIES

CAUCHER BIRKAR

Abstract

This is a report on some of the main developments in birational geometry in recent years focusing on the minimal model program, Fano varieties, singularities and related topics, in characteristic zero.

1 Introduction

It is not a comprehensive survey of all advances in birational geometry, e.g. we will not touch upon the positive characteristic case which is a very active area of research. We will work over an algebraically closed field k of characteristic zero. Varieties are all quasi-projective.

Birational geometry, with the so-called minimal model program at its core, aims to classify algebraic varieties up to birational isomorphism by identifying "nice" elements in each birational class and then classifying such elements, e.g study their moduli spaces. Two varieties are birational if they contain isomorphic open subsets. In dimension one, a nice element in a birational class is simply a smooth and projective element. In higher dimension though there are infinitely many such elements in each class, so picking a representative is a very challenging problem. Before going any further lets introduce the canonical divisor.

1.1 Canonical divisor. To understand a variety X one studies subvarieties and sheaves on it. Subvarieties of codimension one and their linear combinations, that is, divisors play a crucial role. Of particular importance is the canonical divisor K_X. When X is smooth this is the divisor (class) whose associated sheaf $\mathcal{O}_X(K_X)$ is the canonical sheaf $\omega_X := \det \Omega_X$ where Ω_X is the sheaf of regular differential forms. When X is only normal, K_X is the closure of the canonical divisor of the smooth locus. In general, the canonical divisor is the only special non-trivial divisor attached to X. It plays an important

MSC2010: primary 14E30; secondary 14J45, 14B05, 14C20, 14E05, 14E07.

role in algebraic geometry, e.g. in duality theory and Riemann-Roch formula, and also in differential and arithmetic geometry. It is a central object in birational geometry.

Example. Assume $X = \mathbb{P}^d$. Then $K_X \sim -(d+1)H$ where $H \subset \mathbb{P}^d$ is a hyperplane.

Example. Assume $X \subset \mathbb{P}^d$ is a smooth hypersurface of degree r. Then we have $K_X \sim (-d-1+r)H|_X$ where $H \subset \mathbb{P}^d$ is a hyperplane not containing X.

Example. If X is a toric variety, then $K_X \sim -\Lambda$ where Λ is the sum of the torus-invariant divisors.

1.2 Varieties with special canonical divisor. Let X be a projective variety with "good" singularities (by this we mean klt or lc singularities defined below, see Section 2.4).

$$\text{We say } X \text{ is } \begin{cases} \textit{Fano} & \text{if } K_X \text{ is anti-ample} \\ \textit{Calabi-Yau} & \text{if } K_X \text{ is numerically trivial} \\ \textit{canonically polarised} & \text{if } K_X \text{ is ample} \end{cases}$$

Note that here we consider Calabi-Yau varieties in a weak sense, that is, we do not require the vanishing $h^i(X, \mathcal{O}_X) = 0$ for $0 < i < \dim X$ which is usually assumed in other contexts. For example, abelian varieties are Calabi-Yau by our definition.

The special varieties just defined are of great importance in algebraic geometry (e.g. birational geometry, moduli theory, derived categories), differential geometry (e.g. Kähler-Einstien metrics, stability), arithmetic geometry (e.g. existence and density of rational points), and mathematical physics (e.g. string theory and mirror symmetry). They behave much better compared to a randomly chosen variety.

Example. Assume X is a smooth projective curve of genus g. If $g = 0$, then $X \simeq \mathbb{P}^1$ which is Fano. If $g = 1$, then X is an elliptic curve, hence a Calabi-Yau. If $g \geq 2$, then X is canonically polarised.

Example. Assume $X \subset \mathbb{P}^d$ is a smooth hypersurface of degree r. If $r \leq d$, then X is Fano. If $r = d + 1$, then X is Calabi-Yau. If $r > d + 1$, then X is canonically polarised.

1.3 Minimal model program. Now we give a brief description of the minimal model program (MMP). Pick a variety W. Using resolution of singularities we can modify W so that it is smooth and projective. However, being smooth and projective is not very special as in dimension at least two these properties are shared by infinitely many other varieties in the same birational class. It is then natural to look for a more special representative. One of the main aims of birational geometry is to show that we can dismantle W birationally and reconstruct it using canonically polarised, Calabi-Yau, and Fano varieties. To be more precise we want to establish the following conjecture formulated in its simplest form.

Conjecture 1.4 (Minimal model and abundance)**.** *Each variety W is birational to a projective variety Y with "good" singularities such that either*

- *Y is canonically polarised, or*
- *Y admits a Fano fibration, or*
- *Y admits a Calabi-Yau fibration.*

In particular, even if W is smooth, Y may be singular. In fact singularity theory is an indispensable part of modern birational geometry.

As the name suggests the conjecture actually consists of two parts, the *minimal model conjecture* and the *abundance conjecture*. The minimal model conjecture essentially says that we can find Y such that K_Y is *nef* meaning K_Y intersects every curve non-negatively, or else there is a K_Y-negative fibration $Y \to Z$ which means we have a *Fano fibration*. The abundance conjecture essentially says that if Y is not canonically polarised and if it does not admit a Fano fibration, then it admits a K_Y-trivial fibration $Y \to Z$ which means we have a *Calabi-Yau fibration*. The minimal model conjecture holds in dimension ≤ 4 by Mori [1988], Shokurov [1993], Kawamata [1992c], and Shokurov [2003, 2009] in full generality, and in any dimension for varieties of general type by Birkar, Cascini, Hacon, and McKernan [2010] while the abundance conjecture is proved in dimension ≤ 3 by Miyaoka [1988] and Kawamata [1992a], and in any dimension for varieties of general type by Shokurov [1985] and Kawamata [1984] (also see Birkar [2012] and references therein for more results). We should also mention that the *non-vanishing conjecture* which is a special case of (a suitable reformulation of) the abundance conjecture implies the minimal model conjecture by Birkar [2010, 2011].

Given a smooth projective W, how can we get to Y? This is achieved via *running the MMP* which is a step by step program making the canonical divisor K_W more positive by successively removing or replacing curves along which K_W is not positive. It gives a (conjecturally finite) sequence of birational transformations

$$W = W_1 \dashrightarrow W_2 \dashrightarrow \cdots \dashrightarrow W_n = Y$$

consisting of *divisorial contractions*, *flips*, and a last step canonically trivial contraction. The required contractions and flips exist by Shokurov [1985] and Kawamata [1984] and Birkar, Cascini, Hacon, and McKernan [2010] and Hacon and McKernan [2010]. An important ingredient is the *finite generation* of the k-algebra

$$R = \bigoplus_{m \geq 0} H^0(W, mK_W)$$

in its various forms; see Birkar, Cascini, Hacon, and McKernan [2010], Hacon and McKernan [2010], and Shokurov [2003].

A serious issue with the MMP is that we do not know whether it actually stops at some step W_n. What is not clear is if the MMP can produce an infinite sequence of flips. In other words, the minimal model conjecture is reduced to the following.

Conjecture 1.5 (Termination)**.** *There is no infinite sequence of flips.*

The two-dimensional case of the MMP is classical developed in the early 20th century by Castelnuovo, Enriques, etc. The three-dimensional case (in characteristic zero) was developed in the 70's-90's through work of many people notably Iitaka, Iskovskikh, Kawamata, Kollár, Mori, Reid, Shokurov, Ueno, etc. The higher dimensional case is still conjectural but a large portion of it has been established since the turn of the century by many people including Birkar, Cascini, Hacon, M^c^Kernan, Shokurov, Xu, etc, involving many difficult problems of local and global nature.

1.6 Pluricanonical systems, Kodaira dimension and Iitaka fibration. Let W be a smooth projective variety. The space of sections $H^0(W, mK_W)$, for $m \in \mathbb{Z}$, and their associated linear systems $|mK_W|$ are of great importance. When W is one-dimensional the linear system $|K_W|$ determines its geometry to a large extent. Indeed the genus g of W is just $h^0(W, K_W)$ which is encoded in $|K_W|$. Moreover, if $g \geq 2$, then $|K_W|$ is base point free, and if in addition W is not hyperelliptic, then $|K_W|$ defines an embedding of X into a projective space of dimension $g-1$. In higher dimension, however, $|K_W|$ often says little about W. One instead needs to study $|mK_W|$ for all $m \in \mathbb{Z}$ in order to investigate the geometry of W. This leads to the notion of *Kodaira dimension* $\kappa(W)$, an important birational invariant of W. This is defined to be the maximum of the dimension of the images of W under the maps defined by the linear systems $|mK_W|$ for $m > 0$. It takes values in $\{-\infty, 0, 1, \ldots, \dim X\}$ where the case $-\infty$ corresponds to the situation when $h^0(W, mK_W) = 0$ for every $m > 0$.

Assume $\kappa(W) \geq 0$, that is, $h^0(W, mK_W) \neq 0$ for some $m > 0$. When $m > 0$ is sufficiently divisible, $|mK_W|$ defines a rational fibration $W \dashrightarrow X$ which is called the *Iitaka fibration* of W. This is usually defined up to birational equivalence. The dimension of X is simply the Kodaira dimension $\kappa(W)$. It is often possible to translate questions about W to corresponding questions about X. An old problem is the following:

Conjecture 1.7. *Assume $\kappa(W) \geq 0$. Then there exists $m \in \mathbb{N}$ depending only on* $\dim W$ *such that $|mK_W|$ defines the Iitaka fibration.*

If W is of *general type*, i.e. if $\kappa(W) = \dim W$, then the conjecture is already known by Hacon and McKernan [2006] and Takayama [2006] (also see Hacon, McKernan, and Xu [2013, 2014] for more recent and more general results). In this case we can take m such that $|mK_W|$ defines a birational embedding of W into some projective space. Note that W is birational to its canonical model X, by Birkar, Cascini, Hacon, and McKernan [2010], which is a canonically polarised variety and understanding $|mK_W|$ is the same as understanding $|mK_X|$.

Now assume $0 \le \kappa(W) < \dim W$. The most general known result is that the conjecture is true if we have bounds on certain invariants of the general fibres of the Iitaka fibration, by Birkar and Zhang [2016]. This is done by using a canonical bundle formula for the Iitaka fibration and translating the conjecture into a question on the base of the fibration. Very roughly the main result of Birkar and Zhang [ibid.] says that the conjecture holds if one understands the case $\kappa(W) = 0$. Note that in this case, assuming the minimal model and abundance conjectures, W is birational to a Calabi-Yau variety, and understanding $|mK_W|$ is the same as understanding such systems on the Calabi-Yau variety.

Finally, assume $\kappa(W) = \infty$. Then all the linear systems $|mK_W|$, for $m > 0$, are empty. By the minimal model and abundance conjectures, W is birational to a variety Y admitting a Fano fibration $Y \to Z$. The general fibres of this fibration are Fano varieties. It is then natural to focus on Fano varieties F and study the linear systems $|-mK_F|$, for $m > 0$, in detail. There has been extensive studies of these systems, especially in low dimension, but general higher dimensional results are quite recent; see Birkar [2016a,b].

1.8 Fano varieties, and connection with families, singularities, and termination. Let X be a Fano variety. A difficulty with investigating $|-mK_X|$ is that, unlike the case of varieties of general type, these systems can change dramatically if we change X birationally. On the other hand, a standard inductive technique to study $|-mK_X|$ is to use the elements of $|-mK_X|$ (usually with bad singularities) to create a particular kind of covering family of subvarieties of X and then use induction by restricting to members of this family. A difficulty in this approach is that a member of this family is not necessarily Fano, so it is hard to apply induction, again unlike the case of varieties of general type. Despite these difficulties there has been lots of progress in recent years.

In general there is $m \in \mathbb{N}$ depending only on $\dim X$ such that $|-mK_X|$ is non-empty. Moreover, there is an element of $|-mK_X|$ with good singularities by Birkar [2016a, Theorem 1.1]: this is a special case of *boundedness of complements* (see Theorem 3.3 below). In addition if we put a bound on the singularities of X, that is, if X is ϵ-lc where $\epsilon > 0$, then we can choose m so that $|-mK_X|$ defines a birational embedding of X into some projective space by Birkar [ibid., Theorem 1.2] (see Theorem 3.5 below). In fact one can go further in this case and show that we can choose m so that $-mK_X$ is very ample, hence $|-mK_X|$ defines an embedding of X into some projective space, and that the set of such X form a bounded family by Birkar [2016b, Theorem 1.1]: this is the so-called *BAB conjecture* (see Theorem 3.7 below). These results are proved along with various other results and in conjunction with Shokurov's theory of complements. We will give ample explanations in subsequent sections.

So far we have only mentioned *global Fano* varieties but there are other (relative) Fano varieties. Assume X has good singularities, $f: X \to Z$ is a surjective projective morphism, and $-K_X$ is ample over Z. We call X *Fano over* Z. If Z is a point, then X is a usual Fano variety otherwise in general X is not projective. When $\dim X > \dim Z > 0$, then f is a Fano fibration. Such fibrations appear naturally in birational geometry, and in other contexts, e.g. families and moduli of Fano's.

Now assume f is birational. A special case is a *flipping contraction*, one of the corner stones of the MMP. Existence of flips basically means understanding the linear systems $|-mK_X|$ relatively over Z. Another important special case is when f is the identity morphism in which case we are just looking at the germ of a point on a variety, hence we are doing *singularity theory*. Another connection with singularity theory is that of singularities of $\mathbb{R}$-*linear systems* of divisors on varieties, in general, that is the variety may not be Fano and the divisors may not be related to canonical divisors (see Theorem 4.5 below). This is necessary for the proof of BAB. Therefore, studying Fano varieties in the relative setting naturally overlaps with other important topics in birational and algebraic geometry.

There is also connection with the termination conjecture. It is understood that the termination conjecture is about understanding singularities (see Section 6.5). Moreover, understanding singularities is essentially about understanding Fano varieties in the relative birational case. On the other hand, problems about families of Fano varieties fits well in this theory (see Sections 6.1 and 6.7). It is then no surprise that recent advances on Fano varieties described above is expected to have a profound impact on further developments in birational geometry.

2 Preliminaries

In this section we recall some basic notions. We will try to keep technicalities to a minimum throughout the text. Most of what we need can be found in Kollár and Mori [1998] and Birkar, Cascini, Hacon, and McKernan [2010].

2.1 Contractions. A *contraction* is a projective morphism $f: X \to Z$ of varieties such that $f_*\mathcal{O}_X = \mathcal{O}_Z$. In particular, f is surjective with connected fibres.

2.2 Hyperstandard sets. Let $\mathfrak{R}$ be a subset of $[0,1]$. We define

$$\Phi(\mathfrak{R}) = \left\{1 - \frac{r}{m} \mid r \in \mathfrak{R}, m \in \mathbb{N}\right\}$$

to be the set of *hyperstandard multiplicities* associated to $\mathfrak{R}$. We usually assume $0, 1 \in \mathfrak{R}$ without mention, so $\Phi(\mathfrak{R})$ includes $\Phi(\{0, 1\})$.

2.3 Divisors and resolutions. In algebraic geometry Weil divisors usually have integer coefficients. However, in birational geometry it is standard practice to consider $\mathbb{R}$-divisors. An $\mathbb{R}$-divisor on a normal variety X is of the form $M = \sum a_i M_i$ where M_i are distinct prime divisors and $a_i \in \mathbb{R}$. By $\mu_{M_i} M$ we mean the coefficient a_i. We say M is $\mathbb{R}$-Cartier if M can be written as an $\mathbb{R}$-linear combination of (not necessarily prime) Cartier divisors. For two $\mathbb{R}$-divisors M and N, $M \sim_{\mathbb{R}} N$ means $M - N$ is an $\mathbb{R}$-linear combination of principal Cartier divisors (a principal divisor is the divisor of zeros and poles of a rational function).

If X is equipped with a projective morphism $f : X \to Z$, an $\mathbb{R}$-Cartier divisor M is *nef over* Z if $M \cdot C \geq 0$ for every curve C contracted to a point by f. We say M is *ample over* Z if it is a positive $\mathbb{R}$-linear combination of ample Cartier divisors. We say M is *big over* Z if $M \sim_{\mathbb{R}} A + D$ where A is ample over Z and $D \geq 0$.

A *log resolution* $\phi \colon W \to X$ of (X, M) is a projective birational morphism where W is smooth, and the union of the excpetional locus of ϕ and the birational transform of $\operatorname{Supp} M$ has simple normal crossing singularities.

2.4 Pairs. An important feature of modern birational geometry is that the main objects are pairs rather than varieties. Pairs are much better behaved when it comes to induction and passing from a variety to a birational model.

A *pair* (X, B) consists of a normal variety X and an $\mathbb{R}$-divisor $B \geq 0$ such that $K_X + B$ is $\mathbb{R}$-Cartier. If the coefficients of B are ≤ 1, we say B is a *boundary*.

Let $\phi \colon W \to X$ be a log resolution of (X, B). Let

$$K_W + B_W := \phi^*(K_X + B).$$

The *log discrepancy* of a prime divisor D on W with respect to (X, B) is defines as

$$a(D, X, B) := 1 - \mu_D B_W.$$

We say (X, B) is *lc* (resp. *klt*)(resp. ϵ-*lc*) if every coefficient of B_W is ≤ 1 (resp. < 1)(resp. $\leq 1 - \epsilon$). When $B = 0$ we just say X is lc, etc, instead of $(X, 0)$.

A *non-klt place* of (X, B) is a prime divisor D on birational models of X such that $a(D, X, B) \leq 0$. A *non-klt centre* is the image on X of a non-klt place. When (X, B) is lc, a non-klt centre is also called a *lc centre*.

If we remove the condition $B \geq 0$, the above definitions still make sense but we add *sub* to each notion defined, e.g. instead of lc we say sub-lc, etc.

Example. The simplest kind of pair is a *log smooth* one, that is, a pair (X, B) where X is smooth and Supp B has simple normal crossing singularities. In this case (X, B) being lc (resp. klt) means every coefficient of B is ≤ 1 (resp. < 1).

Example. Let X be the cone over a rational curve of degree n (for a more precise definition see the example following Theorem 3.7). Then X is klt. But if X is the cone over an elliptic curve, then X is lc but not klt.

Example. Let X be a klt surface. Let $\phi\colon W \to X$ be the minimal resolution. The exceptional curves are all smooth rational curves and they intersect in a special way. There is a whose classification of the possible configurations (cf. Kollár and Mori [1998, Section 4]). Once we know the configuration and the self-intersections of the exceptional divisors it is a matter of an easy calculation to determine all the log discrepancies.

2.5 Generalised pairs. These pairs appear mainly when one considers the canonical bundle formula of a fibration, e.g. see case (2) of Section 5.1. A generalised pair is roughly speaking a pair together with a birational polarisation, that is, a nef divisor on some birational model. They play an important role in relation with Conjecture 1.7 by Birkar and Zhang [2016] and most of the results of Birkar [2016a,b]. For the sake of simplicity we will try to avoid using these pairs and their subtle properties as much as possible but for convenience here we recall the definition in the projective case only. For detailed studies of generalised pairs see Birkar and Zhang [2016] and Birkar [2016a].

A projective *generalised (polarised) pair* consists of

- a normal projective variety X',
- an $\mathbb{R}$-divisor $B' \geq 0$ on X',
- a projective birational morphism $\phi\colon X \to X'$ from a normal variety, and
- a nef $\mathbb{R}$-Cartier divisor M on X,

such that $K_{X'} + B' + M'$ is $\mathbb{R}$-Cartier, where $M' := \phi_* M$. We usually refer to the pair by saying $(X', B' + M')$ is a projective generalised pair with data $X \xrightarrow{\phi} X'$ and M. However, we want ϕ and M to be birational data, that is, if we replace X with a higher model, e.g. a resolution, and replace M with its pullback, then we assume the new data defines the same generalised pair.

Now we define generalised singularities. Replacing X we can assume ϕ is a log resolution of (X', B'). We can write

$$K_X + B + M = \phi^*(K_{X'} + B' + M')$$

for some uniquely determined B. We say $(X', B' + M')$ is *generalised lc* (resp. *generalised klt*) if every coefficient of B is ≤ 1 (resp. < 1).

Example. Assume $(X', B' + M')$ is a projective generalised pair with data $X \overset{\phi}{\to} X'$ and M, and assume $M = \phi^* M'$. Then $(X', B' + M')$ is generalised lc (resp. generalised klt) iff (X', B') is lc (resp. klt). In other words, in this case M' does not contribute to singularities.

Example. Let $X' = \mathbb{P}^2$, and $\phi\colon X \to X'$ be the blowup of a closed point $x' \in X'$. Assume $H \subset$ is a hyperplane. Let $M = 3\phi^* H - tE$ where E is the exceptional divisor of ϕ and $t \in [0, 3]$ is a real number. Then letting $B' = 0$, $(X', B' + M')$ is a projective generalised pair with data $X \overset{\phi}{\to} X'$ and M. Note that $M' = 0$. Now we can determine B in the formula above. Calculating intersection numbers we find $B = (t-1)E$. Therefore, $(X', B' + M')$ is generalised lc (resp. generalised klt) iff $t \leq 2$ (resp. $t < 2$).

3 Fano varieties

3.1 Facets of Fano varieties. Grothendieck insisted on studying varieties (and schemes) in a relative setting. This philosophy has been very successfully implemented in birational geometry. This is particularly interesting in the case of Fano varieties, or we should say relative Fano varieties.

Let (X, B) be a klt pair and $f\colon X \to Z$ be a surjective projective morphism, and assume $-(K_X + B)$ is ample over Z. We then say (X, B) is *Fano over Z*. This relative notion unifies various classes of objects of central importance. There are three distinct cases.

- *Global case:* this is when Z is just a point, hence (X, B) is a *Fano pair* in the usual sense.
- *Fibration case:* this is when $\dim X > \dim Z > 0$, that is, f is a genuine fibration and its general fibres are global Fano pairs.
- *Birational case:* this is when f is birational. There are several important subcases here. If f is extremal and contracts one divisor, then f is a *divisorial contraction*. If f is extremal and contracts some subvariety but not a divisor, then f is a *flipping contraction*. If f is an isomorphism, then (X, B) is just the germ of a klt singularity.

3.2 Complements and anti-pluri-canonical systems. Assume (X, B) is an lc pair equipped with a projective morphism $X \to Z$. The *theory of complements* is essentially the study of the systems $|-n(K_X+B)|$ where $n \in \mathbb{N}$, in a relative sense over Z. Obviously this is interesting only when some of these systems are not non-empty, e.g. Fano case. The theory was introduced by Shokurov [1993]. The theory was further developed by Shokurov [2000], Y. G. Prokhorov and Shokurov [2001, 2009], and Birkar [2016a,b].

A *strong n-complement* of K_X+B over a point $z \in Z$ is of the form K_X+B^+ where over some neighbourhood of z we have:

- (X, B^+) is lc,
- $n(K_X+B^+) \sim 0$, and
- $B^+ \geq B$.

From the definition we get

$$-n(K_X+B) \sim nB^+ - nB \geq 0$$

over some neighbourhood of z which in particular means the linear system $|-n(K_X+B)|$ is not empty over z, and that it contains a "nice" element. An n-complement (see Birkar [2016a]) is defined similarly but it is more complicated, so for simplicity we avoid using it. However, if $B=0$, a complement and a strong complement are the same thing.

Theorem 3.3 (Birkar [ibid., Theorems 1.7, 1.8, 1.9])**.** *Let d be a natural number and $\mathfrak{R} \subset [0,1]$ be a finite set of rational numbers. Then there exists a natural number n depending only on d and $\mathfrak{R}$ satisfying the following. Assume (X,B) is a pair and $X \to Z$ a contraction such that*

- *(X,B) is lc of dimension d,*
- *the coefficients of B are in $\Phi(\mathfrak{R})$,*
- *X is Fano type over Z, and*
- *$-(K_X+B)$ is nef over Z.*

Then for any point $z \in Z$, there is a strong n-complement K_X+B^+ of K_X+B over z. Moreover, the complement is also an mn-complement for any $m \in \mathbb{N}$.

Here X of *Fano type* over Z means (X,G) is Fano over Z for some G. The theorem was conjectured by Shokurov [2000, Conjecture 1.3], it was proved in dimension 2 by Shokurov [ibid., Theorem 1.4], (see also Y. G. Prokhorov and Shokurov [2009, Corollary 1.8], and Shokurov [1993] for some cases). Y. G. Prokhorov and Shokurov [2001, 2009] proved various inductive statements regarding complements including some unconditional cases in dimension 3.

Example. When $X \to Z$ is toric morphism and $B = 0$ we can take $n = 1$ and B^+ to be the sum of the torus-invariant divisors.

Remark. Assume Z is a point. Assume for simplicity that $B = 0$ and that $-K_X$ is ample, that is, X is a usual Fano variety. When X is a smooth 3-fold, Šokurov [1979] proved that $|-K_X|$ contains a smooth K3 surface. In particular, K_X has a 1-complement. This is probably where the higher dimensional theory of complements originates.

Remark. Assume $X \to Z$ is birational. Assume again for simplicity that $B = 0$ and that $-K_X$ is ample over Z. When $X \to Z$ is a flipping contraction contracting one smooth rational curve only, Mori (cf. Kollár and Mori [1992, Theorem 1.7]) showed that there always exists a 1-complement over each $z \in Z$ but in the analytic sense, i.e. it exists over an analytic neighbourhood of z. This is used in Mori's proof of existence of 3-fold flips, see Mori [1988].

Remark. Assume $X \to Z$ is an isomorphism, so we are looking at the germ of a klt singularity (X, B) around a point $x \in X$. For simplicity again assume $B = 0$. In general the Cartier index of K_X is not bounded even in dimension 2. The point of complement theory in this case is that the n-complement $K_X + B^+$ has Cartier index n which is bounded.

Remark. When X is a 3-fold with terminal singularities, $-K_X$ is ample over Z, and $B = 0$, the *general elephant conjecture* of Reid asks whether a general element of the linear system $|-K_X|$, relatively over Z, has canonical singularities. This is true in various cases, e.g. when X is Gorenstein and Z is a point by Reid [n.d.], or when $X \to Z$ is identity by Reid [1987].

Example. Lets look at the particular case of surfaces in the local case. Assume X is a surface, $X \to Z$ is the identity, and $B = 0$. If $x \in X$ is smooth, then K_X is a 1-complement of itself, that is, we can take $B^+ = 0$. In the singular case, from classification of the possible singularities one gets the following, by Shokurov [2000, p. 5.2.3]:

$$\text{if } x \in X \text{ is a type} \begin{cases} A \text{ singularity, then } K_X \text{ has a 1-complement.} \\ D \text{ singularity, then } K_X \text{ has a 2-complement.} \\ E_6 \text{ singularity, then } K_X \text{ has a 3-complement.} \\ E_7 \text{ singularity, then } K_X \text{ has a 4-complement.} \\ E_8 \text{ singularity, then } K_X \text{ has a 6-complement.} \end{cases}$$

3.4 Effective birationality. Let X be a Fano variety. Theorem 3.3 says that $|-mK_X|$ is non-empty containing a nice element for some $m > 0$ depending only on $\dim X$. If we bound the singularities of X, we then have a much stronger statement.

Theorem 3.5 (Birkar [2016a, Theorem 1.2]). *Let d be a natural number and $\epsilon > 0$ a real number. Then there is a natural number m depending only on d and ϵ such that if X is any ϵ-lc Fano variety of dimension d, then $|-mK_X|$ defines a birational map.*

Note that m indeed depends on d as well as ϵ because the theorem implies the volume $\mathrm{vol}(-K_X)$ is bounded from below by $\frac{1}{m^d}$. Without the ϵ-lc assumption, $\mathrm{vol}(-K_X)$ can get arbitrarily small or large; see Hacon, McKernan, and Xu [2014, Example 2.1.1]. In dimension 2, the theorem is a consequence of BAB proved by V. Alexeev [1994], and in dimension 3, special cases are proved by Jiang [2015] using different methods. Cascini and McKernan have independently proved the theorem for canonical singularities, that is when $\epsilon = 1$, using quite different methods.

It is worth mentioning that the theorem also holds in the relative setting. It follows immediately from the global case stated above.

3.6 Boundedness of Fano varieties: BAB. It is possible to strengthen Theorem 3.5 so that $|-mK_X|$ defines an actual embedding. This follows from the next result.

Theorem 3.7 (Birkar [2016b, Theorem 1.1]). *Let d be a natural number and ϵ a positive real number. Then the projective varieties X such that*

- *(X, B) is ϵ-lc of dimension d for some boundary B, and*
- *$-(K_X + B)$ is nef and big,*

form a bounded family.

This was known as the Borisov-Alexeev-Borisov or BAB conjecture. Various special cases of it was considered by many people. It was known in the following cases (by taking $B = 0$): surfaces by V. Alexeev [1994], toric varieties by A. A. Borisov and L. A. Borisov [1992], Fano 3-folds with terminal singularities and Picard number one by Kawamata [1992b], Fano 3-folds with canonical singularities by Kollár, Miyaoka, Mori, and Takagi [2000], smooth Fano varieties by Kollár, Miyaoka, and Mori [1992], spherical Fano varieties by V. A. Alexeev and Brion [2004], Fano 3-folds with fixed Cartier index of K_X by A. Borisov [2001], and more generally, Fano varieties of given dimension with fixed Cartier index of K_X by Hacon, McKernan, and Xu [2014]; in a given dimension, the Fano varieties X equipped with a boundary Δ such that $K_X + \Delta \equiv 0$, (X, Δ) is ϵ-lc, and such that the coefficients of Δ belong to a DCC set, by Hacon, McKernan, and Xu [ibid.] (also see Hacon and Xu [2015] and Birkar [2016a, Theorem 1.4]).

Example. Now we look at an example of a non-bounded family of singular Fano surfaces. For $n \geq 2$ consider

$$\begin{array}{ccc} E & \subset W_n & \xrightarrow{f} X_n \\ & \downarrow & \\ & \mathbb{P}^1 & \end{array}$$

where X_n is the cone over a rational curve of deg n, f is blowup of the vertex, and E is the exceptional curve. In other words, W_n is the projective bundle of $\mathcal{O}_{\mathbb{P}^1} \oplus \mathcal{O}_{\mathbb{P}^1}(-n)$, E is the section given by the summand $\mathcal{O}_{\mathbb{P}^1}(-n)$, and X_n is obtained from W_n by contracting E. Then an easy calculation, using $E^2 = -n$, shows that

$$K_{W_n} + \frac{n-2}{n} E = f^* K_{X_n},$$

hence X_n is a $\frac{2}{n}$-lc Fano variety with one singular point (the larger is n, the deeper is the singularity). In particular, since the set of numbers $\{\frac{n-2}{n} \mid n \in \mathbb{N}\}$ is not finite, the set $\{X_n \mid n \in \mathbb{N}\}$ is not a bounded family. This example explains the role of the number ϵ in Theorem 3.7.

Example. In this example we sketch the proof of Theorem 3.7 in dimension two following V. Alexeev and Mori [2004]. For simplicity assume $B = 0$ and that $-K_X$ is ample. There is $\Delta \geq 0$ such that (X, Δ) is ϵ-lc and $K_X + \Delta \sim_{\mathbb{R}} 0$. Let $\phi\colon W \to X$ be the minimal resolution and let $K_W + \Delta_W$ be the pullback of $K_X + \Delta$. Since (X, Δ) is klt, the exceptional divisors of ϕ are all smooth rational curves. Moreover, by basic properties of minimal resolutions, $\Delta_W \geq 0$. In particular, (W, Δ_W) is an ϵ-lc pair. Now a simple calculation of intersection numbers shows that $-E^2 \leq l$ for every exceptional curve of ϕ where $l \in \mathbb{N}$ depends only on ϵ. If the number of exceptional curves of ϕ is bounded, then the Cartier index of $-K_X$ is bounded which in turn implies $-nK_X$ is very ample for some bounded n. In particular, this holds if the Picard number of W is bounded from above. If in addition $\mathrm{vol}(-K_X)$ is bounded, then X belongs to a bounded family. Note that $\mathrm{vol}(-K_X) = \mathrm{vol}(-K_W)$.

Running an MMP on K_W we get a morphism $W \to V$ where V is either $\mathbb{P}^2$ or a rational ruled surface (like W_n in the previous example), and the morphism is a sequence of blowups at smooth points. Let Δ_V be the pushdown of Δ_W. Then (V, Δ_V) is ϵ-lc and $K_V + \Delta_V \sim_{\mathbb{R}} 0$. It is easy to show that there are finitely many possibilities for V. In particular, from $\mathrm{vol}(-K_W) \leq \mathrm{vol}(-K_V)$, we deduce that $\mathrm{vol}(-K_X) = \mathrm{vol}(-K_W)$ is bounded from above. Thus it is enough to prove that the number of blowups in $W \to V$ is bounded. This number can be bounded by an elementary analysis of possible intersection numbers in the sequence (see V. Alexeev and Mori [ibid., Section 1] for more details).

3.8 Birational automorphism groups. An interesting consequence of Theorem 3.7 concerns the Jordan property of birational automorphism groups of rationally connected varieties. Y. Prokhorov and C. Shramov [2016, Theorem 1.8] proved the next result assuming Theorem 3.7.

Corollary 3.9 (Birkar [2016b, Corollary 1.3]). *Let d be a natural number. Then there is a natural number h depending only on d satisfying the following. Let X be a rationally connected variety of dimension d over k. Then for any finite subgroup G of the birational automorphism group* $\mathrm{Bir}(X)$*, there is a normal abelian subgroup H of G of index at most h. In particular,* $\mathrm{Bir}(X)$ *is Jordan.*

Here X *rationally connected* means that every two general closed points can be joined by a rational curve. If we take $X = \mathbb{P}^d$ in the corollary, then we deduce that the Cremona group $\mathrm{Cr}_d := \mathrm{Bir}(\mathbb{P}^d)$ is Jordan, answering a question of Serre [2009, p. 6.1].

4 Singularities of linear systems

4.1 Lc thresholds of $\mathbb{R}$-linear systems. Let (X, B) be a pair. The *log canonical threshold* (lc threshold for short) of an $\mathbb{R}$-Cartier $\mathbb{R}$-divisor $L \geq 0$ with respect to (X, B) is defined as

$$\mathrm{lct}(X, B, L) := \sup\{t \mid (X, B + tL) \text{ is lc}\}.$$

It is a way of measuring the singularities of L taking into account the singularities of (X, B) as well.

Now let A be an $\mathbb{R}$-Cartier $\mathbb{R}$-divisor. The $\mathbb{R}$-linear system of A is

$$|A|_{\mathbb{R}} = \{L \geq 0 \mid L \sim_{\mathbb{R}} A\}.$$

We then define the *lc threshold* of $|A|_{\mathbb{R}}$ with respect to (X, B) (also called global lc threshold or α-invariant) as

$$\mathrm{lct}(X, B, |A|_{\mathbb{R}}) := \inf\{\mathrm{lct}(X, B, L) \mid L \in |A|_{\mathbb{R}}\}$$

which coincides with

$$\sup\{t \mid (X, B + tL) \text{ is lc for every } L \in |A|_{\mathbb{R}}\}.$$

This is an asymptotic invariant, so not surprisingly it is hard to compute in specific cases and study in general.

Due to connections with the notion of stability and existence of Kähler-Einstein metrics, lc thresholds of $\mathbb{R}$-linear systems have attracted a lot of attention, particularly, when A is ample. An important special case is when X is Fano and $A = -K_X$ in which case many examples have been calculated, e.g. see Cheltsov and K. A. Shramov [2008].

Example. If $X = \mathbb{P}^d$, $B = 0$, and $A = -K_X$, then

$$\operatorname{lct}(X, B, |A|_{\mathbb{R}}) = \frac{1}{d+1}.$$

On the other hand, if $X \subset \mathbb{P}^d$ is a smooth hypersurface of degree $r \leq d$, $B = 0$, and $A = -K_X$, then

$$\operatorname{lct}(X, B, |A|_{\mathbb{R}}) = \frac{1}{d+1-r}$$

by Cheltsov and K. A. Shramov [ibid., Example 1.3].

Another reason for studying the above threshold is connection with boundedness of Fano varieties. Indeed it plays a central role in the proof of Theorem 3.7.

Theorem 4.2 (Birkar [2016b, Theorem 1.4]). *Let d be a natural number and ϵ a positive real number. Then there is a positive real number t depending only on d, ϵ satisfying the following. Assume*

- *(X, B) is a projective ϵ-lc pair of dimension d, and*
- *$A := -(K_X + B)$ is nef and big.*

Then

$$\operatorname{lct}(X, B, |A|_{\mathbb{R}}) \geq t.$$

This was conjectured by Ambro [2016] who proved it in the toric case. It can be derived from Theorem 3.7 but in reality it is proved before Theorem 3.7 (see next section). Jiang [2015, 2014] proved it in dimension two.

The lc threshold of an $\mathbb{R}$-linear system $|A|_{\mathbb{R}}$ is defined as an infimum of usual lc thresholds. Tian [1990, Question 1] asked whether the infimum is a minimum when $A = -K_X$ and X is Fano. The question was reformulated and generalised to Fano pairs in Cheltsov and K. A. Shramov [2008, Conjecture 1.12]. The next result gives a positive answer when the lc threshold is at most 1.

Theorem 4.3 (Birkar [2016b, Theorem 1.5]). *Let (X, B) be a projective klt pair such that $A := -(K_X + B)$ is nef and big. Assume that* $\operatorname{lct}(X, B, |A|_{\mathbb{R}}) \leq 1$. *Then there is $0 \leq D \sim_{\mathbb{R}} A$ such that*

$$\operatorname{lct}(X, B, |A|_{\mathbb{R}}) = \operatorname{lct}(X, B, D).$$

Moreover, if B is a $\mathbb{Q}$-boundary, then we can choose $D \sim_{\mathbb{Q}} A$, hence in particular, the lc threshold is a rational number.

Shokurov has an unpublished proof of the theorem in dimension two.

4.4 Lc thresholds of $\mathbb{R}$-linear systems with bounded degree. Next we treat lc thresholds associated with divisors on varieties, in a general setting. To obtain any useful result, one needs to impose certain boundedness conditions on the invariants of the divisor and the variety.

Theorem 4.5 (Birkar [2016b, Theorem 1.6]). *Let d, r be natural numbers and ϵ a positive real number. Then there is a positive real number t depending only on d, r, ϵ satisfying the following. Assume*

- *(X, B) is a projective ϵ-lc pair of dimension d,*
- *A is a very ample divisor on X with $A^d \le r$, and*
- *$A - B$ is ample.*

Then

$$\operatorname{lct}(X, B, |A|_{\mathbb{R}}) \ge t.$$

This is one of the main ingredients of the proof of Theorem 4.2 but it is also interesting on its own. We explain briefly some of the assumptions of the theorem. The condition $A^d \le r$ means that X belongs to a bounded family of varieties, actually, if we choose A general in its linear system, then (X, A) belongs to a bounded family of pairs. We can use the divisor A to measure how "large" other divisors are on X. Indeed, the ampleness of $A - B$ roughly speaking says that the "degree" of B is bounded from above, that is,

$$\deg_A B := A^{d-1}B < A^d \le r.$$

Without such boundedness assumptions, one would not find a positive lower bound for the lc threshold as the next example shows.

Example. Assume $(X = \mathbb{P}^2, B)$ is ϵ-lc and $S \subset X$ is a line. Let $L = A = lS$ where $l \in \mathbb{N}$. Then the multiplicity of L at any closed point $x \in L$ is l, hence the lc threshold $\operatorname{lct}(L, X, B) \le \frac{1}{l}$. Thus the larger is l, the smaller is the threshold. Next we illustrate how the threshold depends on the degree of B. Let T be another line and x be the intersection point $S \cap T$. Let $X_1 \to X$ be the blowup at x, and let x_1 be the intersection of the exceptional divisor E_1 and the birational transform $S^\sim$. Let $X_2 \to X_1$ be the blowup at x_1, and let x_2 be the intersection of the new exceptional divisor E_2 and $S^\sim$. At each step we blowup the intersection point of $S^\sim$ and the newest exceptional divisor.

Put $W := X_r$. Then the exceptional locus of $\phi\colon W \to X$ consists of a chain of curves all of which are -2-curves except one which is a -1-curve. Then $-K_W$ is nef over X, in fact, it is semi-ample over X. Thus there is $0 \le B_W \sim_{\mathbb{R}} \alpha\phi^* H - K_W$ for some $\alpha > 0$ such that (W, B_W) is $\frac{1}{2}$-lc and $K_W + B_W \sim_{\mathbb{R}} 0/X$. Now let B be the pushdown of B_W.

Then (X, B) is $\frac{1}{2}$-lc. Now let $L = S + T$. Then the coefficient of E_r in $\phi^* L$ is $r + 1$, hence

$$\operatorname{lct}(L, X, B) = \operatorname{lct}(\phi^* L, W, B_W) \leq \frac{1}{r+1}.$$

Thus there is no lower bound on the lc threshold if r is arbitrarily large. This does not contradict Theorem 4.5 because when $r \gg 0$, the degree $\deg_A B \gg 0$ and $A - B$ cannot be ample (here $A = lS$ with l fixed).

5 Brief sketch of proofs of main results

In this section we sketch some of the ideas of the proofs of Theorem 3.3, Theorem 3.5, Theorem 4.5 and Theorem 3.7. We try to remove technicalities as much as possible but this comes at the expense of being imprecise in various places and not elaborating on many of the new ideas.

5.1 Sketch of proof of boundedness of complements. (Theorem 3.3) For simplicity we look at the global case, that is, when Z is a point. Pick a sufficiently small $\epsilon \in (0, 1)$. Let $Y \to X$ be the birational morphism which extracts all the prime divisors with log discrepancy smaller than ϵ. Let $K_Y + B_Y$ be the pullback of $K_X + B$. Define Θ_Y to be the same as B_Y except that we replace each coefficient in $(1-\epsilon, 1)$ with 1. Run an MMP on $-(K_Y + \Theta_Y)$ and let Y' be the resulting model and $\Theta_{Y'}$ be the pushdown of Θ_Y. We can run such MMP because Y turns out to be of Fano type, so we can run MMP on any divisor on Y.

As a consequence of local and global ACC of Hacon, McKernan, and Xu [2014, Theorems 1.1 and 1.5] (in practice we need their generalisations to generalised pairs, see Birkar and Zhang [2016, Theorems 1.5 and 1.6]), we can show that the MMP does not contract any component of $\lfloor \Theta_Y \rfloor$, $(Y', \Theta_{Y'})$ is lc, and $-(K_{Y'} + \Theta_{Y'})$ is nef. It is enough to construct a bounded complement for $K_{Y'} + \Theta_{Y'}$. Replacing (X, B) with $(Y', \Theta_{Y'})$ and applying further reductions, we can reduce the problem to one of the following cases:

1. B has a component S with coefficient 1 and $-(K_X + B)$ is nef and big, or
2. $K_X + B \equiv 0$ along a fibration $f : X \to T$, or
3. (X, B) is *exceptional*.

Here exceptional means that for any choice of $0 \leq P \sim_{\mathbb{R}} -(K_X + B)$ the pair $(X, B + P)$ is klt. These cases require very different inductive treatment.

Case (1): First apply *divisorial adjunction* to define $K_S + B_S = (K_X + B)|_S$. Further modification of the setting allows us to ensure that S is Fano type. Moreover, the coefficients of B_S happen to be in a set $\Phi(\mathfrak{S})$ for some fixed finite set $\mathfrak{S}$. By induction on dimension $K_S + B_S$ has a strong n-complement for some bounded n. The idea then is to lift the complement to X using vanishing theorems. In the simplest case when (X, B) is log smooth and $B = S$, we look at the exact sequence

$$H^0(-n(K_X + B)) \to H^0(-n(K_X + B)|_S) \to H^1(-n(K_X + B) - S) = 0$$

where the vanishing follows from Kawamata-Viehweg vanishing theorem noting that

$$-n(K_X + B) - S = K_X - n(K_X + B) - (K_X + B) = K_X - (n+1)(K_X + B)$$

Since $K_S + B_S$ has a strong n-complement, the middle space in the above sequence is non-trivial which implies the left hand side is also non-trivial by lifting the section corresponding to the complement. One then argues that the lifted section gives a strong n-complement for $K_X + B$.

Case (2): Apply the *canonical bundle formula* (also called adjunction for fibre spaces, derived from Kawamata [1998]) to write

$$K_X + B \sim_{\mathbb{R}} f^*(K_T + B_T + M_T)$$

where B_T is the *discriminant divisor* and M_T is the *moduli divisor*. It turns out that the coefficients of B_T happen to be in a set $\Phi(\mathfrak{S})$ for some fixed finite set $\mathfrak{S}$, and that pM_T is integral for some bounded number $p \in \mathbb{N}$. Now we want to find a complement for $K_T + B_T + M_T$ and pull it back to X. There is a serious issue here: $(T, B_T + M_T)$ is not a pair in the usual sense but it is a generalised pair. Thus we actually need to prove Theorem 3.3 (at least in the global case) in the more general setting of generalised pairs. This makes life a lot more difficult but fortunately everything turns out to work. Once we have a bounded complement for $K_T + B_T + M_T$ it is straightforward to derive a bounded complement for $K_X + B$.

Case (3): In this case we use effective birationality. Perhaps after decreasing ϵ, the exceptionality condition implies that (X, B) is ϵ-lc. For simplicity assume $B = 0$ and that X is a Fano variety. Also assume we already have Theorem 3.5. Then there is a bounded number $m \in \mathbb{N}$ such that $|-mK_X|$ defines a birational map. Pick $M \in |-mK_X|$ and let $B^+ = \frac{1}{m}M$. Since X is exceptional, (X, B^+) is automatically klt, hence $K_X + B^+$ is a strong m-complement. Although this gives some ideas of how one may get a bounded complement but in practice we cannot give a complete proof of Theorem 3.5 before proving Theorem 3.3. The two theorems are actually proved together. See Birkar [2016a, Sections 6 and 7] for more details.

5.2 Sketch of proof of effective birationality. (Theorem 3.5) Let $m \in \mathbb{N}$ be the smallest number such that $|-mK_X|$ defines a birational map, and let $n \in \mathbb{N}$ be a number such that $\mathrm{vol}(-nK_X) > (2d)^d$. Initially we take n to be the smallest such number but we will modify it during the proof. We want to show that m is bounded from above. The idea is first to show that $\frac{m}{n}$ is bounded from above, and then at the end show that m is bounded.

Applying a standard elementary technique we can create a covering family $\mathcal{G}$ of subvarieties of X such that if $x, y \in X$ are any pair of general closed points, then there is $0 \le \Delta \sim_{\mathbb{Q}} -(n+1)K_X$ and $G \in \mathcal{G}$ such that (X, Δ) is lc at x with the unique non-klt centre G, and (X, Δ) is not klt at y.

Assume $\dim G = 0$ for all G. Then $G = \{x\}$ is an isolated non-klt centre. Using multiplier ideals and vanishing theorems we can lift sections from G and show that $|-nK_X|$ defines a birational map after replacing n with a bounded multiple, hence in particular $\frac{m}{n}$ is bounded from above in this case.

Now lets assume all G have positive dimension. If $\mathrm{vol}(-mK_X|_G)$ is large, then again using some elementary arguments, we can create a new non-klt centre G' containing x but with $\dim G' < \dim G$. Thus we can replace G with G' and apply induction on dimension of G. We can then assume $\mathrm{vol}(-mK_X|_G)$ is bounded from above.

Similar to the previous paragraph, we can cut G and decrease its dimension if $\mathrm{vol}(-nK_X|_G)$ is bounded from below. Showing this lower boundedness is the hard part. A key point here is that although G is not necessarily a divisor and although the singularities of (X, Δ) away from x maybe quite bad but still there is a kind of adjunction formula, that is, if F is the normalisation of G, then we can write

$$(K_X + \Delta)|_F \sim_{\mathbb{R}} K_F + \Theta_F + P_F$$

where Θ_F is a boundary divisor with coefficients in a fixed DCC set Ψ depending only on d, and P_F is pseudo-effective. Replacing n with $2n$ and adding to Δ we can easily make P_F big and effective.

Now we would ideally want to apply induction on d but the difficulty is that F may not be Fano, in fact, it can be any type of variety. Another issue is that the singularities of $(F, \Theta_F + P_F)$ can be pretty bad. To overcome these difficulties we use the fact that $\mathrm{vol}(-mK_X|_G)$ is bounded from above. From this boundedness one can deduce that there is a bounded projective log smooth pair $(\overline{F}, \Sigma_{\overline{F}})$ and a birational map $\overline{F} \dashrightarrow F$ such that $\Sigma_{\overline{F}}$ is reduced containing the exceptional divisor of $\overline{F} \dashrightarrow F$ and the support of the birational transform of Θ_F (and other relevant divisors).

Surprisingly, the worse the singularities of $(F, \Theta_F + P_F)$ the better because we can then produce divisors on $\overline{F}$ with bounded "degree" but with arbitrarily small lc thresholds which would contradict a baby version of Theorem 4.5. Indeed assume $(F, \Theta_F + P_F)$ is not klt. A careful study of the above adjunction formula allows to write $K_F + \Lambda_F := K_X|_F$ where $\Lambda_F \le \Theta_F$ and (F, Λ_F) is sub-ϵ-lc. Put $I_F = \Theta_F + P_F - \Lambda_F$. Then

$$I_F = K_F + \Theta_F + P_F - K_F - \Lambda_F \sim_{\mathbb{R}} (K_X + \Delta)|_F - K_X|_F = \Delta|_F \sim_{\mathbb{R}} -(n+1)K_X|_F.$$

Moreover, $K_F + \Lambda_F + I_F$ is ample.

Let $\phi\colon F' \to F$ and $\psi\colon F' \to \overline{F}$ be a common resolution. Pull back $K_F+\Lambda_F+I_F$ to F' and then push it down to $\overline{F}$ and write it as $K_{\overline{F}}+\Lambda_{\overline{F}}+I_{\overline{F}}$. Then the above ampleness gives

$$\phi^*(K_F+\Lambda_F+I_F) \le \psi^*(K_{\overline{F}}+\Lambda_{\overline{F}}+I_{\overline{F}})$$

which implies that $(\overline{F}, \Lambda_{\overline{F}}+I_{\overline{F}})$ is not sub-klt. From this one deduces that $(\overline{F}, \Gamma_{\overline{F}}+I_{\overline{F}})$ is not klt where $\Gamma_{\overline{F}} = (1-\epsilon)\Sigma_{\overline{F}}$. Finally, one argues that the degree of $I_{\overline{F}}$ gets arbitrarily small if $\mathrm{vol}(-nK_X|_G)$ gets arbitrarily small, and this contradicts an easy case of Theorem 4.5.

If singularities of $(F, \Theta_F + P_F)$ are good, then we again face some serious difficulties. Very roughly, in this case, we lift sections from F to X and use this section to modify Δ so that $(F, \Theta_F + P_F)$ has bad singularities, hence we reduce the problem to the above arguments. This shows $\frac{m}{n}$ is bounded.

Finally, to we still need to bound m. This can be done by arguing that $\mathrm{vol}(-mK_X)$ is bounded from above and use this to show X is birationally bounded, and then work on the bounded model. See Birkar [2016a, Section 4] for more details.

5.3 Sketch of proof of boundedness of lc thresholds. (Theorem 4.5) Pick $0 \le N \sim_{\mathbb{R}} A$. Let s be the largest number such that $(X, B+sN)$ is ϵ'-lc where $\epsilon' = \frac{\epsilon}{2}$. It is enough to show s is bounded from below. There is a prime divisor T on birational models of X with log discrepancy $a(T, X, \Delta) = \epsilon'$ where $\Delta := B + sN$. It is enough to show that the multiplicity of T in ϕ^*N is bounded on some resolution $\phi\colon V \to X$ on which T is a divisor. We can assume the image of T on X is a closed point x otherwise we can cut by hyperplane sections and apply induction on dimension.

There is a birational morphism $Y \to X$ from a normal projective variety which contracts exactly T. A key ingredient here is provided by the theory of complements: using the fact that $-(K_Y+T)$ is ample over X, we can find Λ_Y such that (Y, Λ_Y) is lc near T and $n(K_Y+\Lambda_Y) \sim 0/X$ for some bounded number $n \in \mathbb{N}$. One can think of $K_Y+\Lambda_Y$ as a local-global type of complement. The crucial point is that if Λ is the pushdown of Λ_Y, then we can make sure degree of Λ is bounded from above, that is, after replacing A we can assume $A - \Lambda$ is ample. By construction, the log discrepancy $a(T, X, \Lambda) = 0$ and $(X, \operatorname{Supp}\Lambda)$ is bounded.

Next using resolution of singularities we can modify the setting and then assume that (X, Λ) is log smooth and Λ is reduced. The advantage of having Λ is that now T can be obtained by a sequence of blowups which is toroidal with respect to (X, Λ). That is, in every step we blowup the centre of T which happens to be a stratum of (X, Λ); a stratum is just a component of the intersection of some of the components of Λ. The first step is just the blowup of x. One argues that it is enough to bound the number of these blowups.

By the previous paragraph, we can discard any component of Λ not passing through x, hence assume $\Lambda = S_1 + \cdots + S_d$ where S_i are irreducible components. On the other hand, a careful analysis of $Y \to X$ allows us to further modify the situation so that $\operatorname{Supp} \Delta$ does not contain any stratum of (X, Λ) apart from x. This is one of the difficult steps of the whole proof.

Since (X, Λ) is log smooth and bounded, we can find a surjective finite morphism $X \to \mathbb{P}^d$ which maps x to the origin $z = (0 : \cdots : 0 : 1)$ and maps S_i on H_i where $H_1, \ldots, H_d$ are the coordinate hyperplanes passing through z. Since $\operatorname{Supp} \Delta$ does not contain any stratum of (X, Λ) apart from x, it is not hard to reduce the problem to a similar problem on $\mathbb{P}^d$. From now on we assume $X = \mathbb{P}^d$ and that S_i are the coordinate hyperplanes. The point of this reduction is that now (X, Λ) is not only toroidal but actually toric, and $-(K_X + \Lambda)$ is very ample. In particular, replacing Δ with $t\Delta + (1-t)\Lambda$ for some sufficiently small $t > 0$ (and replacing ϵ' accordingly), we can make $K_X + \Delta$ anti-ample. Next by adding to Δ we can assume $K_X + \Delta$ is numerically trivial.

Let $W \to X$ be the sequence of blowups which obtains T as above. Since the blowups are toric, W is a toric variety. If $Y \to X$ is the birational morphism contracting T only, as before, then Y is also a toric variety. Moreover, if $K_Y + \Delta_Y$ is the pullback of $K_X + \Delta$, then (Y, Δ_Y) is ϵ'-lc and $K_Y + \Delta_Y$ is numerically trivial. Now running MMP on $-K_Y$ and using base point freeness gives another toric variety Y' which is Fano and ϵ'-lc. By the toric version of BAB proved by A. A. Borisov and L. A. Borisov [1992], Y' belongs to a bounded family. From this we can produce a klt strong m-complement $K_{Y'} + \Omega_{Y'}$ for some bounded $m \in \mathbb{N}$ which induces a klt strong m-complement $K_Y + \Omega_Y$ which in turn gives a klt strong m-complement $K_X + \Omega$.

Finally Ω belongs to a bounded family as its coefficients are in a fixed finite set and its degree is bounded. This implies that $(X, \Omega + u\Lambda)$ is klt for some $u > 0$ bounded from below. Now an easy calculation shows that the multiplicity of T in the pullback of Λ on W is bounded from above which in turn implies the number of blowups in $W \to X$ is bounded as required.

5.4 Sketch of proof of BAB. (Theorem 3.7) First applying Hacon and Xu [2015, Theorem 1, 3] it is enough to show that K_X has a klt strong m-complement for some bounded number $m \in \mathbb{N}$. Running an MMP on $-K_X$ and replacing X with the resulting model we can assume $B = 0$. By Theorem 3.3, we know that we have an lc strong n-complement $K_X + B^+$. If X is exceptional, then the complement is klt, so we are done in this case. To treat the general case the idea is to modify the complement $K_X + B^+$ into a klt one. We will do this using birational boundedness.

We need to show $\operatorname{vol}(-K_X)$ is bounded from above. This can be proved using arguments similar to the proof of the effective birationality theorem. Once we have this bound, we can show that (X, B^+) is log birationally bounded, that is, there exist a bounded log smooth projective pair $(\overline{X}, \Sigma_{\overline{X}})$ and a birational map $\overline{X} \dashrightarrow X$ such that $\Sigma_{\overline{X}}$ contains the exceptional divisors of $\overline{X} \dashrightarrow X$ and the support of the birational transform of B^+.

Next we pull back $K_X + B^+$ to a high resolution of X and push it down to $\overline{X}$ and denote it by $K_{\overline{X}} + B^+_{\overline{X}}$. Then $(\overline{X}, B^+_{\overline{X}})$ is sub-lc and $n(K_{\overline{X}} + B^+_{\overline{X}}) \sim 0$. Now support of $B^+_{\overline{X}}$ is contained in $\Sigma_{\overline{X}}$ so we can use the boundedness of $(\overline{X}, \Sigma_{\overline{X}})$ to perturb the coefficients of $B^+_{\overline{X}}$. More precisely, perhaps after replacing n, there is $\Delta_{\overline{X}} \sim_{\mathbb{Q}} B^+_{\overline{X}}$ such that $(\overline{X}, \Delta_{\overline{X}})$ is sub-klt and $n(K_{\overline{X}} + \Delta_{\overline{X}}) \sim 0$. Pulling $K_{\overline{X}} + \Delta_{\overline{X}}$ back to X and denoting it by $K_X + \Delta$ we get a sub-klt (X, Δ) with $n(K_X + \Delta) \sim 0$.

Now a serious issue here is that Δ is not necessarily effective. In fact it is by no means clear that its coefficients are even bounded from below. This is one of the difficult steps of the proof. However, this boundedness follows directly from Theorem 4.2. The rest of the argument which modifies Δ to get a klt complement is an easy application of complement theory.

6 Some related problems and topics

6.1 Fano fibrations. One of the possible outcomes of the MMP is a Mori fibre space which is an extremal contraction $X \to Z$ where K_X is anti-ample over Z. This is a special kind of Fano fibration. Fano fibrations and more generally Fano type fibrations appear naturally in the course of applying induction on uniruled varieties, and in the context of moduli theory.

Suppose now that $f: X \to Z$ is a Mori fibre space where X is a 3-fold with $\mathbb{Q}$-factorial terminal singularities. Mori and Prokhorov proved that if Z is a surface, then Z has canonical singularities by Mori and Y. Prokhorov [2008], and if Z is a curve, then the coefficients of the fibres of f are bounded from above by 6 by Mori and Y. G. Prokhorov [2009].

M^c^Kernan proposed a generalisation of the first part to higher dimension:

Conjecture 6.2. *Assume $d \in \mathbb{N}$ and $\epsilon \in \mathbb{R}^{>0}$. Then there is $\delta \in \mathbb{R}^{>0}$ such that if $f: X \to Z$ is a Mori fibre space where X is ϵ-lc $\mathbb{Q}$-factorial of dimension d, then Z is δ-lc.*

On the other hand, independently, Shokurov proposed a more general problem which generalised both parts of Mori and Prokhorov result.

Conjecture 6.3. *Assume $d \in \mathbb{N}$ and $\epsilon \in \mathbb{R}^{>0}$. Then there is $\delta \in \mathbb{R}^{>0}$ such that if*

- *(X, B) is an ϵ-lc pair of dimension d,*
- *$f: X \to Z$ is a contraction with* $\dim Z > 0$*,*

- $K_X + B \sim_{\mathbb{R}} 0/Z$, *and* $-K_X$ *is big*$/Z$,

then we can write

$$K_X + B \sim_{\mathbb{R}} f^*(K_Z + B_Z + M_Z)$$

such that $(Z, B_Z + M_Z)$ *is* δ*-lc where* B_Z *and* M_Z *are the discriminant and moduli parts of adjunction.*

M^c^Kernan's conjecture is known in the toric case by V. Alexeev and A. Borisov [2014]. Shokurov's conjecture is known when $\dim X - \dim Z \leq 1$ by Birkar [2016c], in particular for surfaces, and open in higher dimension but we have the following general result of Birkar [ibid.].

Theorem 6.4. *Shokurov conjecture holds for those* f *such that* $(F, \operatorname{Supp} B|_F)$ *belongs to a bounded family where* F *is a general fibre of* f.

Note that by BAB (more precisely Birkar [2016b, Corollary 1.2]), F automatically belongs to a bounded family. However, one has little control over $\operatorname{Supp} B|_F$ and this is the main difficulty. This issue is similar to the difficulties which appear in the proof of BAB and related results. It is expected that the methods developed to prove BAB also works to prove Shokurov's conjecture but perhaps after some hard work.

6.5 Minimal log discrepancies and termination. The lc threshold plays an important role in birational geometry. This is clear from the proofs described in Section 5. It is also related to the termination conjecture (1.5) by Birkar [2007]. Another more subtle invariant of singularities is the *minimal log discrepancy* (mld) also defined by Shorkuov. Let (X, B) be a pair. The mld of (X, B) denoted $\operatorname{mld}(X, B)$ is defined to be the minimum of log discrepancies $a(D, X, B)$ where D runs over all prime divisors on birational model of X. The mld is way harder to treat than the lc threshold. Shokurov proposed the following:

Conjecture 6.6 (ACC for mld's). *Assume* $d \in \mathbb{N}$ *and* $\Phi \subset [0, 1]$ *is a set of numbers satisfying the descending chain condition (DCC). Then the set*

$$\{\operatorname{mld}(X, B) \mid (X, B) \text{ is an lc pair and coefficients of } B \text{ are in } \Phi\}$$

satisfies the ascending chain condition (ACC).

This is known for surfaces by V. Alexeev [1993] but open in dimension ≥ 3. Its importance is in relation with the termination conjecture and other topics of interest, see Shokurov [2004] and Birkar and Shokurov [2010]. Shokurov showed that this ACC conjecture together with a semi-continuity conjecture about mld's due to Ambro imply the termination conjecture by Shokurov [2004]. The expectation is that the ACC conjecture can be tackled using the theory of complements and the methods described in this text but again after some hard work.

6.7 Stable Fano varieties. Existence of specific metrics, e.g. Kähler-Einstein metrics, on manifolds is a central topic in differential geometry. Unlike canonically polarised and Calabi-Yau manifolds (see Yau [1978] and references therein), Fano manifolds do not always admit such metrics. It is now an established fact that a Fano manifold admits a Kähler-Einstein metric iff it is so-called *K-polystable* (see Chen, Donaldson, and Sun [2015] and references therein).

On the other hand, it is well-known that Fano varieties do not behave as well as canonically polarised varieties in the context of moduli theory. For example, the moduli space would not be separated. A remedy is to consider only *stable* Fano's. The first step of constructing a moduli space is to prove a suitable boundedness result. In the smooth case this is not an issue by Kollár, Miyaoka, and Mori [1992] but in the singular case boundedness is a recent result. Using methods described in Section 5, Jiang [2017] proved such a result by showing that the set of K-semistable Fano varieties X of fixed dimension and $\mathrm{vol}(-K_X)$ bounded from below forms a bounded family.

6.8 Other topics. There are connections between the advances described in this text and other topics of interest not discussed above. Here we only mention some works very briefly. Lehmann, Tanimoto, and Tschinkel [2014] and Lehmann and Tanimoto [2017] relate boundedness of Fano's and related invariants to the geometry underlying Manin's conjecture on distribution of rational points on Fano varieties. One the other hand, Cerbo and Svaldi [2016] studied boundedness of Calabi-Yau pairs where boundedness of Fano varieties appears naturally.

VARIATIONAL AND NON-ARCHIMEDEAN ASPECTS OF THE YAU–TIAN–DONALDSON CONJECTURE

Sébastien Boucksom

Abstract

We survey some recent developments in the direction of the Yau-Tian-Donaldson conjecture, which relates the existence of constant scalar curvature Kähler metrics to the algebro-geometric notion of K-stability. The emphasis is put on the use of pluripotential theory and the interpretation of K-stability in terms of non-Archimedean geometry.

Contents

Introduction

The search for constant curvature metrics is a recurring theme in geometry, the fundamental uniformization theorem for Riemann surfaces being for instance equivalent to the existence of a (complete) Hermitian metric with constant curvature on any one-dimensional complex manifold. On a higher dimensional complex manifold, *Kähler metrics* are defined as Hermitian metrics locally expressed as the complex Hessian of some (plurisubharmonic) function, known as a *local potential* for the metric. As a result, constant curvature problems for Kähler metrics boil down to scalar PDEs for their potentials, a famous

instance being Kähler metrics with constant Ricci curvature, known as *Kähler-Einstein* metrics, whose local potentials satisfy a complex Monge-Ampère equation. This was in fact a main motivation for the introduction of Kähler metrics in Kähler [1933], where it was also noted that the complex Monge-Ampère equation in question can be written as the Euler-Lagrange equation of a certain functional.

In the present paper, we will more generally consider *constant scalar curvature* Kähler metrics (cscK metrics for short) on a compact complex manifold X. Kähler metrics in a fixed cohomology class of X are parametrized by a space $\mathcal{H}$ of (global) Kähler potentials $u \in C^\infty(X)$, cscK metrics corresponding to solutions in $\mathcal{H}$ of a certain fourth-order nonlinear elliptic PDE. Remarkably, the latter is again the Euler-Lagrange equation of a functional M on $\mathcal{H}$, discovered by T. Mabuchi. While M is generally not convex on $\mathcal{H}$ as an open convex subset of $C^\infty(X)$, Mabuchi defined a natural Riemannian L^2-metric on $\mathcal{H}$ with respect to which M does become convex, opening the way to a variational approach to the cscK problem. The picture was further clarified by S.K. Donaldson, who noted that $\mathcal{H}$ behaves like an infinite dimensional symmetric space and emphasized the analogy with the log norm function in Geometric Invariant Theory.

Using this as a guide, one would like to detect the growth properties of M by looking at its slope at infinity along certain geodesic rays in $\mathcal{H}$ arising from algebro-geometric one-parameter subgroups, and prove that positivity of these slopes ensures the existence of a minimizer, which would then be a cscK metric. This is basically the prediction of the *Yau-Tian-Donaldson conjecture*, positivity of the algebro-geometric slopes at infinity being equivalent to *K-stability*. In the Kähler-Einstein case, this conjecture was famously solved a few years ago by Chen, S. Donaldson, and Sun [2015a,b,c], thereby completing intensive research on positively curved Kähler-Einstein metrics with many key contributions by G.Tian.

The more elementary case of convex functions on (finite dimensional) Riemannian symmetric spaces (see Section 1.3) and experience from the direct method of the calculus of variations suggest to try to attack the general case of the conjecture along the following steps:

1. extend M to a convex functional on a certain metric completion $\bar{\mathcal{H}}$, in which coercivity (i.e. linear growth) implies the existence of a minimizer;

2. prove that a minimizer u of M in $\bar{\mathcal{H}}$ is a weak solution to the cscK PDE in some appropriate sense, and show that ellipticity of this equation implies that u is smooth, hence a cscK potential;

3. show that M is either coercive, or bounded above on some geodesic ray in $\bar{\mathcal{H}}$;

4. approximate any geodesic ray (u_t) in $\bar{\mathcal{H}}$ by algebro-geometric rays $(u_{j,t})$ in $\mathcal{H}$, in such a way that (uniform) positivity of the slopes of M along $(u_{j,t})$ forces $M(u_t) \to +\infty$ at infinity.

As of this writing, (1) and (3) are fully understood, as a combination of Chen [2000b], Darvas [2015], Darvas and Rubinstein [2017], Berman and Berndtsson [2017], Berman, Boucksom, Eyssidieux, Guedj, and Zeriahi [2011], and Berman, Boucksom, and Jonsson [2015]. On the other hand, while (2) and (4) are known in the Kähler-Einstein case Berman, Boucksom, Eyssidieux, Guedj, and Zeriahi [2011] and Berman, Boucksom, and Jonsson [2015], they remain wide open in general[1]. The goal of this text is to survey these developments, as well as the analysis of the algebro-geometric slopes at infinity in terms of non-Archimedean geometry, building on Kontsevich and Tschinkel [2000] and Boucksom, Favre, and Jonsson [2016, 2015]. It is organized as follows:

- Section 1 describes the 'baby case' of convex functions on the space of Hermitian norms of a fixed vector space, introducing alternative Finsler metrics and the space of non-Archimedean norms as the cone at infinity;
- Section 2 recalls the basic formalism of Kähler potentials and energy functionals;
- Section 3 reviews the link between the metric geometry of $\mathcal{H}$ and pluripotential theory, and discusses (1), (2) and (3) above;
- Section 4 introduces the non-Archimedean counterparts to Kähler potentials and the energy functionals, and presents a proof of (4) in the Kähler-Einstein case.

Acknowledgments. My current view of the subject has been framed by collaborations and countless discussions with many mathematicians. Without attempting to be exhaustive, I would like to thank in particular Bo Berndtsson, Jean-Pierre Demailly, Ruadhaí Dervan, Dennis Eriksson, Philippe Eyssidieux, Paul Gauduchon, Henri Guenancia, Tomoyuki Hisamoto, Mihai Păun, Valentino Tosatti and David Witt Nyström, and to express my profound gratitude to Robert Berman, Charles Favre, Vincent Guedj, Mattias Jonsson and Ahmed Zeriahi for the key role their ideas have been playing in our joint works over the years.

1 Convex functions on spaces of norms

The complexification G of any compact Lie group K is a reductive complex algebraic group, giving rise to a Riemannian symmetric space G/K and a conical Tits building.

[1] A proof of (2) has recently been announced by Chen and Cheng [2017, 2018a,b]

The latter can be viewed as the asymptotic cone of G/K, and the growth properties of any convex, Lipschitz continuous function on G/K are encoded in an induced function on the building. While this picture is well-known (see for instance Kapovich, Leeb, and Millson [2009]), it becomes very explicit for the unitary group $U(N)$, for which $G/K \simeq \mathcal{N}$ is the space of Hermitian norms on $\mathbb{C}^N$. The goal of this section is to discuss this case in elementary terms, along with alternative Finsler metrics on $\mathcal{N}$, providing a finite dimensional version of the more sophisticated Kähler geometric setting considered afterwards.

1.1 Finsler geometry on the space of norms. Let V be a complex vector space of finite dimension N, and denote by $\mathcal{N}$ the space of Hermitian norms γ on V, viewed as an open subset of the (N^2-dimensional) real vector space $\mathrm{Herm}(V)$ of Hermitian forms h. The ordered spectrum of $h \in \mathrm{Herm}(V)$ with respect to $\gamma \in \mathcal{N}$ defines a point $\lambda_\gamma(h)$ in the *Weyl chamber*

$$\mathcal{C} = \{\lambda \in \mathbb{R}^N \mid \lambda_1 \geq \cdots \geq \lambda_N\} \simeq \mathbb{R}^N/\mathfrak{S}_N,$$

where the symmetric group $\mathfrak{S}_N$ acts on $\mathbb{R}^N$ by permuting coordinates.

Lemma 1.1. *For each symmetric* (i.e. $\mathfrak{S}_N$*-invariant*) *norm* χ *on* $\mathbb{R}^N$*, we have*

$$\chi\left(\lambda_\gamma(h+h')\right) \leq \chi\left(\lambda_\gamma(h)\right) + \chi\left(\lambda_\gamma(h')\right)$$

for all $\gamma \in \mathcal{N}$ *and* $h, h' \in \mathrm{Herm}(V)$.

Proof. Given $\lambda, \lambda' \in \mathcal{C}$, one says that λ is *majorized by* λ', written $\lambda \preceq \lambda'$, if

$$\lambda_1 + \cdots + \lambda_i \leq \lambda'_1 + \cdots + \lambda'_i$$

for all i, with equality for $i = N$. It is a well-known and simple consequence of the Hahn–Banach theorem that $\lambda \preceq \lambda'$ iff λ is in the convex envelope of the $\mathfrak{S}_N$-orbit of λ', which implies $\chi(\lambda) \leq \chi(\lambda')$ by convexity, homogeneity and $\mathfrak{S}_N$-invariance of χ. The Lemma now follows from the classical Ky Fan inequality $\lambda_\gamma(h+h') \preceq \lambda_\gamma(h) + \lambda_\gamma(h')$. □

Thanks to Lemma 1.1, setting $|h|_{\chi,\gamma} := \chi(\lambda_\gamma(h))$ defines a continuous Finsler norm $|\cdot|_\chi$ on $\mathcal{N}$, and hence a length metric d_χ on $\mathcal{N}$, with $d_\chi(\gamma,\gamma')$ defined as usual as the infimum of the lengths $\int_0^1 |\dot{\gamma}_t|_{\chi,\gamma_t}\,dt$ of all smooth paths $(\gamma_t)_{t\in[0,1]}$ in $\mathcal{N}$ joining γ to γ'. By equivalence of norms in $\mathbb{R}^N$, all metrics d_χ on $\mathcal{N}$ are Lipschitz equivalent.

Example 1.2. *The metric* d_2 *induced by the* ℓ^2*-norm on* $\mathbb{R}^N$ *is the usual Riemannian metric of* $\mathcal{N}$ *identified with the Riemannian symmetric space* $\mathrm{GL}(N,\mathbb{C})/U(N)$*. In particular,* $(\mathcal{N}, d_2)$ *is a complete* $\mathrm{CAT}(0)$*-space, a nonpositive curvature condition implying that any two points of* $\mathcal{N}$ *are joined by a unique (length minimizing) geodesic.*

Example 1.3. *The metric d_∞ induced by the ℓ^∞-norm on $\mathbb{R}^N$ admits a direct description as a sup-norm*

$$d_\infty(\gamma,\gamma') = \sup_{v\in V\setminus\{0\}} \left|\log\gamma(v) - \log\gamma'(v)\right|,$$

whose exponential is the best constant $C > 0$ such that $C^{-1}\gamma \le \gamma' \le C\gamma$ on V.

In order to describe the geometry of $(\mathfrak{N}, d_\chi)$, introduce for each basis $e = (e_1,\dots,e_N)$ of V the embedding

$$\iota_e : \mathbb{R}^N \hookrightarrow \mathfrak{N}$$

that sends $\lambda \in \mathbb{R}^N$ to the Hermitian norm for which e is orthogonal and e_i has norm $e^{-\lambda_i}$. The image $\iota_e(\mathbb{R}^N)$ is thus the set of norms in $\mathfrak{N}$ that are diagonalized in the given basis e. Any two $\gamma,\gamma' \in \mathfrak{N}$ can be jointly diagonalized in some basis e, i.e. $\gamma = \iota_e(\lambda)$, $\gamma' = \iota_e(\lambda')$ with $\lambda,\lambda' \in \mathbb{R}^N$. After permutation, the vector $\lambda'-\lambda$ determines an element $\lambda(\gamma,\gamma') \in \mathfrak{C}$ which only depends on γ,γ', and is obtained by applying $-\log$ to the spectrum of γ' with respect to γ. The following result, proved in Boucksom and Eriksson [2018], generalizes the well-known Riemannian picture for d_2.

Theorem 1.4. *For each symmetric norm χ on $\mathbb{R}^N$, the induced Finsler metric d_χ on $\mathfrak{N}$ is given by $d_\chi(\gamma,\gamma') = \chi(\lambda(\gamma,\gamma'))$ for all $\gamma,\gamma' \in \mathfrak{N}$. It is further characterized as the unique metric on $\mathfrak{N}$ such that $\iota_e : (\mathbb{R}^N,\chi) \hookrightarrow (\mathfrak{N}, d_\chi)$ is an isometric embedding for all bases e.*

1.2 Convergence to non-Archimedean norms. By a *geodesic ray* $(\gamma_t)_{t\in\mathbb{R}_+}$ in $\mathfrak{N}$, we mean a constant speed Riemannian geodesic ray, i.e. $d_2(\gamma_t,\gamma_s)$ is a constant multiple of $|t-s|$. Every geodesic ray is of the form $\gamma_t = \iota_e(t\lambda)$ for some basis e and $\lambda \in \mathbb{R}^N$, the latter being uniquely determined up to permutation as the spectrum of the Hermitian form $\dot\gamma_t$ with respect to γ_t for any value of t. As a result, (γ_t) is also a (constant speed) geodesic ray for all Finsler metrics d_χ, and indeed satisfies $d_\chi(\gamma_t,\gamma_s) = \chi(\lambda)|t-s|$. The metric d_χ might admit other geodesic rays in general, but we will not consider these in what follows.

Two geodesic rays (γ_t), (γ'_t) are called *asymptotic* if γ_t and γ'_t stay at bounded distance with respect to any of the Lipschitz equivalent metrics d_χ, i.e. are uniformly equivalent as norms on V. This defines an equivalence relation on the set of geodesic rays, whose quotient naturally identifies with a space of *non-Archimedean norms*.

To see this, pick a geodesic ray $\gamma_t = \iota_e(t\lambda)$. Then $\gamma_t(v)^2 = \sum_i |v_i|^2 e^{-2\lambda_i t}$ for each vector $v = \sum_i v_i e_i$ in V, from which one easily gets that $\gamma_t(v)^{1/t}$ converges to

$$\alpha\left(\sum_i v_i e_i\right) := \max_{v_i\neq 0} e^{-\lambda_i}. \tag{1-1}$$

as $t \to \infty$. The function $\alpha : V \to \mathbb{R}_+$ so defined satisfies

(i) $\alpha(v + v') \le \max\{\alpha(v), \alpha(v')\}$;

(ii) $\alpha(\tau v) = \alpha(v)$ for all $\tau \in \mathbb{C}^*$;

(iii) $\alpha(v) = 0 \iff v = 0$,

which means that α is an element of the space $\mathfrak{N}^{\mathrm{NA}}$ of non-Archimedean norms on V with respect to the *trivial absolute value* $|\cdot|_0$ on the ground field $\mathbb{C}$, i.e. $|0|_0 = 0$ and $|\tau|_0 = 1$ for $\tau \in \mathbb{C}^*$. The closed balls of such a norm are linear subspaces of V, and the data of α thus amounts to that of an $\mathbb{R}$-filtration of V, or equivalently a flag of linear subspaces together with a tuple of real numbers; for this reason, $\mathfrak{N}^{\mathrm{NA}}$ is also known in the literature as the *(conical) flag complex*. The space $\mathfrak{N}^{\mathrm{NA}}$ has a natural $\mathbb{R}_+^*$-action $(t, \alpha) \mapsto \alpha^t$, whose only fixed point is the *trivial norm* α_0 on V.

The existence of a basis of V compatible with a given flag implies that any non-Archimedean norm $\alpha \in \mathfrak{N}^{\mathrm{NA}}$ can be diagonalized in some basis $e = (e_i)$, in the sense that it satisfies Equation (1-1) for some $\lambda \in \mathbb{R}^N$. The image of λ in $\mathbb{R}^N/\mathfrak{S}_N$ is uniquely determined by α, and a complete invariant for the (non-transitive) action of $G = \mathrm{GL}(V)$ on $\mathfrak{N}^{\mathrm{NA}}$, inducing an identification

$$\mathfrak{N}^{\mathrm{NA}}/G \simeq \mathbb{R}^N/\mathfrak{S}_N.$$

The structure of $\mathfrak{N}^{\mathrm{NA}}$ can be analyzed just as that of $\mathfrak{N}$ by introducing for each basis e the embedding

$$\iota_e^{\mathrm{NA}} : \mathbb{R}^N \hookrightarrow \mathfrak{N}^{\mathrm{NA}}$$

sending $\lambda \in \mathbb{R}^N$ to the non-Archimedean norm (Equation (1-1)). Any two norms can be jointly diagonalized, i.e. belong to the image of ι_e for some e, and it is proved in Boucksom and Eriksson [2018] that there exists a unique metric d_χ^{NA} on $\mathfrak{N}^{\mathrm{NA}}$ for which each $\iota_e^{\mathrm{NA}} : (\mathbb{R}^N, \chi) \to (\mathfrak{N}^{\mathrm{NA}}, d_\chi^{\mathrm{NA}})$ is an isometric embedding. It is worth mentioning that the Lipschitz equivalent metric spaces $(\mathfrak{N}^{\mathrm{NA}}, d_\chi^{\mathrm{NA}})$, while complete, are *not* locally compact as soon as $N > 1$.

Example 1.5. *Every (algebraic)* 1*-parameter subgroup* $\rho : \mathbb{C}^* \to \mathrm{GL}(V)$ *defines a non-Archimedean norm* $\alpha_\rho \in \mathfrak{N}^{\mathrm{NA}}$*, characterized by*

$$\alpha_\rho(v) \le r \iff \lim_{\tau \to 0} \tau^{\lceil \log r \rceil} \rho(\tau) \cdot v \text{ exists in } V.$$

If $e = (e_i)$ *is a basis of eigenvectors for* ρ *with* $\rho(\tau) \cdot e_i = \tau^{\lambda_i} e_i$, $\lambda_i \in \mathbb{Z}$, *then* $\alpha_\rho = \iota_e(\lambda)$. *This shows that the lattice points* $\mathfrak{N}_{\mathbb{Z}}^{\mathrm{NA}}$, i.e. *the images of* $\mathbb{Z}^N$ *by the embeddings* ι_e*, are exactly the norms attached to* 1*-parameter subgroups, and ultimately leads to an identification of* $(\mathfrak{N}^{\mathrm{NA}}, d_2)$ *with the (conical) Tits building of the reductive algebraic group* $\mathrm{GL}(V)$.

Coming back to geodesic rays, one proves that the non-Archimedean norms $\alpha = \lim \gamma_t^{1/t}$, $\alpha' = \lim \gamma_t'^{1/t}$ defined by two rays (γ_t), (γ_t') are equal iff the rays are asymptotic, and that d_χ^{NA} computes the slope at infinity of d_χ, i.e.

$$d_\chi^{\mathrm{NA}}(\alpha, \alpha') = \lim_{t\to\infty} \frac{d_\chi(\gamma_t, \gamma_t')}{t}. \tag{1-2}$$

1.3 Slopes at infinity of a convex function. If $f : \mathbb{R}_+ \to \mathbb{R}$ is convex, $(f(t) - f(0))/t$ is a nondecreasing function of t. The *slope at infinity*

$$f'(\infty) := \lim_{t\to+\infty} \frac{f(t)}{t} \in (-\infty, +\infty]$$

is thus well-defined, and finite if f is Lipschitz continuous. It is characterized as the supremum of all $s \in \mathbb{R}$ such that $f(t) \geq st + O(1)$ on $\mathbb{R}_+$, and f is bounded above iff $f'(\infty) \leq 0$.

A function $F : \mathfrak{N} \to \mathbb{R}$ on the space of Hermitian norms is (geodesically) convex iff $F \circ \iota_e : \mathbb{R}^N \to \mathbb{R}$ is convex for each basis e, and similarly for a function on $\mathfrak{N}^{\mathrm{NA}}$. Assume further that F is Lipschitz. Then $F(\gamma_t)$ is convex and Lipschitz continuous on $\mathbb{R}_+$ for each geodesic ray γ, and the slope at infinity $\lim_{t\to+\infty} F(\gamma_t)/t$ only depends on the equivalence class $\alpha \in \mathfrak{N}^{\mathrm{NA}}$ defined by γ. As a result, F determines a function

$$F^{\mathrm{NA}} : \mathfrak{N}^{\mathrm{NA}} \to \mathbb{R},$$

characterized by $F(\gamma_t)/t \to F^{\mathrm{NA}}(\alpha)$ for each ray (γ_t) asymptotic to $\alpha \in \mathfrak{N}^{\mathrm{NA}}$, and this function is further convex and Lipschitz continuous by Equation (1-2).

Theorem 1.6. *Let $F : \mathfrak{N} \to \mathbb{R}$ be a convex, Lipschitz continuous function, and fix a base point $\gamma_0 \in \mathfrak{N}$ and a symmetric norm χ on $\mathbb{R}^N$. The following are equivalent:*

(i) $F : \mathfrak{N} \to \mathbb{R}$ is an exhaustion function, i.e. *proper and bounded below;*

(ii) F is coercive, i.e. $F(\gamma) \geq \delta\, d_\chi(\gamma, \gamma_0) - C$ *for some constants $\delta, C > 0$;*

(iii) $F^{\mathrm{NA}}(\alpha) > 0$ for all nontrivial $\alpha \in \mathfrak{N}^{\mathrm{NA}}$;

(iv) there exists $\delta > 0$ such that $F^{\mathrm{NA}} \geq \delta\, d_\chi^{\mathrm{NA}}$.

These conditions are further satisfied as soon as F admits a unique minimizer.

Proof. Clearly, (ii) implies (i), and (i) implies that $F(\gamma_t)$ is unbounded for any geodesic ray, hence has a positive slope at infinity, which yields (iii). Let us now prove (iii)$\Longrightarrow$(ii). Assuming by contradiction that there exists a sequence γ_j in $\mathfrak{N}$ such that

$$F(\gamma_j) \leq \delta_j d_\chi(\gamma_j, \gamma_0) - C_j \tag{1-3}$$

with $\delta_j \to 0$ and $C_j \to +\infty$, we are going to construct a non-constant geodesic ray (γ_t) along which F is bounded above, contradicting the positivity of the slope at infinity along this ray. By Lipschitz continuity, Equation (1-3) implies $T_j := d_\chi(\gamma_j, \gamma_0) \to \infty$. For each j, let $(\gamma_{j,t})_{t\in[0,T_j]}$ be the geodesic segment joining γ_0 to γ_j, parametrized so that $t = d_\chi(\gamma_{j,t}, \gamma_0)$. By Ascoli's theorem, $(\gamma_{j,t})$ converges to a geodesic ray (γ_t), uniformly on compact sets of $\mathbb{R}_+$. By convexity of F, we have

$$\frac{F(\gamma_{j,t}) - F(\gamma_0)}{t} \leq \frac{F(\gamma_j) - F(\gamma_0)}{T_j},$$

hence $F(\gamma_{j,t}) \leq \delta_j t + F(\gamma_0)$, which yields in the limit the upper bound $F(\gamma_t) \leq F(\gamma_0)$. At this point, we have thus shown that (i), (ii) and (iii) are equivalent. That (ii)$\Longrightarrow$(iv) follows from Equation (1-2), while (iv) clearly implies (iii).

Assume finally that F admits a unique minimizer, which we may take as the base point γ_0. If F is not coercive, the previous argument yields a nonconstant ray (γ_t) such that $F(\gamma_t) \leq F(\gamma_0) = \inf F$, which shows that all γ_t are mininizers of F, and hence $\gamma_t = \gamma_0$ by uniqueness, a contradiction. □

2 The constant scalar curvature problem for Kähler metrics

This section recalls the basic formalism of constant curvature Kähler metrics, and introduces the corresponding energy functionals.

2.1 Kähler metrics with constant curvature. Let X be a compact complex manifold, and denote by n its (complex) dimension. The data of a Hermitian metric on the tangent bundle T_X is equivalent to that of a positive $(1,1)$-form ω, locally expressed in holomorphic coordinates (z_j) as $\omega = \sqrt{-1}\sum_{ij} \omega_{ij}\, dz_i \wedge d\bar{z}_j$ with (ω_{ij}) a smooth family of positive definite Hermitian matrices. One says that ω is *Kähler* if it satisfies the following equivalent conditions:

(i) $d\omega = 0$;

(ii) ω admits local potentials, i.e. smooth real valued valued functions u such that $\omega = \sqrt{-1}\partial\bar{\partial}u$, or $\omega_{ij} = \partial^2 u/\partial z_i \partial \bar{z}_j$ in local coordinates;

(iii) the Levi-Civita connection ∇ of ω on the tangent bundle T_X coincides with the Chern connection, i.e. the unique Hermitian connection with $\nabla^{0,1} = \bar{\partial}$.

The Kähler condition thus ensures compatibility between Riemannian and complex Hermitian geometry. The (normalized) curvature tensor $\Theta_\omega(T_X) := \frac{\sqrt{-1}}{2\pi}\nabla^2$ of a Kähler metric is a $(1,1)$-form with values in the Hermitian endomorphisms of T_X, whose trace with respect to T_X coincides with the *Ricci curvature* $\mathrm{Ric}(\omega)$ in the sense of Riemannian geometry. In other words, the Ricci tensor of a Kähler metric can be seen as the curvature of the induced metric on the dual of the *canonical bundle* $K_X := \det T_X^\star$, the factor 2π being included in the curvature so that the de Rham cohomology class of the closed $(1,1)$-form $\mathrm{Ric}(\omega)$ coincides with the first Chern class

$$c_1(X) := c_1(T_X) = -c_1(K_X).$$

In terms of the normalized operator $\mathrm{dd^c} := \frac{\sqrt{-1}}{2\pi}\partial\bar\partial$ and a local function u with $\omega = \mathrm{dd^c}\, u$, we have

$$\mathrm{Ric}(\omega) = -\,\mathrm{dd^c} \log\det\left(\frac{\partial^2 u}{\partial z_j \partial \bar z_k}\right),$$

which accounts for the ubiquity of the *complex Monge-Ampère operator* $u \mapsto \det\left(\partial^2 u/\partial z_j \partial \bar z_k\right)$ in Kähler geometry. Taking the trace of $\mathrm{Ric}(\omega)$ with respect to ω yields the *scalar curvature*

$$S(\omega) = n\frac{\mathrm{Ric}(\omega)\wedge\omega^{n-1}}{\omega^n} = \Delta \log\det\left(\frac{\partial^2 u}{\partial z_j \partial \bar z_k}\right).$$

Denote by $V := \int_X \omega^n = [\omega]^n$ the volume of ω, and observe that the mean value of $S(\omega)$ is the cohomological constant

$$V^{-1}\int_X S(\omega)\omega^n = nV^{-1}\int_X \mathrm{Ric}(\omega)\wedge\omega^{n-1} = -n\lambda$$

with

$$\lambda := V^{-1}\left(c_1(K_X)\cdot[\omega]^{n-1}\right).$$

As a result, there exists a unique function $\rho \in C^\infty(X)$, the *Ricci potential* of ω, such that

$$\begin{cases} \Delta\rho = S(\omega) + n\lambda \\ \int_X e^\rho \omega^n = 1. \end{cases}$$

This defines a smooth, positive probability measure $\mu_0 := e^\rho\omega^n$ which we call the *Ricci normalized volume form of* ω.

To the above three notions of curvature correspond the following three versions of the constant curvature problem.

(a) Requiring the full curvature tensor of ω to be constant, i.e.

$$\Theta_\omega(T_X) = -\frac{\lambda}{n}\omega\otimes \mathrm{id}_{T_X},$$

is a very strong condition which implies uniformization, in the sense that (X, ω) must be isomorphic (after scaling the metric) to the complex projective space ($\lambda < 0$), a finite quotient of a compact complex torus ($\lambda = 0$), or a cocompact quotient of the complex hyperbolic ball ($\lambda > 0$).

(b) A *Kähler-Einstein metric* (KE for short) is a Kähler metric ω of constant Ricci curvature, i.e. satisfying $\mathrm{Ric}(\omega) = -\lambda\omega$, the Kähler analogue of the Einstein equation. Passing to cohomology classes yields the necessary proportionality condition

$$c_1(K_X) = \lambda[\omega] \tag{2-1}$$

in $H^2(X, \mathbb{R})$, which implies that the canonical bundle has a sign: X is either *canonically polarized* ($\lambda > 0$), *Calabi-Yau* ($\lambda = 0$) or *Fano* ($\lambda < 0$).

(c) Finally, a *constant scalar curvature Kähler metric* (cscK for short) is a Kähler metric ω with $S(\omega)$ constant, i.e. $S(\omega) = -n\lambda$. Here the sign of λ only gives very weak information on the positivity properties of K_X. Note that $S(\omega)$ is constant iff the Ricci potential ρ is harmonic, hence constant by compactness of X.

While a KE metric ω is trivially cscK, it is remarkable that the converse is also true as soon as the (necessary) cohomological proportionality condition holds, the reason being

$$(2\text{-}1) \Longrightarrow \mathrm{Ric}(\omega) = -\lambda\omega + dd^c \rho. \tag{2-2}$$

This follows indeed from the $\partial\bar\partial$-lemma, which states that an exact (p, q)-form on a compact Kähler manifold is $\partial\bar\partial$-exact, hence Equation (2-1) $\Longleftrightarrow$ $\mathrm{Ric}(\omega) = -\lambda\omega + dd^c f$ for some $f \in C^\infty(X)$. Taking the trace with respect to ω shows that $f - \rho$ is harmonic, hence constant, proving Equation (2-2).

Thanks to the same $\partial\bar\partial$-lemma, one can introduce *global* potentials for Kähler metrics in a fixed cohomology class. More precisely, given a Kähler form ω, any other Kähler form in the cohomology class of ω is of the form $\omega_u := \omega + dd^c u$ with u a *Kähler potential*, i.e. an element of the open, convex set of smooth functions

$$\mathcal{H} := \{u \in C^\infty(X) \mid \omega_u > 0\}.$$

Assuming Equation (2-1), and hence $\mathrm{Ric}(\omega) = -\lambda\omega + dd^c \rho$, a simple computation yields

$$\mathrm{Ric}(\omega_u) + \lambda\omega_u = dd^c \log\left(\frac{e^{\lambda u}\mu_0}{\omega_u^n}\right),$$

and ω_u is thus Kähler-Einstein iff u satisfies the complex Monge-Ampère equation

$$\mathrm{MA}(u) := V^{-1}\omega_u^n = c\, e^{\lambda u}\mu_0 \tag{2-3}$$

where $c > 0$ is a normalizing constant ensuring that the right-hand side is a probability measure.

2.2 Energy functionals. A fundamental feature of the cscK problem, discovered by Mabuchi [1986], is that the corresponding (fourth order) PDE $S(\omega_u) + n\lambda = 0$ for a potential u can be written as the Euler-Lagrange equation of a functional $M : \mathcal{H} \to \mathbb{R}$, the *Mabuchi K-energy functional*. It is characterized by

$$\frac{d}{dt} M(u_t) = -\int_X \dot{u}_t \left(S(\omega_{u_t}) + n\lambda\right) \mathrm{MA}(u_t)$$

for any smooth path (u_t) in $\mathcal{H}$, and normalized by $M(0) = 0$. Note that $M(u)$ is invariant under translation of a constant, hence only depends on the Kähler metric ω_u. The Chen–Tian formula for M Chen [2000a] and Tian [2000] yields a decomposition

$$M = M_{\mathrm{ent}} + M_{\mathrm{pp}},$$

where the *entropy part*

$$M_{\mathrm{ent}}(u) := \int_X \log\left(\frac{\mathrm{MA}(u)}{\mu_0}\right) \mathrm{MA}(u) \in [0, +\infty)$$

is the relative entropy of the probability measure $\mathrm{MA}(u)$ with respect to the Ricci normalized volume form μ_0, and the *pluripotential part* $M_{\mathrm{pp}}(u)$ is a linear combination of terms of the form $\int_X u\, \omega_u^j \wedge \omega^{n-j}$ and $\int_X u\ \mathrm{Ric}(\omega) \wedge \omega_u^j \wedge \omega^{n-j-1}$.

Assume now that the cohomological proportionality condition $c_1(K_X) = \lambda[\omega]$ holds, so that ω_u is cscK iff u satisfies the complex Monge-Ampère Equation (2-3). Besides the K-energy M, another (simpler) functional also has Equation (2-3) as its Euler–Lagrange equation. Indeed, the complex Monge-Ampère operator $\mathrm{MA}(u)$ is the derivative of a functional $E : \mathcal{H} \to \mathbb{R}$, i.e.

$$\frac{d}{dt} E(u_t) = \int_X \dot{u}_t\, \mathrm{MA}(u_t)$$

The functional E, normalized by $E(0) = 0$, is called the *Monge-Ampère energy* (with strong fluctuations in both notation and terminology across the literature), and is explicitly given by

$$E(u) = \frac{1}{n+1} \sum_{j=0}^{n} V^{-1} \int_X u\, \omega_u^j \wedge \omega^{n-j}. \tag{2-4}$$

It follows that ω_u is cscK (equivalently, KE) iff u is a critical point of the *Ding functional* $D : \mathcal{H} \to \mathbb{R}$, defined as $D := L - E$ with

$$L(u) := \begin{cases} \lambda^{-1} \log\left(\int_X e^{\lambda u} \mu_0\right) & \text{if } \lambda \neq 0 \\ \int_X u\, \mu_0 & \text{if } \lambda = 0. \end{cases}$$

Note that $E(u+c) = E(u) + c$ and $L(u+c) = L(u) + c$ for $c \in \mathbb{R}$, so that $D(u)$, just as $M(u)$, is invariant under translation of u by a constant, and hence only depends on the Kähler form ω_u.

3 The variational approach

This section first describes the L^p-geometry of the space of Kähler potentials, with respect to which the K-energy becomes convex. This is used to relate the coercivity of M, its growth along geodesic rays, and the existence of minimizers.

3.1 The Mabuchi L^2-metric and weak geodesics. As we saw above, cscK metrics are characterized as critical points of the K-energy $M : \mathcal{H} \to \mathbb{R}$. In order to set up a variational approach to the cscK problem, an ideal scenario would thus be that M be convex with respect to the linear structure of $\mathcal{H}$ as an open convex subset of the vector space $C^\infty(X)$, which would in particular imply that cscK metrics correspond to minimizers of M.

While convexity in this sense fails in general, Mabuchi realized in Mabuchi [1987] that M does become convex with respect to a more sophisticated notion of geodesics in $\mathcal{H}$. The infinite dimensional manifold $\mathcal{H}$ is indeed endowed with a natural Riemannian metric, defined at $u \in \mathcal{H}$ as the L^2-scalar product with respect to the volume form $\mathrm{MA}(u) = V^{-1}\omega_u^n$. Mabuchi computed the Levi-Civita connection and curvature of this L^2-metric, and proved that the (Riemannian) Hessian of M is everywhere nonnegative, so that M is convex along (smooth) geodesics in $\mathcal{H}$.

The existence of a geodesic joining two given points in $\mathcal{H}$ thus becomes a pressing issue, and new light was shed on this problem in Semmes [1992] and S. K. Donaldson [1999], with the key observation that the equation for geodesics in $\mathcal{H}$ can be rewritten as a complex Monge-Ampère equation. In terms of the one-to-one correspondence between paths $(u_t)_{t\in I}$ of functions on X parametrized by a open interval $I \subset \mathbb{R}$ and S^1-invariant functions U on the product $X \times \mathbb{D}_I$ of X with the annulus

$$\mathbb{D}_I := \{\tau \in \mathbb{C} \mid -\log|\tau| \in I\}$$

given by setting

$$U(x,\tau) = u_{-\log|\tau|}(x), \tag{3-1}$$

a smooth path $(u_t)_{t\in I}$ in $\mathcal{H}$ is a geodesic iff U satisfies the complex Monge-Ampère equation

$$(\omega + dd^c U)^{n+1} = 0. \tag{3-2}$$

Finding a geodesic $(u_t)_{t\in[0,1]}$ joining two given points $u_0, u_1 \in \mathcal{H}$ thus amounts to solving Equation (3-2) with prescribed boundary data. While uniqueness is a simple matter, existence is much more delicate (and turns out to fail in general), as vanishing of the right-hand side makes this nonlinear elliptic equation degenerate. Since the restriction of the $(1,1)$-form $\omega + dd^c U$ to each slice $X \times \{\tau\}$ is required to be positive, Equation (3-2) imposes that $\omega + dd^c U \geq 0$, which means by definition that U is ω-psh (for plurisubharmonic). Thanks to this observation, geodesics can be approached using pluripotential theory.

Denote by $\mathrm{PSH}(X,\omega)$ the space of ω-psh functions on X, i.e. pointwise limits of decreasing sequences in $\mathcal{H}$, by Błocki and Kołodziej [2007]. Following Berndtsson [2015, §2.2], we define a *subgeodesic* in $\mathrm{PSH}(X,\omega)$ as a family $(u_t)_{t\in I}$ of ω-psh functions whose corresponding function U on $X \times \mathbb{D}_I$ is ω-psh, a condition which implies in particular that $u_t(x)$ is a convex function of t. A *weak geodesic* $(u_t)_{t\in I}$ is a subgeodesic which is *maximal*, i.e. for any compact interval $[a,b] \subset I$ and any subgeodesic $(v_t)_{t\in(a,b)}$,

$$\lim_{t\to a} v_t \leq u_a \text{ and } \lim_{t\to b} v_t \leq u_b \Longrightarrow v_t \leq u_t \text{ for } t \in (a,b).$$

Lemma 3.1. *Darvas [2017] Let $(u_t)_{t\in I}$ be a weak geodesic in $\mathrm{PSH}(X,\omega)$, and pick a compact interval $[a,b] \subset I$. If $u_b - u_a$ is bounded above, then $t \mapsto \sup_X(u_t - u_a)$ is affine on $[a,b]$.*

Proof. After reparametrizing, we assume for ease of notation that $a = 0$ and $b = 1$, and set $m := \sup_X(u_1 - u_0)$. For $t \in [0,1]$, the inequality $\sup_X(u_t - u_0) \leq tm$ follows directly from the convexity of $t \mapsto u_t(x)$. Since $v_t(x) := u_1(x) + (t-1)m$ is a subgeodesic with $v_0 \leq u_0$ and $v_1 \leq u_1$, maximality of (u_t) implies $v_t \leq u_t$ for $t \in [0,1]$, and hence

$$tm = \sup_X(u_1 - u_0) + (t-1)m \leq \sup_X(u_t - u_0).$$

□

Given $u_0, u_1 \in \mathrm{PSH}(X,\omega)$, the weak geodesic $(u_t)_{t\in(0,1)}$ joining them is defined as the usc upper envelope of the family of all subgeodesics $(v_t)_{t\in(0,1)}$ such that $\lim_{t\to 0} v_t \leq u_0$, $\lim_{t\to 1} v_t \leq u_1$ (or $u_t \equiv -\infty$ if no such subgeodesic exists). When u_0, u_1 are bounded, the weak geodesic (u_t) is locally bounded, and a 'balayage' argument shows that the corresponding function U is the unique locally bounded solution to Equation (3-2) in the sense of Bedford and Taylor [1976], with the prescribed boundary data. Even for $u_0, u_1 \in \mathcal{H}$, exemples due to Lempert and Vivas [2013] show that the weak geodesic (u_t) joining them is not C^2 in general, but initial work by Chen [2000b], succesively refined in Błocki [2012] and Chu, Tosatti, and Weinkove [2017], eventually established that U is locally $C^{1,1}$.

3.2 L^p-geometry in the space of Kähler potentials. Just as the Riemannian metric on the space of norms $\mathcal{N}$ can be generalized to a Finsler ℓ^p-metric for any $p \in [1, \infty]$ (cf. Section 1.1), it was noticed by T. Darvas that the Mabuchi L^2-metric on $\mathcal{H}$ admits an immediate generalization to an L^p-Finsler metric, by replacing the L^2-norm with the L^p-norm in the above definition. The associated pseudometric d_p on $\mathcal{H}$ is defined by letting $d_p(u, u')$ be the infimum of the L^p-lengths

$$\int_0^1 \|\dot{u}_t\|_{L^p(\mathrm{MA}(u_t))} dt$$

of all smooth paths $(u_t)_{t \in [0,1]}$ in $\mathcal{H}$ joining u to u'. We trivially have $d_p \le d_{p'}$ for $p \le p'$, but the fact that d_p is actually a metric (i.e. separates distinct points) is a nontrivial result in this infinite dimensional setting, proved in Chen [2000b] for $p = 2$ and in Darvas [2015] for d_1, and hence for all d_p.

The space $\mathcal{H}$ is not complete for any of the metrics d_p, and the description of the completion was completely elucidated in Darvas [ibid.] in terms of pluripotential theory, following an earlier attempt by V. Guedj. The class

$$\mathcal{E} \subset \mathrm{PSH}(X, \omega)$$

of ω-psh functions u with *full Monge-Ampère mass*, introduced by Guedj-Zeriahi in Guedj and Zeriahi [2007] (see also Boucksom, Eyssidieux, Guedj, and Zeriahi [2010]), may be described as the largest class of ω-psh functions on which the Monge-Ampère operator $u \mapsto \mathrm{MA}(u)$ is defined and satisfies:

(i) $\mathrm{MA}(u)$ is a probability measure that puts no mass on pluripolar sets, i.e. sets of the form $\{\psi = -\infty\}$ with ψ ω-psh;

(ii) the operator is continuous along decreasing sequences.

For $p \in [1, \infty]$, the class $\mathcal{E}^p \subset \mathcal{E}$ of ω-psh functions with *finite L^p-energy* is defined as the set of $u \in \mathcal{E}$ that are L^p with respect to $\mathrm{MA}(u)$. For domains in $\mathbb{C}^n$, the analogue of $\mathcal{E}^p$ was first introduced by U. Cegrell in his pioneering work Cegrell [1998].

Example 3.2. *If X is a Riemann surface, a function $u \in \mathrm{PSH}(X, \omega)$ belongs to $\mathcal{E}$ iff the measure $\omega + dd^c u$ puts no mass on polar sets, and u is in $\mathcal{E}^1$ iff it satisfies the classical finite energy condition $\int_X du \wedge d^c u < +\infty$, which means that the gradient of u is in L^2.*

The following results are due to T. Darvas.

Theorem 3.3. *Darvas [2015] The metric d_p admits a unique extension to $\mathcal{E}^p$ that is continuous along decreasing sequences, and $(\mathcal{E}^p, d_p)$ is the completion of $(\mathcal{H}, d_p)$. Further:*

(i) $d_p(u, u')$ *is Lipschitz equivalent to* $\|u - u'\|_{L^p(\mathrm{MA}(u))} + \|u - u'\|_{L^p(\mathrm{MA}(u'))}$;

(ii) *the weak geodesic* $(u_t)_{t\in[0,1]}$ *joining any two* $u_0, u_1 \in \mathcal{E}^p$ *is contained in* $\mathcal{E}^p$*, and is a constant speed geodesic in the metric space* $(\mathcal{E}^p, d_p)$*,* i.e. $d_p(u_t, u_{t'}) = c|t - t'|$ *for some constant* c.

3.3 Energy functionals on $\mathcal{E}^1$. The weakest metric d_1 turns out to be the most relevant one for Kähler geometry, due to its close relationship with the Monge-Ampère energy E. By Berman, Boucksom, Guedj, and Zeriahi [2013] and Darvas [2015], mixed Monge-Ampère integrals of the form

$$\int_X u_0\, \omega_{u_1} \wedge \cdots \wedge \omega_{u_n}$$

with $u_i \in \mathcal{E}^1$ are well-defined, and continuous with respect to the u_i in the d_1-topology. In particular, the Monge-Ampère operator is continuous in this topology, and Equation (2-4) yields a continuous extension of E to $\mathcal{E}^1$, which is proved to be convex on subgeodesics, and *affine* on weak geodesics.

Lemma 3.4. *If* $u, u' \in \mathcal{E}^1$ *satisfy* $u \le u'$*, then* $d_1(u, u') = E(u') - E(u)$.

Proof. By monotone regularization, it is enough to prove this for $u, u' \in \mathcal{H}$. The corresponding weak geodesic $(u_t)_{t\in[0,1]}$ is then $C^{1,1}$, and its L^1-length $\int_{t=0}^1 \int_X |\dot{u}_t|\,\mathrm{MA}(u_t)$ computes $d_1(u, u')$. By Lemma 3.1, $u_t(x)$ is a nondecreasing function of t, hence $\dot{u}_t \ge 0$, which yields

$$d_1(u, u') = \int_0^1 dt \int_X \dot{u}_t\,\mathrm{MA}(u_t) = \int_0^1 \left(\frac{d}{dt} E(u_t)\right) dt = E(u') - E(u).$$

□

When dealing with translation invariant functionals such as M and D, it is useful to introduce the translation invariant functional $J : \mathcal{E}^1 \to \mathbb{R}_+$ defined by

$$J(u) := V^{-1} \int_X u\,\omega^n - E(u),$$

which vanishes iff u is constant and satisfies $J(u) = d_1(u, 0) + O(1)$ on functions normalized by $\sup u = 0$, thanks to Lemma 3.4.

Since the pluripotential part $M_{\mathrm{pp}}(u)$ of the Mabuchi K-energy is a linear combination of integrals of the form $\int_X u\,\omega_u^j \wedge \omega^{n-j}$ and $\int_X u\,\mathrm{Ric}(\omega) \wedge \omega_u^j \wedge \omega^{n-j-1}$, it admits a continuous extension $M_{\text{pp}} : \mathcal{E}^1 \to \mathbb{R}$. As to the entropy part M_{ent}, it extends to a lower semicontinuous functional

$$M_{\text{ent}} : \mathcal{E}^1 \to [0, +\infty],$$

by defining $M_{\text{ent}}(u)$ to be the relative entropy of $\mathrm{MA}(u)$ with respect to μ_0. Finiteness of $M_{\text{ent}}(u)$ is a subtle condition, which amounts to saying that $\mathrm{MA}(u)$ has a density f with respect to Lebesgue measure such that $f \log f$ is integrable.

Theorem 3.5. *Berman, Boucksom, Eyssidieux, Guedj, and Zeriahi [2011], Berman and Berndtsson [2017], Chen, L. Li, and Păun [2016], and Berman, Darvas, and Lu [2017] The extended functionals satisfy the following properties.*

(i) For each $C > 0$, the set of $u \in \mathcal{E}^1$ with $\sup_X u = 0$ and $M_{\text{ent}}(u) \le C$ is compact in the d_1-topology.

(ii) $|M_{\text{pp}}(u)| \le AJ(u) + B$ for some constant $A, B > 0$.

(iii) The functional $M : \mathcal{E}^1 \to (-\infty, +\infty]$ is lower semicontinuous and convex on weak geodesics.

3.4 Variational characterization of cscK metrics. The Mabuchi K-energy M is *coercive* if $M \ge \delta J - C$ on $\mathcal{E}^1$ by for some constants $\delta, C > 0$. By Berman, Darvas, and Lu [2017], it is in fact enough to test this on $\mathcal{H}$. We then have the following basic dichotomy.

Theorem 3.6. *Darvas and He [2017], Darvas and Rubinstein [2017], and Berman, Boucksom, and Jonsson [2015] If the K-energy M is coercive, then it admits a minimizer in $\mathcal{E}^1$. If not, then for any $u \in \mathcal{H}$, there exists a unit speed weak geodesic ray $(u_t)_{t\in[0,+\infty)}$ in $\mathcal{E}^1$ emanating from u, normalized by $\sup_X(u_t - u) = 0$, along which $M(u_t)$ is nonincreasing.*

Proof. Assume that M is coercive, and let $u_j \in \mathcal{E}^1$ be a minimizing sequence, which can be normalized by $\sup u_j = 0$ by translation invariance. Since $M(u_j)$ is bounded above, $J(u_j)$ is bounded, by coercivity, hence so is $|M_{\text{pp}}(u_j)| \le AJ(u_j) + B$. As a result, $M_{\text{ent}}(u_j)$ is also bounded, which means that u_j stays in a compact subset of $\mathcal{E}^1$. After passing to a subsequence, we may thus assume that u_j admits a limit $u \in \mathcal{E}^1$, which is a minimizer of M by lower semicontinuity.

Assume now that M is not coercive, i.e. $M(u_j) \le \delta_j J(u_j) - C_j$ for some sequences $u_j \in \mathcal{E}^1$ with $\sup(u_j - u) = 0$, $\delta_j \to 0$ and $C_j \to +\infty$. We then argue as in Theorem 1.6. Since $M_{\text{ent}}(u_j) \ge 0$ and $M_{\text{pp}}(u_j) \ge -AJ(u_j) - B$, $(A + \delta_j)J(u_j) \ge C_j - B$ tends to ∞, hence so does

$$T_j := d_1(u_j, u) = J(u_j) + O(1).$$

Denote by $(u_{j,t})_{t\in[0,T_j]}$ the weak geodesic connecting u to u_j, parametrized so that $d_1(u_{j,t},u_{j,s}) = |t-s|$, and note that $\sup_X(u_{j,t}-u) = 0$ for all t, by Lemma 3.1. By convexity of M along $(u_{j,t})$, we get

$$\frac{M(u_{j,t})-M(u)}{t} \le \frac{M(u_j)-M(u)}{T_j} \le \delta_j. \tag{3-3}$$

for $j \gg 1$. For each $T > 0$ fixed, $|M_{\mathrm{pp}}(u_{j,t})| \le AJ(u_{j,t}) + B$ is bounded for $t \le T$, hence so is $M_{\mathrm{ent}}(u_{j,t})$, by Equation (3-3). By Theorem 3.5, the 1-Lipschitz maps $t \mapsto u_{j,t}$ thus send each compact subset of $\mathbb{R}_+$ to a fixed compact set in $\mathcal{E}^1$, and Ascoli's theorem shows that $(u_{j,t})$ converges uniformly on compact sets of $\mathbb{R}_+$ to a ray $(u_t)_{t\in\mathbb{R}_+}$ in $\mathcal{E}^1$ (after passing to a subsequence). By local uniform convergence, (u_t) is a weak geodesic, and satisfies $\sup(u_t-u) = 0$ and $d_1(u_t,u_s) = |t-s|$. Further, $M(u_t) \le M(u)$ by Equation (3-3) and lower semicontinuity, which implies that $M(u_t)$ decreases, by convexity. □

Using their key convexity result and a perturbation argument, Berman-Berndtsson proved in Berman and Berndtsson [2017] that cscK metrics in the class $[\omega]$ minimize M, and that the identity component $\mathrm{Aut}^0(X)$ of the group of holomorphic automorphisms acts transitively on these metrics. In Berman, Darvas, and Lu [2016], Berman-Darvas-Lu went further and proved that the existence of *one* cscK metric ω_u implies that any other minimizer of M lies in the $\mathrm{Aut}^0(X)$-orbit of u, and hence is smooth. Using this, we have:

Corollary 3.7. *Darvas and Rubinstein [2017] and Berman, Darvas, and Lu [2016] If* $\mathrm{Aut}^0(X)$ *is trivial and M admits a minimizer $u \in \mathcal{H}$, then M is coercive.*

Proof. By Berman, Darvas, and Lu [2016], u is the unique minimizer of M in $\mathcal{E}^1$, up to a constant. Assume by contradiction that M is not coercice, and let (u_t) be the ray constructed in Theorem 3.6. Since $M(u_t) \le M(u) = \inf M$, u_t must be equal to u up to a constant, and hence $u_t = u$ by normalization, which contradicts $d_1(u_t,u) = t$. □

If a minimizer u of M lies in $\mathcal{H}$, then $u+tf$ is in $\mathcal{H}$ for all test functions $f \in C^\infty(X)$ and $0 < t \ll 1$, hence $M(u+tf) \ge M(u)$, which implies that u is a critical point of M, i.e. ω_u is cscK. This simple perturbation argument cannot be performed for a minimizer in $\mathcal{E}^1$, which is a major remaining difficulty[2] on the analytic side of the cscK problem. In the Kähler-Einstein case, we have however:

Theorem 3.8. *Berman, Boucksom, Guedj, and Zeriahi [2013] and Berman, Boucksom, Eyssidieux, Guedj, and Zeriahi [2011] If the cohomological proportionality condition, Equation (2-1) holds, any mimizer of M in $\mathcal{E}^1$ lies in $\mathcal{H}$, and hence defines a Kähler-Einstein metric.*

[2]This difficulty has recently been overcome by Chen and Cheng [2017, 2018a,b].

Proof. It is not hard to show that a minimizer for M is also a minimizer for the Ding functional $D = L - E$, whose critical points in $\mathcal{H}$ are solutions of the complex Monge-Ampère Equation (2-3). The main step is now to prove that a minimizer $u \in \mathcal{E}^1$ of D satisfies Equation (2-3) in the sense of pluripotential theory, for the complex Monge-Ampère arsenal can then be used to infer ultimately that u is smooth. The projection argument to follow goes back to Aleksandrov in the setting of real Monge-Ampère equations. Given a test function $f \in C^\infty(X)$, the *psh envelope* $P(u+f)$ is defined as the largest ω-psh function dominated by $u+f$. The functional L makes sense on any function u, ω-psh or not, and satisfies $u \le v \implies L(u) \le L(v)$. We thus get for each $t > 0$

$$L(u) - E(u) = D(u) \le D(P(u+tf)) \le L(u+tf) - E(P(u+tf)).$$

The key ingredient is now a differentiability result proved in Berman and Boucksom [2010], which implies that $t \mapsto E(P(u+tf))$ is differentiable at 0, with derivative equal to $\int_X f \, \mathrm{MA}(u)$. This yields indeed

$$\int_X f \, \mathrm{MA}(u) = \lim_{t\to 0_+} \frac{E(P(u+tf)) - E(u)}{t} \le$$
$$\le \lim_{t\to 0_+} \frac{L(u+tf) - L(u)}{t} = \frac{\int_X f\, e^{\lambda u}\mu_0}{\int_X e^{\lambda u}\omega_0},$$

which proves, after replacing f with $-f$, that u is a weak solution of Equation (2-3). □

4 Non-Archimedean Kähler geometry and K-stability

In this final section, we turn to the non-Archimedean aspects of the cscK problem. We reformulate K-stability as a positivity property for the non-Archimedean analogue of the K-energy M, and explain how uniform K-stability implies coercivity, in the Kähler-Einstein case.

4.1 Non-Archimedean pluripotential theory. If X is a complex algebraic variety, we denote by X^{NA} its *Berkovich analytification* (viewed as a topological space) with respect to the *trivial absolute value* $|\cdot|_0$ on $\mathbb{C}$ Berkovich [1990]. When $X = \operatorname{Spec} A$ is affine, with A a finitely generated $\mathbb{C}$-algebra, X^{NA} is defined as the set of all multiplicative seminorms $|\cdot| : A \to \mathbb{R}_+$ compatible with $|\cdot|_0$, endowed with the topology of pointwise convergence. In the general case, X can be covered by finitely many affine open sets X_i, and X^{NA} is defined by gluing together the analytifications X_i^{NA} along their common open subsets $(X_i \cap X_j)^{\mathrm{NA}}$.

Assume from now on that X is projective, equipped with an ample line bundle L. The topological space X^{NA} is then compact (Hausdorff), and can be viewed as a compactification of the space of real-valued valuations $v : \mathbb{C}(X)^* \to \mathbb{R}$ on the function field of X, identifying v with the multiplicative norm $|\cdot| = e^{-v}$. In particular, the trivial valuation on $\mathbb{C}(X)$ defines a special point $0 \in X^{\mathrm{NA}}$, fixed under the natural $\mathbb{R}_+^*$-action $(t, |\cdot|) \mapsto |\cdot|^t$.

In this trivially valued setting, (the analytification of) L comes with a canonical *trivial metric*. Any section $s \in H^0(X, L)$ thus defines a continuous function $|s|_0 : X^{\mathrm{NA}} \to [0, 1]$, the value of $-\log|s|_0$ at a valuation v being equal to that of v on the local function corresponding to s in a trivialization of L at the center of v.

The space $\mathcal{H}^{\mathrm{NA}}$ of *non-Archimedean Kähler potentials* (with respect to L) is defined as the set of continuous functions $\varphi \in C^0(X^{\mathrm{NA}})$ of the form

$$\varphi = \frac{1}{k} \max_i \{\log|s_i|_0 + \lambda_i\}$$

with (s_i) a finite set of sections of $H^0(kL)$ without common zeroes and $\lambda_i \in \mathbb{R}$, those with $\lambda_i \in \mathbb{Q}$ forming $\mathcal{H}^{\mathrm{NA}}_{\mathbb{Q}} \subset \mathcal{H}^{\mathrm{NA}}$. In order to motivate this definition, recall that the data of a Hermitian norm γ on $H^0(kL)$ defines a Fubini-Study/Bergman type metric on L, whose potential with respect to a reference metric $|\cdot|_0$ on L can be written as

$$\mathrm{FS}_k(\gamma) := \frac{1}{k} \log \max_{s \in H^0(kL) \setminus \{0\}} \frac{|s|_0}{\gamma(s)} = \frac{1}{2k} \log \sum_i |s_i|_0^2$$

for any γ-orthonormal basis (s_i). Similarly, any non-Archimedean norm α on $H^0(kL)$ in the sense of Section 1.2 admits an orthogonal basis (s_i), and we then have

$$\mathrm{FS}_k^{\mathrm{NA}}(\alpha) := \frac{1}{k} \log \max_{s \in H^0(kL) \setminus \{0\}} \frac{|s|_0}{\alpha(s)} = \frac{1}{k} \max_i \{\log|s_i|_0 + \lambda_i\}.$$

with $\lambda_i = -\log \alpha(s_i)$. Denoting respectively by $\mathcal{N}_k$ and $\mathcal{N}_k^{\mathrm{NA}}$ the spaces of Hermitian and non-Archimedean norms on $H^0(kL)$, we thus have two natural maps

$$\mathrm{FS}_k : \mathcal{N}_k \to \mathcal{H}, \quad \mathrm{FS}_k^{\mathrm{NA}} : \mathcal{N}_k^{\mathrm{NA}} \to \mathcal{H}^{\mathrm{NA}},$$

and $\mathcal{H}^{\mathrm{NA}} = \bigcup_k \mathrm{FS}_k^{\mathrm{NA}}(\mathcal{N}_k^{\mathrm{NA}})$ by definition. This is to be compared with the fact that $\bigcup_k \mathrm{FS}_k(\mathcal{N}_k)$ is dense in $\mathcal{H}$, a consequence of the fundamental Bouche–Catlin–Tian–Zelditch asymptotic expansion of Bergman kernels.

Non-Archimedean Kähler potentials are closely related to *test configurations* for (X, L), i.e. $\mathbb{C}^*$-equivariant partial compactifications $(\mathcal{X}, \mathcal{L}) \to \mathbb{C}$ of the product $(X, L) \times \mathbb{C}^*$, with $\mathcal{L}$ a $\mathbb{Q}$-line bundle.

Proposition 4.1. *Every test configuration* $(\mathcal{X}, \mathcal{L})$ *gives rise in a natural way to a function* $\varphi_{\mathcal{L}} \in C^0(X^{\mathrm{NA}})$*, which belongs to* $\mathcal{H}^{\mathrm{NA}}_{\mathbb{Q}}$ *if* $\mathcal{L}$ *is ample, and is a difference of functions in* $\mathcal{H}^{\mathrm{NA}}_{\mathbb{Q}}$ *in general. Further, two test configurations* $(\mathcal{X}_i, \mathcal{L}_i)$*,* $i = 1, 2$ *yield the same function on* X^{NA} *if and only if* $\mathcal{L}_1$ *and* $\mathcal{L}_2$ *coincide after pulling-back to some higher test configuration.*

To define $\varphi_{\mathcal{L}}$, denote respectively by $\mathcal{L}'$ and $L_{\mathcal{X}'}$ the pullbacks of $\mathcal{L}$ and L to the graph $\mathcal{X}'$ of the canonical $\mathbb{C}^*$-equivariant birational map $\mathcal{X} \dashrightarrow X \times \mathbb{C}$, and note that

$$\mathcal{L}' = L_{\mathcal{X}'} + D$$

for a unique $\mathbb{Q}$-Cartier divisor D supported in the central fiber $\mathcal{X}'_0$. Every valuation v on X admits a natural $\mathbb{C}^*$-invariant (Gauss) extension $G(v)$ to $\mathbb{C}(X)(t) \simeq \mathbb{C}(\mathcal{X}')$, which can be evaluated on D by chosing a local equation for (a Cartier multiple of) D at the center of $G(v)$, and we set $\varphi_{\mathcal{L}}(v) := G(v)(D)$.

Example 4.2. *Every* 1*-parameter subgroup* $\rho : \mathbb{C}^* \to \mathrm{GL}(H^0(kL))$ *with* kL *very ample defines a test configuration* $(\mathcal{X}, \mathcal{L})$*, obtained as the closure of the orbit of* $X \hookrightarrow \mathbb{P}H^0(kL)^*$*. The* $\mathbb{Q}$*-line bundle* $\mathcal{L}$ *is ample, and every test configuration* $(\mathcal{X}, \mathcal{L})$ *with* $\mathcal{L}$ *ample arises this way. By Example 1.5,* ρ *also defines a non-Archimedean norm* α_ρ *on* $H^0(kL)$*, and we have*

$$\varphi_{\mathcal{L}} = \mathrm{FS}^{\mathrm{NA}}_k(\alpha_\rho).$$

Combined with Proposition 4.1, this implies that $\mathcal{H}^{\mathrm{NA}}_{\mathbb{Q}}$ *is in one-to-one correspondence with the set of all normal, ample test configurations.*

A more general *L-psh function* is defined as a usc function $\varphi : X^{\mathrm{NA}} \to [-\infty, +\infty)$ that can be written as the pointwise limit of a decreasing sequence (or net, rather) in $\mathcal{H}^{\mathrm{NA}}$, defining a space $\mathrm{PSH}^{\mathrm{NA}}$. These functions are bounded above, and the maximum principle takes the simple form

$$\sup_{X^{\mathrm{NA}}} \varphi = \varphi(0),$$

with $0 \in X^{\mathrm{NA}}$ the trivial valuation. The space $\mathrm{PSH}^{\mathrm{NA}}$ is endowed with a natural topology of pointwise convergence on divisorial points, in which functions with $\sup \varphi = 0$ form a compact set. This is proved in Boucksom and Jonsson [2018], building on previous work Boucksom, Favre, and Jonsson [2016] dealing with Berkovich spaces over the field $\mathbb{C}((t))$ of formal Laurent series.

Example 4.3. *If* $\mathfrak{a}$ *is a coherent ideal sheaf on* X*, setting* $|\mathfrak{a}| = \max_{f \in \mathfrak{a}} |f|$ *defines a continuous function* $|\mathfrak{a}| : X^{\mathrm{NA}} \to [0, 1]$*. Given* $c > 0$*, one shows that the function* $c \log |\mathfrak{a}|$ *is* L*-psh if and only if* $L \otimes \mathfrak{a}^c$ *is nef, in the sense that* $\mu^* L - cE$ *is nef on the normalized blow-up* $\mu : X' \to X$ *of* $\mathfrak{a}$*, with exceptional divisor* E*.*

4.2 From geodesic rays to non-Archimedean potentials. We assume from now on that X is a projective manifold equipped with an ample line bundle L, and $\omega \in c_1(L)$ is a Kähler form. Recall that a subgeodesic ray $(u_t)_{t\in\mathbb{R}_+}$ in $\mathrm{PSH}(X,\omega)$ is encoded in the associated S^1-invariant ω-psh function

$$U(x,\tau) = u_{-\log|\tau|}(x)$$

on $X \times \mathbb{D}^*$. We shall say that (u_t) has *linear growth* if $u_t \le at + b$ for some constants $a, b \in \mathbb{R}$, i.e. $U + a\log|\tau| \le b$, a condition which automatically holds when (u_t) is a weak geodesic ray emanating from $u_0 \in \mathcal{H}$, as a consequence of Lemma 3.1.

To a subgeodesic ray (u_t) with linear growth, we shall associate an L-psh function

$$U^{\mathrm{NA}} : X^{\mathrm{NA}} \to [-\infty, +\infty),$$

following a procedure initiated in Boucksom, Favre, and Jonsson [2008]. Imposing

$$(U + a\log|\tau|)^{\mathrm{NA}} = U^{\mathrm{NA}} - a,$$

we may assume that U is bounded above, and hence extends to an ω-psh function on $X \times \mathbb{D}$. Consider first the case where U has *analytic singularities*, i.e. locally satisfies

$$U = c\log\max_i |f_i| + O(1)$$

for a fixed constant $c > 0$ and finitely many holomorphic functions (f_i). The (integrally closed) ideal sheaf

$$\mathfrak{a} := \{f \in \mathcal{O}_{X\times\mathbb{D}} \mid c\log|f| \le U + O(1)\}$$

is then coherent, and $\mathbb{C}^*$-invariant by S^1-invariance of U. We thus have a weight decomposition $\mathfrak{a} = \sum_{i=0}^{r} \tau^i \mathfrak{a}_i$ for an increasing sequence of coherent ideal sheaves $\mathfrak{a}_0 \subset \mathfrak{a}_1 \subset \cdots \subset \mathfrak{a}_r = \mathcal{O}_X$ on X. One further proves that $L \otimes \mathfrak{a}_i^c$ is nef for each i, yielding L-psh functions $c\log|\mathfrak{a}_i|$ on X^{NA} by Example 4.3, and hence an L-psh function

$$U^{\mathrm{NA}} = c\log|\mathfrak{a}| := c\max_i\{\log|\mathfrak{a}_i| - i\}.$$

In the general case, the *multiplier ideals* $\mathcal{J}(kU)$, $k \in \mathbb{N}^*$, are $\mathbb{C}^*$-invariant coherent ideal sheaves on $X \times \mathbb{D}$. They satisfy the fundamental subadditivity property

$$\mathcal{J}((k+k')U) \subset \mathcal{J}(kU)\cdot\mathcal{J}(k'U),$$

which implies the existence of the pointwise limit

$$U^{\mathrm{NA}} := \lim_{k\to\infty} \tfrac{1}{k}\log|\mathcal{J}(kU)|$$

on X^{NA}. A variant of Siu's uniform generation theorem Berman, Boucksom, and Jonsson [2015, §3.2] further shows the existence of k_0 such that $p_X^*((k+k_0)L) \otimes \mathcal{J}(kU)$ is globally generated on $X \times \mathbb{D}$ for all k, and it follows that U^{NA} is indeed L-psh.

Example 4.4. *Pick $k \gg 1$, and let $\gamma_t = \iota_s(t\lambda)$ be a geodesic ray in $\mathcal{N}_k$ associated to a basis $s = (s_i)$ of $H^0(kL)$ and $\lambda \in \mathbb{R}^N$. The image $u_t := \mathrm{FS}_k(\gamma_t)$ is then a subgeodesic ray in $\mathcal{H}$ with linear growth, and $U^{\mathrm{NA}} = \mathrm{FS}_k^{\mathrm{NA}}\left(\iota_s^{\mathrm{NA}}(\lambda)\right)$ is the image of the non-Archimedean norm defined by (γ_t). If λ is further rational, U has analytic singularities, and blowing-up $X \times \mathbb{C}$ along the associated $\mathbb{C}^*$-invariant ideal $\mathfrak{a}$ defines a test configuration $(\mathcal{X}, \mathcal{L})$ such that $U^{\mathrm{NA}} = \varphi_{\mathcal{L}}$.*

The function U^{NA} basically captures the Lelong numbers of U, and we have in particular $U^{\mathrm{NA}} = 0$ iff U has zero Lelong numbers at all points of $X \times \{0\}$. More specifically, let $\mathcal{X}$ be a normal test configuration for X, pick an irreducible component E of the central fiber $\mathcal{X}_0$, and set $b_E := \mathrm{ord}_E(\mathcal{X}_0)$. The normalized $\mathbb{C}^*$-invariant valuation $b_E^{-1}\,\mathrm{ord}_E$ on $\mathbb{C}(\mathcal{X}) \simeq \mathbb{C}(X)(\tau)$ restricts to a divisorial (or trivial) valuation on $\mathbb{C}(X)$, defining a point $x_E \in X^{\mathrm{NA}}$. By Boucksom, Hisamoto, and Jonsson [2017, Theorem 4.6], every divisorial point in X^{NA} is of this type, which means that U^{NA} is determined by its values on such points, and Demailly's work on multiplier ideals shows that

$$-b_E U^{\mathrm{NA}}(x_E) = \lim_{k\to\infty} \tfrac{1}{k}\,\mathrm{ord}_E\left(\mathcal{J}(kU)\right)$$

coincides with the generic Lelong number along E of the pull-back of U (cf. Boucksom, Favre, and Jonsson [2008, Proposition 5.6]).

4.3 Non-Archimedean energy functionals. Ideally, we would like to associate to each functional F in Section 2.2 a non-Archimedean analogue F^{NA}, in such a way that

$$F^{\mathrm{NA}}(U^{\mathrm{NA}}) = \lim_{t\to\infty} \frac{F(u_t)}{t} \tag{4-1}$$

for all weak geodesic rays (u_t). To get started, a special case of the pioneering work of A.Chambert-Loir and A.Ducros on forms and currents in Berkovich geometry Chambert-Loir and Ducros [2012] enables to define a mixed non-Archimedean Monge-Ampère operator

$$(\varphi_1, \dots, \varphi_n) \mapsto \mathrm{MA}(\varphi_1, \dots, \varphi_n) \tag{4-2}$$

on n-tuples (φ_i) in $\mathcal{H}^{\mathrm{NA}}$, with values in *atomic* probability measures on X^{NA}. When the φ_i arise from test configurations $(\mathcal{X}_i, \mathcal{L}_i)$, we can assume after pulling back that all $\mathcal{X}_i$ are equal to the same $\mathcal{X}$, and we then have

$$\mathrm{MA}(\varphi_1, \dots, \varphi_n) = \sum_E b_E (\mathcal{L}_1|_E \cdot \ldots \cdot \mathcal{L}_n|_E)\delta_{x_E},$$

where $\mathcal{X}_0 = \sum_E b_E E$ is the irreducible decomposition and the $x_E \in X^{\mathrm{NA}}$ are the associated divisorial points.

We next introduce the *non-Archimedean Monge-Ampère energy* $E^{\mathrm{NA}} : \mathcal{H}^{\mathrm{NA}} \to \mathbb{R}$ using the analogue of Equation (2-4). As in the Kähler case, E^{NA} is nondecreasing, hence extends by monotonicity to $\mathrm{PSH}^{\mathrm{NA}}$, which defines a space

$$\mathcal{E}^{1,\mathrm{NA}} := \{E^{\mathrm{NA}} > -\infty\} \subset \mathrm{PSH}^{\mathrm{NA}}$$

of *L-psh functions φ with finite L^1-energy*. It is proved in Boucksom, Favre, and Jonsson [2015] and Boucksom and Jonsson [2018] that the mixed Monge-Ampère operator Equation (4-2) admits a unique extension to $\mathcal{E}^{1,\mathrm{NA}}$ with the usual continuity property along monotonic sequences, and that

$$J^{\mathrm{NA}}(\varphi) := \sup \varphi - E^{\mathrm{NA}}(\varphi) \in [0, +\infty)$$

vanishes iff $\varphi \in \mathcal{E}^1$ is constant.

Example 4.5. *A test configuration $(\mathcal{X}, \mathcal{L}) \to \mathbb{C}$, being a product away from the central fiber, admits a natural compactification $(\bar{\mathcal{X}}, \bar{\mathcal{L}}) \to \mathbb{P}^1$. The non-Archimedean Monge-Ampère energy $E^{\mathrm{NA}}(\varphi)$ of the corresponding function $\varphi = \varphi_{\mathcal{L}} \in \mathcal{H}^{\mathrm{NA}}_{\mathbb{Q}}$ is then equal to the self-intersection number $\left(c_1(\bar{\mathcal{L}})^{n+1}\right)$, up to a normalization factor. Alternatively,*

$$E^{\mathrm{NA}}(\varphi) = \lim_{k\to\infty} \frac{w_k}{k h^0(kL)}$$

with $w_k \in \mathbb{Z}$ the weight of the induced $\mathbb{C}^*$-action on the determinant line $\det H^0(\mathcal{X}_0, k\mathcal{L}_0)$*, see for instance Boucksom, Hisamoto, and Jonsson [2017, §7.1].*

If (u_t) is a weak geodesic ray in $\mathcal{E}^1$, $E(u_t) = at + b$ is affine. Using that U is more singular than $\mathcal{J}(kU)^{1/k}$, one shows that

$$E^{\mathrm{NA}}(U^{\mathrm{NA}}) \geq a = \lim_{t\to\infty} E(u_t)/t, \tag{4-3}$$

which implies in particular that U^{NA} belongs to $\mathcal{E}^{1,\mathrm{NA}}$. However, this inequality can be strict in general without further assumptions.

Example 4.6. *Let ω be the Fubini-Study metric on $X = \mathbb{P}^1$, normalized to mass 1. A compact, polar Cantor set $K \subset \mathbb{P}^1$ carries a natural probability measure without atoms, and the potential u of this measure with respect to ω is smooth outside K, has zero Lelong numbers and does not belong to $\mathcal{E}$. By Ross and Witt Nyström [2014] and Darvas [2017], u defines a locally bounded weak geodesic ray (u_t) emanating from 0 such that $E(u_t) = at$ with $a < 0$. However, the corresponding ω-psh function U on $X \times \mathbb{D}$ has zero Lelong numbers, hence $U^{\mathrm{NA}} = 0$ and $E^{\mathrm{NA}}(U^{\mathrm{NA}}) = 0$.*

The Mabuchi K-energy M and the Ding functional D also admit non-Archimedean analogues M^{NA} and D^{NA}. While the pluripotential part $M^{\mathrm{NA}}_{\mathrm{pp}}$ of M^{NA} is defined in complete analogy with M_{pp} as a linear combination of mixed Monge-Ampère integrals, the entropy part $M^{\mathrm{NA}}_{\mathrm{ent}}$ as well as L^{NA} turn out to be of a completely different nature, involving the *log discrepancy function*

$$A_X : X^{\mathrm{NA}} \to [0, +\infty].$$

The latter is the maximal lower semicontinuous extension of the usual log discrepancy on divisorial valuations, and we then have

$$M^{\mathrm{NA}}_{\mathrm{pp}}(\varphi) = \int_{X^{\mathrm{NA}}} A_X \,\mathrm{MA}(\varphi)$$

and

$$L^{\mathrm{NA}}(\varphi) = \begin{cases} \lambda^{-1} \inf_{X^{\mathrm{NA}}}(A_X + \lambda\varphi) & \text{if } \lambda \neq 0 \\ \sup_{X^{\mathrm{NA}}} \varphi = \varphi(0) & \text{if } \lambda = 0. \end{cases}$$

where we have set as before $\lambda = V^{-1}(K_X \cdot L^{n-1})$.

Example 4.7. *Boucksom, Hisamoto, and Jonsson [2017] If $(\mathcal{X}, \mathcal{L})$ is an ample test configuration, then $M^{\mathrm{NA}}(\varphi)$ coincides with the* Donaldson-Futaki *invariant of $(\mathcal{X}, \mathcal{L})$, up to a nonnegative error term that vanishes precisely when $\mathcal{X}_0$ is reduced. Further, (X, L) is* K-semistable *iff $M^{\mathrm{NA}}(\varphi) \geq 0$ for all $\varphi \in \mathcal{H}^{\mathrm{NA}}_{\mathbb{Q}}$, and* K-stable *iff equality holds only for φ a constant. Following Boucksom, Hisamoto, and Jonsson [2017] and Dervan [2016], we say that (X, L) is* uniformly K-stable *if $M^{\mathrm{NA}} \geq \delta J^{\mathrm{NA}}$ on $\mathcal{H}^{\mathrm{NA}}_{\mathbb{Q}}$ for some $\delta > 0$.*

We can now state the following result, which builds in part on previous work by Phong, Ross, and Sturm [2008] and Berman [2016].

Theorem 4.8. *Boucksom, Hisamoto, and Jonsson [2016] and Berman, Boucksom, and Jonsson [2015] Let (u_t) be any subgeodesic ray in $\mathcal{E}^1$, normalized by* $\sup u_t = 0$.

(i) If (u_t) has analytic singularities, then Equation (4-1) holds for E and M_{pp}.

(ii) If (u_t) has strongly analytic singularities, then Equation (4-1) holds for M_{ent}.

(iii) In the Fano case, Equation (4-1) holds for L.

Here we say that (u_t) (or U) has *strongly analytic singularities* if U satisfies near each point of $X \times \{0\}$

$$U = \tfrac{c}{2} \log \sum_i |f_i|^2 \bmod C^\infty$$

for a fixed constant $c > 0$ and finitely many holomorphic functions (f_i).

4.4 A version of the Yau–Tian–Donaldson conjecture. In its usual formulation, the Yau–Tian–Donaldson conjecture states that $c_1(L)$ contains a cscK metric if and only if (X, L) is K-(poly)stable. In the following form, it says that M satisfies the analogue of Theorem 1.6.

Conjecture 4.9. *Let (X, L) be a polarized projective manifold, $\omega \in c_1(L)$ be a Kähler form, and assume that $\mathrm{Aut}^0(X, L) = \mathbb{C}^*$. The following are equivalent:*

(i) there exists a cscK metric in $c_1(L)$;

(ii) M is coercive;

(iii) (X, L) is uniformly K-stable.

The implications (i)$\Longrightarrow$(ii)$\Longrightarrow$(iii) were respectively proved in Berman, Darvas, and Lu [2016] (cf. Corollary 3.7) and Boucksom, Hisamoto, and Jonsson [2016] (cf. Theorem 4.8). By Theorem 3.6, (ii) implies the existence of a minimizer $u \in \mathcal{E}^1$ for M, and the key obstacle to get (i) is then to establish that u is smooth[3]. Assume now that (iii) holds. If (ii) fails, Theorem 3.6 yields a weak geodesic ray (u_t) in $\mathcal{E}^1$, emanating from 0 and normalized by $\sup u_t = 0$, $E(u_t) = -t$, along which $M(u_t)$ decreases, and hence $\lim M(u_t)/t \le 0$. Two major difficulties arise:

1. While U^{NA} belongs to $\mathcal{E}^{1,\mathrm{NA}}$, we cannot prove at the moment of this writing that (iii) propagates to $M^{\mathrm{NA}} \ge \delta J^{\mathrm{NA}}$ on the whole of $\mathcal{E}^{1,\mathrm{NA}}$.
2. Even taking (1) for granted, Example 4.6 shows that $M^{\mathrm{NA}}(U^{\mathrm{NA}})$ cannot be expected to compute exactly the slope at infinity of $M(u_t)$.

These difficulties can be overcome in the Kähler-Einstein case, by relying on the Ding functional as well.

Theorem 4.10. *Berman, Boucksom, and Jonsson [2015] Conjecture 4.9 holds if the proportionality condition $c_1(K_X) = \lambda[\omega]$ is satisfied.*

Sketch of proof. For $\lambda \ge 0$, all three conditions in the conjecture are known to be always satisfied, and we thus focus on the Fano case. Theorem 3.8 completes the proof of (ii)$\Longrightarrow$(i), which was anyway proved long before Tian [2000] by using Aubin's continuity method. Assume (iii), and consider a ray (u_t) as above. In the Fano case, we have $M \ge D$, which shows that $D(u_t) = L(u_t) - E(u_t)$ is bounded above as well. We infer from Theorem 4.8 that $\varphi := U^{\mathrm{NA}}$ satisfies

$$L^{\mathrm{NA}}(\varphi) = \lim_{t\to\infty} \frac{L(u_t)}{t} \le \lim_{t\to\infty} \frac{E(u_t)}{t} = -1 \le E^{\mathrm{NA}}(\varphi).$$

[3] As already mentioned, this has recently been overcome by Chen and Cheng [2017, 2018a,b]

Relying on the Minimal Model Program along the same lines as C. Li and Xu [2014], one proves on the other hand that (iii) implies $D^{\mathrm{NA}} \geq \delta J^{\mathrm{NA}}$ on $\mathcal{H}^{\mathrm{NA}}$, and then on $\mathcal{E}^{1,\mathrm{NA}}$ as well. As φ is normalized by $\sup \varphi = 0$, this means

$$L^{\mathrm{NA}}(\varphi) \geq (1-\delta) E^{\mathrm{NA}}(\varphi) \geq \delta - 1,$$

a contradiction. □

AUTOMORPHISMS AND DYNAMICS: A LIST OF OPEN PROBLEMS

Serge Cantat

Abstract

We survey a few results concerning groups of regular or birational transformations of projective varieties, with an emphasis on open questions concerning these groups and their dynamical properties.

Contents

1 Introduction

1.1 Algebraic transformations. Let $\mathbf{k}$ be a field and d be a positive integer. Consider a smooth projective variety $X_{\mathbf{k}}$ of dimension d, defined over the field $\mathbf{k}$. Attached to $X_{\mathbf{k}}$ are two groups of algebraic transformations: its group of *birational transformations* $\mathrm{Bir}(X_{\mathbf{k}})$ and the subgroup of (biregular) *automorphisms* $\mathrm{Aut}(X_{\mathbf{k}})$. An element f of $\mathrm{Bir}(X_{\mathbf{k}})$ is defined by its graph $\mathfrak{G}_f \subset X_{\mathbf{k}} \times X_{\mathbf{k}}$; by definition, $\mathfrak{G}_f$ is an irreducible algebraic subvariety of dimension d such that the two projections $\mathfrak{G}_f \to X_{\mathbf{k}}$ have degree one, and in the

Keywords: Projective varieties, groups of automorphisms, transformation groups, complex dynamics, birational geometry.

case of automorphisms, the two projections are isomorphisms (in particular, they do not contract any algebraic subset of positive dimension onto a point).

For simplicity, unless otherwise specified, we assume that $\mathbf{k} = \mathbf{C}$ is the field of complex numbers. We denote by X the variety, with no reference to its field of definition, and by $X(\mathbf{C})$ its complex points; thus, $X(\mathbf{C})$ is also a compact, complex manifold of dimension d (and of real dimension $2d$). The group $\mathrm{Bir}(X)$ coincides with the group of bimeromorphic transformations of $X(\mathbf{C})$, and $\mathrm{Aut}(X)$ coincides with the subgroup of holomorphic diffeomorphisms.

A birational transformation $f : X \dashrightarrow X$ is a *pseudo-automorphism* if there exist two Zariski closed subsets Z and Z' of codimension ≥ 2 in X such that f induces an isomorphism from $X \setminus Z$ to $X \setminus Z'$. Equivalently, f and its inverse f^{-1} do not contract any hypersurface (they are “isomorphisms in codimension 1”). Pseudo-automorphisms constitute an important subgroup $\mathrm{Psaut}(X)$ of $\mathrm{Bir}(X)$ that contains $\mathrm{Aut}(X)$. As we shall see, automorphisms are quite rare in dimension ≥ 3; pseudo-automorphisms appear more frequently, for instance in the study of some special varieties, such as rational varieties and Calabi-Yau varieties.

1.2 Examples.

1.2.1 Projective spaces. Consider the projective space $\mathbb{P}^d_{\mathbf{k}}$ of dimension d. Its group of automorphisms is the group of linear projective transformations $\mathsf{PGL}_{d+1}(\mathbf{k})$. Its group of birational transformations is known as the Cremona group in d variables. In homogeneous coordinates $[x_1 : \ldots : x_{d+1}]$, every birational transformation f of $\mathbb{P}^d_{\mathbf{k}}$ can be written as

$$f[x_1 : \ldots : x_{d+1}] = [f_1 : \ldots : f_{d+1}] \tag{1}$$

where the f_i are homogeneous polynomials in the variables x_i, of the same degree, and without common factor of positive degree. In the affine coordinates $X_i = x_i/x_{d+1}$, it is defined by rational fractions

$$F_i(X_1, \ldots, X_d) = \frac{f_i(X_1, \ldots, X_d, 1)}{f_{d+1}(X_1, \ldots, X_d, 1)}. \tag{2}$$

When $d = 1$, $\mathrm{Bir}(\mathbb{P}^1_{\mathbf{k}})$ coincides with the group of automorphisms $\mathsf{PGL}_2(\mathbf{k})$. When $d \geq 2$, $\mathrm{Bir}(\mathbb{P}^d_{\mathbf{k}})$ is much bigger than $\mathsf{PGL}_{d+1}(\mathbf{k})$. In dimension 2, it contains all monomial transformations

$$(X_1, X_2) \mapsto (X_1^a X_2^b, X_1^c X_2^b) \tag{3}$$

with $ad - bc = \pm 1$, all transformations $(X_1, X_2) \mapsto (X_1, X_2 + h(X_1))$, for every $h \in \mathbf{k}(X_1)$, all linear projective transformations, hence all compositions of such maps. When

$\mathbf{k} = \mathbf{C}$, the Hénon map

$$(X_1, X_2) \mapsto (X_2, X_1 + X_2^2 + c) \tag{4}$$

provides a transformation of the plane with a rich dynamics (its topological entropy is equal to $\log(2)$ for every parameter c, it has infinitely many periodic points, ...).

1.2.2 Abelian varieties. Next, consider an elliptic curve $E = \mathbf{C}/\Lambda$, where Λ is a lattice in $\mathbf{C}$. The product $A = E^d$ is a complex torus of dimension d; it is also a projective variety, hence an example of an abelian variety. The group of birational transformations of A coincides with its group of automorphisms. It contains the group A itself, acting by translations, as well as the group $\mathsf{GL}_d(\mathbf{Z})$, acting by linear transformations on A (or more precisely on its universal cover $\mathbf{C}^d$, preserving the lattice Λ^d, hence also on A after taking the quotient by Λ^d).

1.2.3 Calabi-Yau varieties. As a third example, fix an integer $d \geq 1$, and consider a smooth hypersurface X in $(\mathbb{P}^1_{\mathbf{C}})^{d+1}$ which is defined in the open set $\mathbf{C}^{d+1}$ of $\mathbb{P}^1(\mathbf{C})^{d+1}$ by a polynomial equation $P(x_1, \ldots, x_{d+1}) = 0$ whose degree is equal to 2 with respect to each coordinate x_j. Geometrically, this means that for every index $1 \leq i \leq d+1$, the projection $\pi_i \colon X \to (\mathbb{P}^1_{\mathbf{C}})^d$ which forgets the i-th coordinate is a morphism of degree 2. The involution that permutes the two points in the fibers of π_i is a birational involution σ_i of X.

When $d \geq 2$, these hypersurfaces of degree $(2, 2, \ldots, 2)$ in $(\mathbb{P}^1_{\mathbf{C}})^{d+1}$ are examples of *Calabi-Yau varieties*: they are simply connected, they support a holomorphic d-form that does not vanish, and they do not split as the product of two varieties of smaller dimension. Thus, the involutions σ_i are pseudo-automorphisms because $\mathrm{Bir}(X) = \mathrm{Psaut}(X)$ for all Calabi-Yau varieties, as one sees by pulling back a non-vanishing holomorphic d-form.

In dimension ≤ 2, these pseudo-automorphisms are in fact regular automorphisms. In dimension 1, X is a curve of genus 1, and the involutions determine a dihedral group, acting by affine transformations of type $z \mapsto \pm z + a$ on the elliptic curve. In dimension $d = 2$, X is a K3 surface, and the involutions determine a large group of automorphisms of X: if the equation P is generic, then $\mathrm{Aut}(X) = \mathrm{Bir}(X)$ is generated by those three involutions, there are no relations between these involutions (they generate a group isomorphic to the free product $\mathbf{Z}/2\mathbf{Z} \star \mathbf{Z}/2\mathbf{Z} \star \mathbf{Z}/2\mathbf{Z}$), and the composition $\sigma_1 \circ \sigma_2 \circ \sigma_3$ has a rich dynamical behaviour (its topological entropy is $\log(9 + 4\sqrt{5})$).

For $d \geq 3$, the involutions σ_i are pseudo-automorphisms with indeterminacy points. For a generic choice of the equation P, the involutions σ_i generate $\mathrm{Psaut}(X)$, there are no relations between the σ_i, and $\mathrm{Aut}(X)$ is trivial (see Cantat and Oguiso [2015]).

1.3 Plan. Our goal is to review some important facts concerning the group $\mathrm{Aut}(X)$, the algebraic structure of its subgroups, and the dynamical properties of its elements. The emphasis is on open problems, in which algebraic geometry, group theory, and dynamics are simultaneously involved.

This article comprises two main parts. The first one concerns groups of automorphisms of smooth complex projective varieties, and their action on the cohomology of the variety. The second part concerns the dynamics: we focus on automorphisms with a dynamical behavior of low complexity because their study has been surprisingly neglected, while it offers interesting questions at the interface between dynamics and algebraic geometry.

We focus on $\mathrm{Aut}(X)$ for simplicity. As Section 1.2.3 shows, it would be better to work with pseudo-automorphisms, or even with birational transformations. In fact, most of the questions which are described below could be stated for pseudo-automorphisms of compact kähler manifolds (see Remark 2.1); and some of them concern birational transformations of projective varieties over an arbitrary field.

2 Groups of automorphisms

2.1 Automorphisms. Let X be a smooth complex projective variety. Its group of automorphisms is a complex Lie group (for the topology of uniform convergence), whose Lie algebra is the finite dimensional algebra of regular vector fields on X. But $\mathrm{Aut}(X)$ may have infinitely many components, as shown in Section 1.2.2 by the example of the abelian variety $(\mathbf{C}/\Lambda)^d$, where $\Lambda \subset \mathbf{C}$ is a lattice and $d \geq 2$.

Consider the action of $\mathrm{Aut}(X)$ on the cohomology $H^*(X;\mathbf{Z})$ of $X(\mathbf{C})$; this gives a linear representation

$$\mathrm{Aut}(X) \to \mathsf{GL}(H^*(X;\mathbf{Z})). \tag{5}$$

The connected component of the identity $\mathrm{Aut}(X)^0 \subset \mathrm{Aut}(X)$ acts trivially on the cohomology, and is therefore contained in the kernel of this representation. If an element $f \in \mathrm{Aut}(X)$ acts trivially on the second cohomology group $H^2(X;\mathbf{Z})$, it preserves the cohomology class of a kähler form κ on X (resp. the first Chern class of an ample line bundle L on X); this means that the volume (resp. degree) of the graph of f is uniformly bounded on the kernel of the representation (5). Since subvarieties with a fixed volume (resp. degree) form a bounded family, one can use Douady spaces (or Hilbert Schemes) to obtain the following fact: *the connected component of the identity in* $\mathrm{Aut}(X)^0 \subset \mathrm{Aut}(X)$ *has finite index in the kernel of the linear representation* $\mathrm{Aut}(X) \to \mathsf{GL}(H^2(X;\mathbf{Z}))$ (see Grothendieck [1995] and Lieberman [1978] for a proof).

Thus, the group $\mathrm{Aut}(X)$ splits into two basic parts: its neutral component $\mathrm{Aut}(X)^0$, and its discrete image

$$\mathrm{Aut}(X)^* \subset \mathsf{GL}(H^*(X;\mathbf{Z})). \tag{6}$$

The group of connected components $\mathrm{Aut}(X)/\mathrm{Aut}(X)^0$ is an extension of $\mathrm{Aut}(X)^*$ by a finite group.

Remark 2.1. One may replace $H^2(X;\mathbf{Z})$ by the subgroup $\mathrm{N}^1(X)$ generated by cohomology classes of algebraic hypersurfaces of X (or more precisely by the Poincaré dual of their homology classes). The kernel of the representation $\mathrm{Aut}(X) \mapsto \mathsf{GL}(\mathrm{N}^1(X))$ is, again, equal to a finite extension of $\mathrm{Aut}(X)^0$. Doing so, it is possible to phrase some of the following questions for varieties which are defined over fields of arbitrary characteristic.

One may also replace $\mathrm{Aut}(X)$ by $\mathrm{Psaut}(X)$. Indeed, since pseudo-automorphisms are isomorphisms in codimension 1, the group $\mathrm{Psaut}(X)$ acts linearly on $\mathrm{N}^1(X)$ (and $H^2(X;\mathbf{Z})$ when $\mathbf{k} = \mathbf{C}$). Thus, all questions concerning the action of $\mathrm{Aut}(X)$ on $H^2(X;\mathbf{Z})$ can be stated for the action of $\mathrm{Psaut}(X)$ on $\mathrm{N}^1(X)$ (even when the characteristic of $\mathbf{k}$ is positive).

2.2 The realization problem. Two main problems arise: given a connected algebraic group G, does there exist a projective variety X such that $\mathrm{Aut}(X)^0$ is isomorphic to G as an algebraic group ? Given a subgroup Γ of $\mathsf{GL}_n(\mathbf{Z})$, for some $n \geq 2$, does there exist a projective variety X and an isomorphism of groups $\Gamma \simeq \mathrm{Aut}(X)^*$? There is also a third, less interesting problem, which asks which pairs (G, Γ) may be simultaneously realized as the connected component and the discrete part of $\mathrm{Aut}(X)$, for some variety X.

The first problem has been solved by Brion in the following strong sense: *any connected algebraic group G over a perfect field is the neutral component of the automorphism group scheme of some normal projective variety X; if the characteristic of the field is 0, one can moreover assume that X is smooth of dimension* $\dim(X) = 2\dim(G)$ (see Brion [2014]; see also Winkelmann [2004] for Kobayashi hyperbolic manifolds).

In the following paragraphs, we focus on the discrete, countable group $\mathrm{Aut}(X)^*$.

2.3 Linear groups and their Zariski closure. Not much has been proven yet concerning the description of the groups $\mathrm{Aut}(X)^*$. To simplify the exposition, we shall say that a group Γ is *abstractly realizable* as a group of automorphisms (in dimension d) if there exist a projective variety X (of dimension d) such that $\mathrm{Aut}(X)$ is isomorphic to Γ (as abstract groups).

Remark 2.2. The group $\mathsf{GL}_n(\mathbf{Z})$ acts on the abelian variety $(\mathbf{C}/\Lambda)^n$ for every lattice $\Lambda \subset \mathbf{C}$. Blowing-up the origin, one gets a new variety X with $\mathrm{Aut}(X)^0 = \{\mathrm{id}_X\}$ and with

$\mathsf{GL}_n(\mathbf{Z}) \simeq \mathrm{Aut}(X)$ if Λ is generic. Thus, every subgroup Γ of $\mathsf{GL}_n(\mathbf{Z})$ acts faithfully on a projective variety of dimension n whose group of automorphisms is discrete. This does not say that Γ is abstractly realizable.

Remark 2.3. A necessary condition for a countable group Γ to be realizable is that Γ admits a linear integral representation $\Gamma \to \mathsf{GL}_m(\mathbf{Z})$ with finite kernel. This is not a sufficient condition: *when $n \geq 2$, there is a finite, cyclic, and central extension of the symplectic group $\mathsf{Sp}_{2n}(\mathbf{Z})$ that does not act faithfully by birational transformations on any complex projective variety* (see Cantat and Xie [2015]).

Instead of looking at the abstract notion of realizability, one may also add some rigidity in the definition; this may be done as follows. Say that a group $\Gamma \subset \mathsf{GL}_m(\mathbf{Z})$ is *strongly realizable* as a group of automorphisms if there is a smooth complex projective variety X, and a linear algebraic representation

$$\varphi\colon \mathsf{GL}_m(\mathbf{R}) \to \mathsf{GL}(H^2(X;\mathbf{R})) \tag{7}$$

which is defined over $\mathbf{Z}$, such that $\mathrm{Aut}(X)^*$ coincides with $\varphi(\Gamma)$. As in Remark 2.1, one may replace $H^2(X;\mathbf{Z})$ by $\mathrm{N}^1(X)$ to define a notion of strong realizability by pseudo-automorphisms, defined over any field $\mathbf{k}$.

Remark 2.4. The cohomology group $H^2(X;\mathbf{C})$ splits into the direct sum of the Dolbeault groups $H^{p,q}(X;\mathbf{C})$ with $p+q=2$. This splitting, the intersection form and the cone of all Kähler classes are $\mathrm{Aut}(X)^*$-invariant (see Griffiths and Harris [1978]). Hence, it would be too much to require φ to be an isomorphism.

There are only countably many distinct groups $\mathrm{Aut}(X)^*$. This follows from the fact that, up to isomorphism, there are only countably many pairwise non-isomorphic extensions of $\mathbf{Q}$ which are finitely generated. On the opposite, for every integer $n \geq 4$, there are uncountably many, pairwise non-isomorphic, subgroups of $\mathsf{GL}_n(\mathbf{Z})$. Thus a counting argument shows that most subgroups Γ of $\mathsf{GL}_n(\mathbf{Z})$ are not realizable as groups of automorphisms. On the other hand, there are only countably many subgroups of $\mathsf{GL}_n(\mathbf{Z})$ which are finitely generated.

Question 2.5. Which subgroups of $\mathsf{GL}_n(\mathbf{Z})$ are abstractly (resp. strongly) realizable as groups of automorphisms ? Is every finitely generated subgroup $\Gamma \subset \mathsf{GL}_n(\mathbf{Z})$ abstractly (resp. strongly) realizable as a group of automorphisms ?

Recently, Lesieutre proved that *if $\mathbf{k}$ is a field of characteristic 0, or a field which is not algebraic over its prime field, then there is a smooth, 6-dimensional projective variety X over $\mathbf{k}$ such that* $\mathrm{Aut}(X)^0$ *is trivial and* $\mathrm{Aut}(X)^*$ *is not finitely generated* (see Lesieutre [2017] and Dinh and Oguiso [2017] for another example). This shows that it is somewhat artificial to assume that Γ is finitely generated.

Remark 2.6. The following problem remains open: does there exist a rational surface S such that $\mathrm{Aut}(S)$ is discrete but not finitely generated ? More precisely, can one find such an example which is a minimal model for the pair $(S, \mathrm{Aut}(S))$, meaning that if $\pi : S \to S'$ is a birational morphism and $\pi \circ \mathrm{Aut}(S) \circ \pi^{-1} \subset \mathrm{Aut}(S')$ then π is an isomorphism ?

In Question 2.5, the dimension of X is not specified; indeed, $\dim(X)$ must a priori be large with respect to n. Changing viewpoint, one may fix the dimension, or fix the type of variety one considers, and try to find constraints on the subgroups $\mathrm{Aut}(X)^* \subset \mathsf{GL}(H^2(X;\mathbf{Z}))$.

Question 2.7. Fix a dimension $d \geq 2$. Define $G^0(X)$ as the neutral component of the Zariski closure of $\mathrm{Aut}(X)^*$ in $\mathsf{GL}(H^2(X;\mathbf{R}))$. What kind of linear algebraic groups $G^0(X)$ do we obtain in this way, when X runs over all possible Calabi-Yau varieties of dimension d ?

Again, by Remark 2.1, the group $\mathrm{Aut}(X)$ may be replaced by the group $\mathrm{Psaut}(X) = \mathrm{Bir}(X)$ and $H^2(X;\mathbf{R})$ by $\mathrm{N}^1(X) \otimes_{\mathbf{Z}} \mathbf{R}$ in this question. For a nice example, see Cantat and Oguiso [2015]. For complex projective K3 surfaces, the groups $G^0(X)$ that one gets are connected components of $\mathsf{SO}_{1,m}(\mathbf{R})$ for some $m \leq 19$, or abelian groups $\mathbf{R}^m$ of rank $m \leq 18$. This comes from Hodge index theorem.

Question 2.5 is stated for Calabi-Yau manifolds because they form one of the most interesting classes of examples, but it may be stated for other classes, for instance for rational varieties. And instead of looking at the action of $\mathrm{Aut}(X)$ on $H^2(X;\mathbf{R})$, one may also consider its action on every Dolbeault subgroup $H^{p,q}(X;\mathbf{C})$ (see Cantat and Dolgachev [2012], Cantat and Zeghib [2012], and Zhang [2013]).

2.4 Real algebraic variation. Consider now a smooth real projective variety $X_{\mathbf{R}}$ of dimension d. Assume that $X(\mathbf{R})$ is non-empty, and fix one of the connected components $S \subset X(\mathbf{R})$ (for the euclidean topology); then S is a closed connected manifold of dimension d. The automorphisms of X which are defined over $\mathbf{R}$ form a subgroup $\mathrm{Aut}(X_{\mathbf{R}})$ of $\mathrm{Aut}(X_{\mathbf{C}})$. A finite index subgroup $\mathrm{Aut}(X_{\mathbf{R}}; S)$ of $\mathrm{Aut}(X_{\mathbf{R}})$ fixes S, and we get a restriction morphism

$$\mathrm{Aut}(X_{\mathbf{R}}; S) \to \mathrm{Diff}^{\infty}(S) \tag{8}$$

where $\mathrm{Diff}^{\infty}(S)$ is the group of $\mathcal{C}^{\infty}$-diffeomorphisms of S. Denoting by $\mathrm{Mod}(S)$ the modular group of S, i.e. the group of connected components of $\mathrm{Diff}^{\infty}(S)$ (see Farb and Margalit [2012]), one gets a homomorphism

$$\alpha_S : \mathrm{Aut}(X_{\mathbf{R}}; S) \to \mathrm{Mod}(S). \tag{9}$$

What can be said on the image of this homomorphism ?

The best is to start with surfaces. First, there are explicit examples of automorphisms f of rational and K3 surfaces for which the mapping class $\alpha_S(f)$ is interesting (see Bedford and Kim [2009] and Moncet [2008]). Second, Kollár and Mangolte obtained the following beautiful result. Fix any smooth real surface $X_{\mathbf{R}}$, which is rational (over $\mathbf{R}$). Then, consider the subgroup $\mathrm{Bir}^\infty(X_{\mathbf{R}})$ of $\mathrm{Bir}(X_{\mathbf{R}})$ defined by the following property: f is in $\mathrm{Bir}^\infty(X_{\mathbf{R}})$ if and only if f and its inverse f^{-1} have no real indeterminacy point – all its indeterminacy points come in complex conjugate pairs. By restriction to $X(\mathbf{R})$, each element f of $\mathrm{Bir}^\infty(X_{\mathbf{R}})$ provides a diffeomorphism of $X(\mathbf{R})$, and therefore a mapping class $\alpha_{X(\mathbf{R})}(f) \in \mathrm{Mod}(X(\mathbf{R}))$. In Kollár and Mangolte [2009] it is proved that *this homomorphism* $\mathrm{Bir}^\infty(X_{\mathbf{R}}) \to \mathrm{Mod}(X(\mathbf{R}))$ *is surjective*.

Question 2.8. Does there exist a real projective K3 surface X such that (i) $X(\mathbf{R})$ is connected and of genus $g \geq 2$ and (ii) the image of $\alpha_{X(\mathbf{R})}\colon \mathrm{Aut}(X_{\mathbf{R}}) \to \mathrm{Mod}(X(\mathbf{R}))$ is surjective ?

I suspect that the answer to this question is negative. Indeed, there may exist a mapping class ψ of the closed, orientable surface of genus 2 with the following property: given any automorphism f of a real K3 surface $X_{\mathbf{R}}$ with an f-invariant connected component $S \subset X(\mathbf{R})$ of genus 2, $\alpha_S(f)$ is not conjugate to ψ.

2.5 Dynamical degrees. Consider an automorphism f of a smooth complex projective variety X. The characteristic polynomial $\chi_f(t)$ of

$$f^*\colon H^2(X;\mathbf{Z}) \to H^2(X;\mathbf{Z}) \tag{10}$$

is an element of $\mathbf{Z}[t]$; it is monic, and its constant term is ± 1. Denote by $\lambda_1(f)$ the largest absolute value of a root of $\chi_f(t)$. The invariance of the Hodge decomposition and of the Kähler cone implies that $\lambda_1(f)$ is in fact one of the roots of $\chi_f(t)$ and, as such, is an algebraic integer. This number $\lambda_1(f)$ is called the first *dynamical degree* of f (subsequent dynamical degrees are obtained by looking at the action of f on the groups $H^{p,p}(X;\mathbf{R})$ with $p > 1$). Now, fix the dimension d of the variety, and define the following set of real integers:

$$\mathfrak{S}_1(d) = \{\lambda_1(f);\ f \in \mathrm{Aut}(X) \text{ for } X \text{ smooth, projective, of dimension } d\}. \tag{11}$$

In dimension 1, $\mathfrak{S}_1(1) = \{1\}$, but in dimension $d \geq 2$, $\mathfrak{S}_1(d)$ is an infinite countable set of algebraic integers. In dimension 2, the Hodge index theorem shows that $\mathfrak{S}_1(2) \setminus \{1\}$ contains only reciprocal quadratic integers and Salem numbers; and its first derive set is non empty: for example the golden mean is an increasing limit of elements of $\mathfrak{S}_1(2)$ (see Diller and Favre [2001]). A deeper result says that *every strictly decreasing sequence of elements of* $\mathfrak{S}_1(2)$ *is finite*; in particular, *given any* $\alpha \in \mathfrak{S}_1(2)$, *there is a real number*

$\epsilon(\alpha) > 0$ *such that* $]\alpha, \alpha+\epsilon(\alpha)[$ *does not intersect* $\mathfrak{S}_1(2)$ (see McMullen [2002a, 2007] and Blanc and Cantat [2016]). In particular, many Salem numbers are not contained in $\mathfrak{S}_1(2)$. The only general constraint known on the elements of $\mathfrak{S}_1(3)$ is due to Lo Bianco: *if* $\alpha \in \mathfrak{S}_1(3)$*, there are at most* 6 *distinct moduli* $|\alpha_i|$ *for the Galois conjugates* α_i *of* α (whatever the degree of the algebraic integer α, see Lo Bianco [2014]).

Question 2.9. Is $\mathfrak{S}_1(3)$ dense in $[1, +\infty[$? Or, on the contrary, does there exist $\epsilon > 0$ such that $\mathfrak{S}_1(3) \cap]1, 1+\epsilon]$ is empty ?

In this question, on may replace $\mathfrak{S}_1(3)$ by the set of dynamical degrees of all *birational* transformations of projective threefolds; here, by definition, the first dynamical degree of a birational transformation $f \in \mathrm{Bir}(X)$ is defined by the limit

(12) $$\lambda_1(f) = \lim_{n\to+\infty} \left((f^n)^*(H)\cdot H^{d-1}\right)^{1/n}$$

where H is some hyperplane section of X, d is the dimension of X, and the integer $(f^n)^*(H)\cdot H^{d-1}$ is the intersection product of the total transform $(f^n)^*(H)$ with $d-1$ copies of H. This limit exists and does not depend on H (see Dinh and Sibony [2005], Dang [2017], and Truong [2016], and Section 3.3 below).

3 Dynamics with low complexity

3.1 Entropy. Given a continuous transformation g of a compact metric space M, the topological *entropy* $\mathrm{h}_{top}(g; M)$ is a measure of the complexity of the dynamics of $g: M \to M$. To define it, fix a scale $\epsilon > 0$ at which you observe the dynamics. Given a period of observation $N \in \mathbf{Z}_+$, count the maximum number of orbits $(x, g(x), \ldots, g^{N-1}(x))$ that are pairwise distinct at scale ϵ, the orbit of x being distinguishable from the orbit of y if the distance from $g^k(x)$ to $g^k(y)$ is larger than ϵ for at least one time $0 \le k < N$. This number of orbits $\mathrm{Orb}(N;\epsilon)$ typically grows exponentially fast with N; thus, one defines $h(g;\epsilon)$ as the supremum limit of $\frac{1}{N}\log(\mathrm{Orb}(N;\epsilon))$ and the entropy $\mathrm{h}_{top}(g; M)$ of g as the limit of $h(g;\epsilon)$ as ϵ goes to 0, i.e. as our observations become arbitrarily accurate.

Topological entropies are hard to estimate for continuous or smooth maps of manifolds. But *the topological entropy of an endomorphism* f *of a smooth complex projective variety* X *is equal to the logarithm of the spectral radius of* $f^*: H^*(X;\mathbf{C}) \to H^*(X;\mathbf{C})$ (the action of f on the cohomology). This wonderful result is due to Gromov and Yomdin (see Gromov [2003, 1987] and Yomdin [1987], and Dinh and Sibony [2005] for an upper bound when f is a rational map). For instance, the entropy is invariant under deformation: if F is an automorphism of a variety $\mathfrak{X}$ that preserves a fibration $\pi: \mathfrak{X} \to B$ with smooth projective fibers and the fibration is locally trivial topologically, then the automorphisms induced by F on the fibers of π have the same entropy.

Endomorphisms with positive entropy have been studied in detail, with special focus on endomorphisms of the projective space $\mathbb{P}^k_{\mathbf{C}}$ and automorphisms of surfaces. We refer to Cantat [2014] and Dinh and Sibony [2010a] for survey papers on the subject. Here, we consider the opposite edge of the spectrum: instead of looking at automorphisms with chaotic dynamics, we ask for a description of automorphisms with dynamics of low complexity.

3.2 Invariant fibrations. Now consider an automorphism f of a smooth complex projective variety X with entropy equal to 0. Then, by the Gromov-Yomdin theorem, the eigenvalues of $f^* \in \mathsf{GL}(H^*(X;\mathbf{Z}))$ all have modulus 1, and being algebraic integers, they must be roots of unity. Changing f in a positive iterate, we may assume that f^* is *unipotent*: all its eigenvalues are equal to 1.

If f^* is the identity, then some further iterate is contained in $\mathrm{Aut}(X)^0$ (see Section 2.1). The dynamics of such an automorphism is well understood. Thus, one may assume that f^* is non-trivial and unipotent; equivalently, the sequence $\| (f^n)^* \|$ grows polynomially quickly with n, as n^k for some $k \geq 1$.

When $\dim(X) = 2$, Gizatullin proved the following: *if f^* is unipotent and $\neq \mathrm{Id}$, then f preserves a (singular) fibration by curves of genus 1 and the growth of $\| (f^n)^* \|$ is quadratic* (see Gizatullin [1980], Diller and Favre [2001], and Cantat [2001]). For instance, if $\pi : X \to B$ is a genus 1 fibration of the surface X with two sections, then the translations along the fibers that map the first section to the second one determine an algebraic transformation of X: this is often an automorphism such that $\| (f^n)^* \|$ grows quadratically. The following question asks whether Gizatullin's classification can be extended to higher dimension.

Question 3.1. Let X be a smooth complex projective variety of dimension 3. Let f be an automorphism of X, such that the linear transformation $f^* \in \mathsf{GL}(H^*(X;\mathbf{C}))$ is non-trivial and unipotent. Does f permute the fibers of a non-trivial meromorphic fibration $\pi : X \dashrightarrow B$?

By "non-trivial meromorphic fibration", I mean that $0 < \dim(B) < \dim(X)$ and π is a dominant rational map; and f permutes the fibers of π if there is a birational transformation f_B of B such that $\pi \circ f = f_B \circ \pi$.

When f is an automorphism of a smooth complex projective variety of dimension 3 and f^* is a non-trivial unipotent matrix, then $\| (f^*)^n \|$ *grows like n^k with $k \in \{2, 4\}$* (see Lo Bianco [2014]). But beside this general statement, not much is known.

One of the first examples to look at is the case of Calabi-Yau varieties. So, let f be an automorphism of a Calabi-Yau variety X of dimension 3, with a non-trivial unipotent action on the cohomology. Consider a kähler form κ on X, with cohomology class $[\kappa] \in H^2(X;\mathbf{R})$; then $n^{-k}(f^n)^*[\kappa]$ converges towards an f-invariant nef class. Is this class related to an f-invariant fibration on X ? This is a version of the abundance conjecture (see Lazić, Oguiso, and Peternell [2016]), precisely in a case which is not solved yet, but with the additional presence of an automorphism.

3.3 Degree growth. If an automorphism satisfies $\lambda_1(f) = 1$, then an iterate of f^* is unipotent, and $\| (f^n)^* \|$ grows polynomially with n. Now, consider a birational transformation $f : X \dashrightarrow X$ of a complex projective variety X. Fix a polarization H of X and define the degree of f with respect to H by the intersection product

$$\deg_H(f) = f^*(H) \cdot H^{d-1} \tag{13}$$

where d is the dimension of X and $f^*(H)$ is the total transform of H by f^{-1}. Changing H into another polarization H', the notion of degree is only perturbed by a bounded multiplicative error: there exists a positive constant c such that

$$\frac{1}{c}\deg_{H'}(f) \leq \deg_H(f) \leq c \deg_{H'}(f) \tag{14}$$

for all $f \in \mathrm{Bir}(X)$ (see Dinh and Sibony [2005], Dang [2017], and Truong [2016]). When $X = \mathbb{P}^d_{\mathbf{C}}$ and $H \subset \mathbb{P}^d_{\mathbf{C}}$ is a hyperplane, then $\deg_H(f)$ is just the degree of the polynomials that define f in homogeneous coordinates (see Section 1.2.1). Instead of assuming that the entropy of f is zero, one may now assume that $\lambda_1(f) = 1$, i.e. that $\deg_H(f^n)$ does not grow exponentially fast with n.

Question 3.2. Let X be a smooth projective variety of dimension d, together with a polarization H. Let f be a birational transformation of X with $\lambda_1(f) = 1$. Does the sequence $\deg_H(f^n)$ grow polynomially ? If not bounded, does this sequence grow at least linearly ?

In other words, can one construct a birational transformation f, say, of $\mathbb{P}^3_{\mathbf{C}}$, such that the sequence $\deg_H(f^n)$ grows like $\exp(\sqrt{n})$, or like $n^2\log(n)$, or like $n^{1/3}$? This is already an open problem for polynomial automorphisms of the affine space $\mathbb{A}^3_{\mathbf{C}}$. One may also ask, as in Question 3.1, whether the equality $\lambda_1(f) = 1$ implies the existence of a non-trivial invariant fibration. While these questions are fully understood in dimension 2 (see Cantat [2013, 2015], Diller and Favre [2001], and Gizatullin [1980]) almost nothing is known in higher dimension (see Urech [2017], as well as Déserti [2017] and Lin [2013] for interesting examples).

This type of question is, in fact, directly related to the algebraic structure of the group $\mathrm{Bir}(X)$. For instance, one says that an element f of $\mathrm{Bir}(X)$ is *distorted* if there exists a finite set $S \subset \mathrm{Bir}(X)$ such that the n-th iterate f^n is a product $g_1 \circ \cdots \circ g_{\ell(n)}$ of elements $g_i \in S$ with $\liminf(\ell(n)/n) = 0$ (see Calegari and Freedman [2006]). Distorted elements satisfy $\lambda_1(f) = 1$. In dimension 2, an element f of $\mathrm{Bir}(\mathbb{P}^2_{\mathbf{C}})$ is distorted if and only if some positive iterate f^N is conjugate to an element of $\mathrm{Aut}(\mathbb{P}^2_{\mathbf{C}})$. Any progress on Questions 3.1 and 3.2 would certainly help classify distorted elements in higher dimension.

3.4 Minimal transformations. A continuous transformation g of a compact metric space M is *minimal* if each of its orbits are dense; equivalently, the only g-invariant closed subsets are M and the empty set. For an algebraic example, consider a complex torus $A = \mathbf{C}^k/\Lambda$, with Λ a cocompact lattice in $\mathbf{C}^k$; then, every totally irrational translation on A is minimal. For another example, take $k = 2$ and $\Lambda = \Lambda_0 \times \Lambda_0$, with Λ_0 a lattice in $\mathbf{C}$. Choose a point a in $\mathbf{C}/\Lambda_0$ such that each orbit of $x \mapsto x + a$ is dense in $\mathbf{C}/\Lambda_0$, and consider the following automorphism of $\mathbf{C}^2/\Lambda$:

$$f(x, y) = (x + a, y + x) \qquad \mathrm{mod}\ (\Lambda). \tag{15}$$

Furstenberg shows in Furstenberg [1961] that every orbit of f is dense in the abelian surface $\mathbf{C}^2/\Lambda$. In fact, Furstenberg proves more: *f preserves the Haar measure on the torus and this is the unique f-invariant probability measure*. Thus, there are minimal automorphisms with no positive iterate in $\mathrm{Aut}(X)^0$ (in Furstenberg's example, the action of f on the cohomology is non-trivial and unipotent).

A minimal automorphism of a curve is a translation on an elliptic curve. In dimension 2, one also proves easily that *any complex projective surface X with a minimal automorphism is an abelian surface*. It would be great to get a similar result in higher dimension:

Question 3.3. Let X be a complex projective variety of dimension 3. Suppose that there is a minimal automorphism f on X. Is X an abelian variety ?

If f is minimal it does not have any periodic orbit. With the Lefschetz formula and Gromov-Yomdin theorem, one sees that the entropies of minimal automorphisms of complex projective varieties vanish. Now, if X has dimension 3, the holomorphic Lefschetz formula says that $h^{1,0}(X) > 0$ or $h^{3,0}(X) > 0$. If $h^{1,0}(X) > 0$, one may use the Albanese morphism to reduce the complexity of the dynamics of f (see Cantat [2010]). If $h^{3,0}(X) > 0$, there is an f-invariant holomorphic 3-form on X; since f does not preserve any strict Zariski closed set (by minimality), this form does not vanish. Thus, the most interesting case is when X is a Calabi-Yau variety of dimension 3 with Euler characteristic equal to 0, and the action of f^m on the cohomology is unipotent for some $m > 0$ (as in Section 3.2).

3.5 Fatou components and real algebraic varieties.

3.5.1 Fatou components on K3 surfaces. Consider an automorphism f of a K3 surface X. Assume that the topological entropy of f on the complex surface $X(\mathbf{C})$ is positive: $h_{top}(f;\mathbf{C}) = \log(\lambda_1(f)) > 0$ where $\lambda_1(f)$ is, by the Gromov-Yomdin theorem, the largest eigenvalue of f on the cohomology of $X(\mathbf{C})$. In that case, f has infinitely many periodic points, and those points equidistribute toward an f-invariant probability measure μ_f (see Cantat [2001, 2014] and Dujardin [2006]). More precisely, denote by $\mathrm{Per}(f;N)$ the set of isolated periodic points of f or period N. Then, the sequence of probability measures

$$\frac{1}{|\mathrm{Per}(f;N)|}\sum_{z\in \mathrm{Per}(f;N)} \delta_z \tag{16}$$

converges toward an f-invariant probability measure μ_f with interesting dynamical properties (this is the unique measure of maximal entropy of f). The same property holds if one replaces $\mathrm{Per}(f;N)$ by the set of saddle periodic points of period N, i.e. by points $x \in X(\mathbf{C})$ such that $f^N(x) = x$ and the differential Df^N_x has two eigenvalues α and β with

$$|\alpha| > 1 > |\beta|; \tag{17}$$

indeed, the number of isolated periodic points and of saddle periodic points grow at the same speed, namely like $\lambda_1(f)^N$.

The measure μ_f is, in general, singular with respect to the Lebesgue measure on $X(\mathbf{C})$. *If μ_f is absolutely continuous with respect to the Lebesgue measure, then (X, f) is a Kummer example: this means that X is a quotient of an abelian surface A and f is induced by a linear automorphism of A* (see Cantat and Dupont [2015]).

But not much is known about the support of the measure μ_f. There may a priori exist a region $\mathcal{U} \subset X(\mathbf{C})$ which is f-invariant and on which the dynamics of f is far from being chaotic. More precisely, define the *Fatou set* $\mathrm{Fat}(f)$ as follows: $x \in X(\mathbf{C})$ is in the Fatou set if there is an open neighborhood $\mathcal{V}$ of x such that the sequence of iterates $(f^m)_{m\in\mathbf{Z}}$ forms a normal family on $\mathcal{V}$, in the sense of Montel. This determines an f-invariant open subset $\mathrm{Fat}(f) \subset X(\mathbf{C})$ on which μ_f vanishes. It is not known yet whether the Fatou set is always empty for automorphisms of complex projective K3 surfaces with positive entropy. There are examples of non-empty Fatou sets on non-projective K3 surfaces and rational surfaces (see McMullen [2002b] and Bedford and Kim [2009]).

Question 3.4. Does there exist a complex projective K3 surface X with an automorphism $f : X \to X$ such that the topological entropy of f is positive and the Fatou set of f is not empty ?

While the theory of closed positive currents, the Hodge theory, and the Pesin theory of smooth dynamical systems may be combined to study the chaotic part of the dynamics from a stochastic viewpoint (see Bedford, Lyubich, and Smillie [1993], Cantat [2001, 2014], De Thélin and Dinh [2012], and Dinh and Sibony [2010b] for instance), not much is known concerning the topological properties of the dynamics, such as the existence of non-empty Fatou components or dense orbits. Thus, Question 3.4 is at the borderline of our knowledge.

3.5.2 Dynamics on real K3 surfaces. Now, add to the hypotheses that X and f are defined over the field of real numbers $\mathbf{R}$, and $X(\mathbf{R})$ is not empty. Fix a connected component S of $X(\mathbf{R})$, and replace f by some positive iterate so that f now preserves S. We obtain two dynamical systems: the complex dynamics given by $f : X(\mathbf{C}) \to X(\mathbf{C})$, and the real dynamics given by $f : S \to S$. The topological entropy of f on S is bounded above by the topological entropy of f on $X(\mathbf{C})$. For rational surfaces, it may happen that these two numbers are equal (and positive, see Bedford and Kim [2009]); in that case most periodic points of f are indeed contained in $X(\mathbf{R})$. For K3 surfaces, there is no example yet with

$$\mathrm{h}_{top}(f; X(\mathbf{R})) > \frac{1}{2}\mathrm{h}_{top}(f; X(\mathbf{C})). \tag{18}$$

At the opposite edge of the possibilities, there is no known example for which $\mathrm{h}_{top}(f; X(\mathbf{C}))$ is positive while $\mathrm{h}_{top}(f; S) = 0$ for some connected component of $X(\mathbf{R})$ (see Moncet [2012]).

Question 3.5. Does there exist a real projective K3 surface $X_{\mathbf{R}}$ with an automorphism $f : X_{\mathbf{R}} \to X_{\mathbf{R}}$ such that $\lambda_1(f) > 1$, $X(\mathbf{R})$ is not empty, and one of the following property occurs

(1) the entropy of f on $X(\mathbf{R})$ is equal to the entropy of f on $X(\mathbf{C})$?

(2) the entropy of f on some component S of $X(\mathbf{R})$ vanishes ?

(3) a connected component S of $X(\mathbf{R})$ is contained in the Fatou set of f ?

Of course, a positive answer to the third of these questions would imply a positive answer to the second question and to Question 3.4. To obtain a positive answer to the first, it would be sufficient to find a component $S \subset X(\mathbf{R})$ which is f invariant and such that the mapping class $\alpha_S(f)$ has a stretching factor equal to $\lambda_1(f)$ on the fundamental group $\pi_1(S)$ (see Farb and Margalit [2012]); thus, Question 3.5 is also related to Section 2.4.

RECURSIVE COMBINATORIAL ASPECTS OF COMPACTIFIED MODULI SPACES

Lucia Caporaso

Abstract

In recent years an interesting connection has been established between some moduli spaces of algebro-geometric objects (e.g. algebraic stable curves) and some moduli spaces of polyhedral objects (e.g. tropical curves).

In loose words, this connection expresses the Berkovich skeleton of a given algebro-geometric moduli space as the moduli space of the skeleta of the objects parametrized by the given space; it has been proved to hold in two important cases: the moduli space of stable curves and the moduli space of admissible covers. Partial results are known in other cases.

This connection relies on the study of the boundary of the algebro-geometric moduli spaces and on its recursive, combinatorial properties, some of which have been long known and are now viewed from a new perspective.

Contents

1 Introduction

We will describe some results in this area by focusing on the moduli spaces of curves, line bundles on curves (i.e. Jacobians), and coverings of curves. As we said, it was clear

MSC2010: primary 14H10; secondary 14TXX.

for a long time that combinatorial aspects play a significant role in compactifying moduli spaces. A notable example is the structure of the Néron model of the Jacobian of a curve. Of course, Néron models are not compact, but they are a first step towards compactifying Jacobians. We begin the paper by describing Néron models, their combinatorial properties, and the recursive structure of their compactification. Then we turn to moduli spaces of curves and illustrate the connection introduced at the beginning. We return to compactified Jacobians in the last section and describe some recent partial results.

2 Compactified Jacobians and Néron models

2.1 Jacobians, Picard schemes and Néron models. Let X be a connected, reduced, projective curve of genus g over an algebraically closed field k. The set of isomorphism classes of line bundles of degree 0 on every irreducible component of X is an algebraic group of dimension g, denoted by J_X, and called the Jacobian of X. More exactly, J_X is the moduli space for line bundles of multidegree $(0, 0, \dots, 0)$ on X.

J_X is projective, hence an abelian variety, if X is smooth but not if X is singular (with exceptions). Constructing compactifications for J_X is a classical problem which can be stated as follows. Let

$$X \hookrightarrow \mathcal{X} \xrightarrow{f} \operatorname{Spec} R$$

be a family of curves over the spectrum of a discrete valuation ring R, with X as special fiber. Assume the generic fiber, $\mathcal{X}_K$, to be a nonsingular curve over the quotient field, K, of R, and let $J_{\mathcal{X}_K} \to \operatorname{Spec} K$ be its Jacobian. The problem is to find "good" models of $J_{\mathcal{X}_K}$ over Spec R, where "good" means: (a) projective, (b) with a moduli interpretation, (c) such that the special fiber depends only on X and not on the family f. We shall refer to such models, and to their special fiber, as *compactified Jacobians*.

We shall begin by looking for models that satisfy (b) and (c) together with the weaker requirement of being separated, rather than projective.

A natural model of $J_{\mathcal{X}_K}$ is the relative Jacobian (a group scheme over R)

$$J_{\mathcal{X}/R} \longrightarrow \operatorname{Spec} R. \tag{1}$$

This is a separated model for $J_{\mathcal{X}_K}$, but it does not have satisfactory moduli properties. Indeed, suppose we have a line bundle $\mathcal{L}$ over $\mathcal{X}$ having relative degree 0 on the fibers of f. Then we have a *moduli morphism* $\mu_{\mathcal{L}_K} : \operatorname{Spec} K \to J_{\mathcal{X}_K}$ whose image corresponds to the restriction of $\mathcal{L}$ to $\mathcal{X}_K$. For a model to have good moduli properties we want the map $\mu_{\mathcal{L}_K}$ to extend to a morphism from Spec R to the model (so that the image of the special point is determined by the restriction of $\mathcal{L}$ to the special fiber). For the relative Jacobian this requirement easily fails.

Another natural model is the relative degree-0 Picard scheme

$$\mathrm{Pic}^0_{\mathfrak{X}/R} \longrightarrow \mathrm{Spec}\, R. \tag{2}$$

Now, this has a good moduli interpretation, as any moduli map $\mu_{\mathfrak{L}_K}$ will certainly extend to a map $\mu_R : \mathrm{Spec}\, R \to \mathrm{Pic}^0_{\mathfrak{X}/R}$, and μ_R is itself a moduli map. The problem now is that the extension μ_R may fail to be unique, that is, (2) is not a separated morphism, in general.

We have thus two natural models, one separated with bad moduli properties, the other with good moduli properties but not separated. Does there exist a compromise with better behaviour than both of them? An answer to this question comes from the theory of Néron models.

Our moduli requirement above (i.e. the existence of a unique extension for maps of the form $\mu_{\mathfrak{L}_K}$) is a special case of the mapping property satisfied by Néron models, whose existence has been established in Néron [1964]. We state the following special case of Néron's famous theorem, using the above notation.

Theorem 2.1.1 (Néron)**.** *There exists a smooth and separated group scheme of finite type*

$$N(J_{\mathfrak{X}_K}) \longrightarrow \mathrm{Spec}\, R,$$

whose generic fiber is $J_{\mathfrak{X}_K}$, satisfying the following mapping property:

Let $Y_R \to \mathrm{Spec}\, R$ be smooth, Y_K its generic fiber, and $\mu_K : Y_K \to J_{\mathfrak{X}_K}$ a morphism. Then μ_K extends uniquely to a morphism $\mu_R : Y_R \to N(J_{\mathfrak{X}_K})$.

Remark 2.1.2. The Néron model does not commute with ramified base change, therefore it is a separated model for $J_{\mathfrak{X}_R}$ with good mapping properties, but not functorial ones.

The relation of the Néron model with the relative Jacobian and the relative Picard scheme has ben established by Raynaud who proved, in Raynaud [1970], that $N(J_{\mathfrak{X}_K}) \to \mathrm{Spec}\, R$ is the maximal separated quotient of $\mathrm{Pic}^0_{\mathfrak{X}/R} \to \mathrm{Spec}\, R$.

2.2 Combinatorics of Néron models. We shall turn to the geometric structure of our Néron models. We assume from now on that the curve X is nodal, write $X = \cup_{v\in V} C_v$ for its irreducible components, and consider the dual graph, G_X, of X:

$$G_X := (V, E = \mathrm{Sing}(X), V \xrightarrow{h} \mathbb{Z}) \tag{3}$$

with $h(v) = g(C_v)$, where $g(C_v)$ is the genus of the normalization, C_v^ν. The genus of G_X is the same as the arithmetic genus of X, i.e.

$$g(X) = g(G_X) = b_1(G_X) + \sum_{v\in V} h(v).$$

It is well known that J_X fits into an exact sequence of algebraic groups:

$$0 \longrightarrow (k^*)^{b_1(G_X)} \longrightarrow J_X \longrightarrow \prod_{v \in V} J_{C_v^\nu} \longrightarrow 0. \tag{4}$$

Denote by N_X the special fiber of $N(J_{\mathcal{X}_K}) \to \operatorname{Spec} R$. We shall state some results of Raynaud [1970], and Oda and Seshadri [1979], which establish that N_X is a disjoint union of copies of the Jacobian of X indexed by a combinatorial invariant of the curve.

To do that we need some combinatorial preliminaries. Fix an orientation on $G = G_X$ (whose choice is irrelevant), let $C_0(G,\mathbb{Z})$ and $C_1(G,\mathbb{Z})$ be the standard groups of i-chains, generated over $\mathbb{Z}$ by V if $i = 0$, and by E if $i = 1$. Next, let $\partial : C_1(G,\mathbb{Z}) \to C_0(G,\mathbb{Z})$ be the usual boundary (mapping an edge e oriented from u to v to $u - v$), and $\delta : C_0(G,\mathbb{Z}) \to C_1(G,\mathbb{Z})$ the coboundary (mapping a vertex v to $\sum e_v^+ - \sum e_v^-$ where the first sum is over all edges originating from v and the second over all edges ending at v).

Now we can state the following.

Proposition 2.2.1 (Raynaud, Oda-Seshadri)**.** *Let $\mathcal{X} \to \operatorname{Spec} R$ have nodal special fiber and regular total space. Then the special fiber, N_X, of the Néron model $N(J_{\mathcal{X}_K}) \longrightarrow \operatorname{Spec} R$ is a union of copies of J_X as follows*

$$N_X \cong \sqcup_{i \in \Phi_X} (J_X)_i \tag{5}$$

where Φ_X is the following finite group

$$\Phi_G \cong \frac{\partial\delta C_0(G,\mathbb{Z})}{\partial C_1(G\mathbb{Z})}.$$

In particular, the number of irreducible components of N_X equals the number of spanning trees of G_X.

The last claim follows from Kirchhoff-Trent, or Kirchhoff matrix,Theorem.

2.3 Compactifying Néron models. From now on we apply the notation introduced in Proposition 2.2.1 and for any connected nodal curve X we denote by N_X the special fiber of the Néron model of the Jacobian associated to a family $\mathcal{X} \to \operatorname{Spec} R$ with $\mathcal{X}$ regular.

If X is a singular curve with $b_1(G_X) \neq 0$ (i.e. X not of "compact type"), then the Néron model $N(J_{\mathcal{X}_K}) \to \operatorname{Spec} R$ is not projective, as its special fiber is not projective by the exact sequence (4).

Now, the Picard scheme has good moduli properties and the Néron model is its maximal separated quotient. We introduce a terminology to distinguish compactified Jacobians which also compactify the Néron model.

A compactified Jacobian $\overline{P} \longrightarrow \operatorname{Spec} R$ is said to be of *Néron type* (or a *Néron compactified Jacobian*) if its special fiber, written $\overline{P}_X$, contains N_X as a dense open subset. We shall also say that $\overline{P}_X$ is of Néron type.

As we shall see, Néron compactified Jacobians do exist, but there exist also interesting compactified Jacobians not of Néron type.

The notion originates from Oda and Seshadri [ibid.] and Caporaso [2008], although the terminology was introduced later, in Caporaso [2012b]. Oda and Seshadri, in Oda and Seshadri [1979], treated the case of a fixed singular curve X (rather than a family of curves), and constructed compactified Jacobians in this less general sense. They nonetheless established the link with Néron models and constructed compactified Jacobians whose smooth locus is isomorphic to N_X. This was extended to families of curves later. In Caporaso [1994] and Caporaso [2008] a class of compactified Jacobians of Néron type was proved to exist and to form a family over the moduli space of stable curves, $\overline{\mathfrak{M}}_g$. Such families, denoted by $\psi_d : \overline{\mathcal{P}}_g^d \longrightarrow \overline{\mathfrak{M}}_g$, are indexed by the integers d such that

$$(d - g + 1, 2g - 2) = 1. \tag{6}$$

For any stable curve X the fiber of ψ_d over X, written $\overline{P}_X^d$, contains N_X as a dense open subset equal to its smooth locus, and it is thus of Néron type.

In a similar vein, in Melo and Viviani [2012] and in Melo, Rapagnetta, and Viviani [2017] other Néron compactified Jacobians were found among the ones constructed by Esteves [2001], and called "fine" compactified Jacobians. The word "fine" is quite appropriate, as all known Néron compactified Jacobians are as fine a moduli space as they can be, i.e. they admit a universal (or "Poincaré") line bundle.

We now show how Néron Jacobians are recursive compactifications of Néron models. First, for a connected graph G, we introduce the following

$$\mathcal{C}(G) := \{S \subset E(G) : \; G - S \text{ is connected}\},$$

with partial order given by reverse inclusion. The maximal element of $\mathcal{C}(G)$ is $\emptyset$, and the minimal elements are the $S \subset E$ such that $G - S$ is a spanning tree. Moreover, $\mathcal{C}(G)$ is a graded poset with respect to the rank function $S \mapsto g(G - S)$.

If G is the dual graph of the curve X then $S \in \mathcal{C}(G)$ is a set of nodes of X. We denote by X_S^ν the desingularization of X at S, so that X_S^ν is a connected nodal curve of genus $g(G - S)$. Recall that $N_{X_S^\nu}$ denotes the special fiber of the Néron model of its Jacobian. The following follows from Caporaso [2008, Thm. 7.9].

Theorem 2.3.1. *Let $\overline{P}_X^d$ be a Néron compactified Jacobian. Then*

$$\overline{P}_X^d = \bigsqcup_{S \in \mathcal{C}(G)} N_S \tag{7}$$

with $N_S \cong N_{X_S^\nu}$ *for every* $S \in \mathcal{C}(G)$*. Moreover* (7) *is a* graded stratification*, i.e. the following hold.*

1. $N_S \cap \overline{N_{S'}} \neq \emptyset \Leftrightarrow N_S \subset \overline{N_{S'}} \Leftrightarrow S' \geq S$.
2. N_S *is locally closed of pure dimension* $g(G - S)$.
3. *The following is a rank-function on* $\mathcal{C}(G)$

$$\mathcal{C}(G) \longrightarrow \mathbb{Z}; \qquad S \mapsto \dim N_S.$$

Remark 2.3.2. The set of strata of minimal dimension in (7) are Néron models of curves whose dual graph is a spanning tree of G_X, hence they are irreducible. By Proposition 2.2.1, the number of such strata is equal to the number of irreducible components of $\overline{P}^d_X$.

If X is not of compact type the strata of (7) are not all connected. Hence one naturally asks whether the stratification can be refined so as to have connected strata. We will answer this question later in the paper.

Remark 2.3.3. The theorem exhibits the compactification of the Néron model of X in terms of the Néron models of partial normalizations of X. This phenomenon is an instance of what seems to be a widespread recursive behaviour for compactified moduli spaces. Namely, to compactify a space (e.g. N_X) one adds at the boundary the analogous spaces associated to simpler objects (e.g. $N_{X'}$ with X' a connected partial normalization of X). Other examples of this recursive pattern will appear later in the paper.

The concept of "graded stratification" used in the Theorem will appear again, so we now define it in general.

A *graded stratification* of an algebraic variety, or a stack, M by a poset $\mathcal{P}$ is a partition $M = \bigsqcup_{p \in \mathcal{P}} M_p$ such that the following hold for every $p, p' \in \mathcal{P}$.

1. $M_p \cap \overline{M_{p'}} \neq \emptyset \Leftrightarrow M_p \subset \overline{M_{p'}} \Leftrightarrow p' \geq p$.
2. M_p is equidimensional and locally closed.
3. The map from $\mathcal{P}$ to $\mathbb{N}$ sending p to $\dim M_p$ is a rank function on $\mathcal{P}$.

3 Moduli of curves: tropicalization and analytification

3.1 Moduli spaces of algebraic and tropical curves. Let $\mathfrak{M}_{g,n}$ be the moduli space of smooth curves of genus g with n marked points. Assume $2g - 2 + n > 0$ so that $\mathfrak{M}_{g,n}$

is never empty. It is well known that $\mathfrak{M}_{g,n}$ is not projective (unless $g = 0, n = 3$) and is compactified by the moduli space of Deligne-Mumford stable curves, $\overline{\mathfrak{M}}_{g,n}$; see Deligne and Mumford [1969], Knudsen [1983a,b], and Gieseker [1982].

We will describe in (9) a stratification of $\overline{\mathfrak{M}}_{g,n}$ which is recursive in the sense of Remark 2.3.3, that is, the boundary strata are expressed in terms of simpler moduli spaces $\mathfrak{M}_{g',n'}$. In this case "simpler"means $g \leq g'$ and of smaller dimension, i.e. $n' < n+3(g-g')$. These boundary strata will be described in (8).

Let $\mathcal{SG}_{g,n}$ be the poset of stable graphs of genus g with n legs, with the following partial order:

$$G_2 \geq G_1 \quad \text{if} \quad G_2 = G_1/S \quad \text{for some} \quad S \subset E(G_1)$$

where G_1/S is the graph obtained by contracting every edge of S to a vertex. By the very definition (introduced in Brannetti, Melo, and Viviani [2011]), edge-contraction preserves g and n, and it is easily seen to preserve stability.

To a stable curve, X, of genus g with n legs there corresponds a dual graph $G_X \in \mathcal{SG}_{g,n}$. With respect to what we defined in (3) the only new piece of data are the legs of G_X which correspond to the n marked points. Recall that the weight, $h(v)$, of a vertex v is the geometric genus of the corresponding component of X. We denote by $\deg(v)$ the degree (or valency) of v.

For $G \in \mathcal{SG}_{g,n}$ we denote by $\mathfrak{M}_G$ the moduli stack of curves whose dual graph is isomorphic to G. We have (see Abramovich, Caporaso, and Payne [2015, Prop. 3.4.1])

$$\mathfrak{M}_G = \Big[\Big(\prod_{v \in V(G)} \mathfrak{M}_{h(v),\deg(v)}\Big)/\mathrm{Aut}(G)\Big]. \tag{8}$$

With this notation and the terminology at the end of Section 2 we state:

Proposition 3.1.1. *The following is a graded stratification of* $\overline{\mathfrak{M}}_{g,n}$

$$\overline{\mathfrak{M}}_{g,n} = \bigsqcup_{G \in \mathcal{SG}_g} \mathfrak{M}_G. \tag{9}$$

One goal of the above descriptive result (whose proof, in Caporaso [2012a], is not hard thanks to our consolidated knowledge of $\overline{\mathfrak{M}}_g$) is to highlight the similarities of $\overline{\mathfrak{M}}_{g,n}$ with the moduli space of extended (abstract) tropical curves, $\overline{M}^{\mathrm{trop}}_{g,n}$, as we are going to show. First of all, an extended tropical curve is a metric graph, i.e. a graph G whose edges are assigned a length, $\ell : E \to \mathbb{R}_{>0} \cup \{\infty\}$. We denote a tropical curve as follows

$$\Gamma = (G; \ell) = (V, E, w; \ell).$$

The genus of Γ is the genus of G. The word "extended" refers to the fact that we include edges of infinite length. In fact, abstract tropical curves are originally defined (in Mikhalkin and Zharkov [2008] and Brannetti, Melo, and Viviani [2011]) as compact spaces, so their edges have finite length. We allow edges of infinite lengths to obtain a compact moduli space which is the "tropicalization" of the moduli space of stable curves.

An extended tropical curve with n marked points is a metric graph as above with the addition of a set of legs of the underlying graph.

There is a natural equivalence relation on tropical curves such that in every equivalence class there is a unique (up to isomorphism) curve whose underlying graph is stable.

The moduli space $\overline{M}^{\rm trop}_{g,n}$ parametrizes extended tropical curves of genus g with n marked points up to this equivalence relation. Its first construction is due to Mikhalkin, for $g = 0$, and to Brannetti-Melo-Viviani for compact tropical curves in any genus. The following statement summarises results from Mikhalkin [2007], Brannetti, Melo, and Viviani [2011], and Caporaso [2012a].

Theorem 3.1.2. *The moduli space of extended tropical curves, $\overline{M}^{\rm trop}_{g,n}$, is a compact and normal topological space of dimension $3g-3+n$. It admits a graded stratification*

$$\overline{M}^{\rm trop}_{g,n} = \bigsqcup_{G \in \mathcal{SG}^*_{g,n}} \overline{M}^{\rm trop}_{G} \tag{10}$$

where $\overline{M}^{\rm trop}_{G}$ is the locus of curves having G as underlying graph and $\mathcal{SG}^*_{g,n}$ is the poset dual to $\mathcal{SG}_{g,n}$ (i.e. with reverse partial order).

3.2 Skeleta and tropicalizations. Proposition 3.1.1 and Theorem 3.1.2 show that $\overline{M}^{\rm trop}_{g,n}$ has a graded stratification dual to that of $\overline{\mathfrak{M}}_{g,n}$. Therefore we ask whether there exists some deeper relation between $\overline{\mathfrak{M}}_{g,n}$ and $\overline{M}^{\rm trop}_{g,n}$.

A positive answer can be given through the theory of analytifications of algebraic schemes developed in Berkovich [1990], and through its connections to tropical geometry; see Maclagan and Sturmfels [2015] and Payne [2009]. Let us introduce the space $\overline{M}^{\rm an}_{g,n}$, the analytification of $\overline{\mathfrak{M}}_{g,n}$ in the sense of Berkovich. Recall that a point in $\overline{M}^{\rm an}_{g,n}$ corresponds, up to base change, to a stable curve over an algebraically closed field K complete with respect to a non-archimedean valuation; as $\overline{M}_{g,n}$ is projective, this is the same as a stable curve over the ring of integers of K.

From the general theory (see also Thuillier [2007] and Abramovich, Caporaso, and Payne [2015]) we have that for every space with a toroidal structure, like the stack $\overline{\mathfrak{M}}_{g,n}$ (with toroidal structure given by its boundary), one associates the *Berkovich skeleton* which is a generalised, extended cone complex onto which the analytification retracts. We write $\overline{\Sigma}(\overline{\mathfrak{M}}_{g,n})$ for the Berkovich skeleton of $\overline{\mathfrak{M}}_{g,n}$ and $\overline{M}^{\rm an}_{g,n} \xrightarrow{\rho} \overline{\Sigma}(\overline{\mathfrak{M}}_{g,n})$ for the retraction.

The connection between tropical geometry and Berkovich theory originates from the fact that Berkovich skeleta can be viewed as tropicalizations of algebraic varieties. As we are going to see, the picture for curves is quite clear, whereas other interesting situations (some treated later in the present paper) are still open to investigations; we refer to Gubler, Rabinoff, and Werner [2016], for recent progress for higher dimensional varieties.

Now, tropical curves can be viewed as tropicalizations (or skeleta) of curves over algebraically closed, complete, non-archimedean fields. This is clarified by the following statement, combining results of Viviani [2013], Tyomkin [2012], and Baker, Payne, and Rabinoff [2016, 2013] (for the first part) and of Abramovich, Caporaso, and Payne [2015] (for the second part).

Theorem 3.2.1. *There exists a* tropicalization *map*

$$\mathrm{trop}: \overline{M}^{\mathrm{an}}_{g,n} \to \overline{M}^{\mathrm{trop}}_{g,n}$$

that sends the class of a stable curve over the (algebraically closed, complete, non-archimedean) field K to its skeleton.

There is a natural isomorphism, $\overline{\Sigma}(\overline{\mathfrak{M}}_{g,n}) \cong \overline{M}^{\mathrm{trop}}_{g,n}$, through which the above map factors as follows

$$\mathrm{trop}: \overline{M}^{\mathrm{an}}_{g,n} \xrightarrow{\rho} \overline{\Sigma}(\overline{\mathfrak{M}}_{g,n}) \xrightarrow{\cong} \overline{M}^{\mathrm{trop}}_{g,n}.$$

We need to define the tropicalization map and explain the word "skeleton". As we said, a point in $\overline{M}^{\mathrm{an}}_{g,n}$ is a class of stable curves, $\mathfrak{X} \to \operatorname{Spec} R$, where R is the valuation ring of K; let X be its special fiber. Then the image of this point via the map trop is the tropical curve $(G;\ell)$, where G is the dual graph of X and, for every node $e \in E(G)$, the value $\ell(e)$ is determined by the local geometry of $\mathfrak{X}$ at e as measured by the given valuation. Such a tropical curve $(G;\ell)$ is called the *skeleton*, of the stable curve $\mathfrak{X} \to \operatorname{Spec} R$ or of the stable curve $\mathfrak{X}_K$ over K.

Concluding in loose words: the skeleton of $\overline{\mathfrak{M}}_{g,n}$ is the moduli space of skeleta of stable curves.

The structure of the proof of the above theorem is such that it may apply to other situations. In fact it has been applied by Cavalieri-Markwig-Ranganathan to another remarkable case, the compactification of the Hurwitz spaces, as we shall now explain.

3.3 Algebraic and tropical admissible covers. Consider the moduli space of admissible covers, $\overline{\mathcal{H}}_\bullet$, which here (as in Cavalieri, Markwig, and Ranganathan [2016]), is the normal compactification of the classical space of Hurwitz covers $\mathcal{H}_\bullet$. We use the subscript •" to simplify the notation needed to express the usual discrete invariants. Indeed, a more precise notation would be $\mathcal{H}_\bullet = \mathcal{H}_{g,h}(\underline{\pi})$ for the Hurwitz space parametrizing degree-d covers of a smooth curve of genus h by a smooth curve of genus g with exactly

b branch points with ramification profile prescribed by a set of b partitions of d, written $\underline{\pi} = (\pi_1, \ldots, \pi_b)$.

In Cavalieri, Markwig, and Ranganathan [2016] the authors define *tropical admissible covers*, construct their moduli space $\overline{H}_\bullet^{\text{trop}}$ and establish an analogue to Theorem 3.2.1. We shall now outline the procedure and give some details.

The first step is to associate a dual combinatorial entity to the algebro-geometric one. Indeed, one associates to an admissible cover a map of graphs, which we call the *dual graph cover*. The set of all dual graph covers is endowed with a poset structure by means of edge-contractions (similarly to the poset set of stable graphs). We denote by $\mathcal{A}_\bullet$ this poset, as its objects can be viewed as *admissible* maps of graphs. For any $\Theta \in \mathcal{A}_\bullet$ we denote by $\mathcal{H}_\Theta$ the locus in $\overline{\mathcal{H}}_\bullet$ of admissible covers whose dual graph map is Θ.

The second step is to enrich the dual combinatorial entity with a tropical, or polyhedral, structure. In Cavalieri, Markwig, and Ranganathan [ibid.] tropical admissible covers are defined by metrizing, in a suitable way, dual maps of graphs. The moduli space of tropical admissible covers is denoted by $\overline{H}_\bullet^{\text{trop}}$, the bar over H indicates that they are "extended", i.e. edge-lengths are allowed to be infinite. For $\Theta \in \mathcal{A}_\bullet$ the stratum parametrizing tropical admissible covers having Θ as underlying graph map is denoted by $\overline{H}_\Theta^{\text{trop}}$ and shown to be the quotient of an extended real cone.

The third and last step is to use analytification and tropicalization to establish an explicit link between the algebraic and the tropical moduli space. Indeed, essentially by construction, we have dual stratifications

$$\overline{\mathcal{H}}_\bullet = \bigsqcup_{\Theta \in \mathcal{A}_\bullet} \mathcal{H}_\Theta \qquad \text{and} \qquad \overline{H}_\bullet^{\text{trop}} = \bigsqcup_{\Theta \in \mathcal{A}_\bullet^*} \overline{H}_\Theta^{\text{trop}}.$$

This duality can be read from the following Theorem.

Theorem 3.3.1 (Cavalieri-Markwig-Ranganathan)**.** *There is a tropicalization map* trop : $\overline{\mathcal{H}}_\bullet^{\text{an}} \to \overline{H}_\bullet^{\text{trop}}$ *which factors as follows*

$$\text{trop} : \overline{\mathcal{H}}_\bullet^{\text{an}} \xrightarrow{\rho} \overline{\Sigma}(\overline{\mathcal{H}}_\bullet) \longrightarrow \overline{H}_\bullet^{\text{trop}}.$$

The map $\overline{\mathcal{H}}_\bullet^{\text{an}} \xrightarrow{\rho} \overline{\Sigma}(\overline{\mathcal{H}}_\bullet)$ is the retraction of $\overline{\mathcal{H}}_\bullet^{\text{an}}$ onto its Berkovich skeleton, as described in subSection 3.2. This result is compatible with the analogous one for $\overline{\mathcal{M}}_g$ through the canonical forgetful maps from $\overline{\mathcal{H}}_\bullet$ to the moduli spaces of stable curves; see Cavalieri, Markwig, and Ranganathan [ibid., Thm. 4].

What about other moduli spaces? Are Theorems 3.2.1 and 3.3.1 part of some general picture where skeleta of algebraic moduli spaces (e.g. the skeleton of $\overline{\mathcal{M}}_{g,n}$) can be described as moduli spaces for combinatorial entities (e.g. tropical curves) which are skeleta of the objects (e.g. stable curves) parametrized by the algebraic moduli spaces? As we saw, the first step is to identify a suitable partially ordered set of combinatorial objects to associate to the algebro-geometric ones.

In the next section we shall look at the theory of compactified Jacobians from this point of view.

4 Compactified Jacobians

4.1 Compactifying Jacobians over $\overline{M}_g$. Let us go back to compactify Jacobians of curves and, with the discussion of the previous section in mind, approach the problem from the point of view of the moduli theory of stable curves. Consider the universal Jacobian over the moduli space of smooth curves and look for a compactification of it over $\overline{\mathfrak{M}}_g$ satisfying the requirements we discussed earlier.

For reasons that will be clear later, it is convenient to extend our considerations to Jacobians of all degree. For a curve $X = \cup_{v \in V} C_v$ and any multidegree $\underline{d} \in \mathbb{Z}^V$ we write $\mathrm{Pic}^{\underline{d}}(X)$ for the moduli space of line bundles of multidegree $\underline{d}$. Now, J_X is identified with $\mathrm{Pic}^{(0,\ldots,0)}(X)$ and we have non-canonical isomorphisms $J_X \cong \mathrm{Pic}^{\underline{d}}(X)$.

The universal degree-d Jacobian over $\mathfrak{M}_g$ is a morphism $\mathcal{P}_g^d \to \mathfrak{M}_g$, whose fiber over the point parametrizing a smooth curve X is $\mathrm{Pic}^d(X)$. We want to construct a compactification of $\mathcal{P}_g^d$ over $\overline{\mathfrak{M}}_g$ by a projective morphism $\overline{\mathcal{P}}_g^d \to \overline{\mathfrak{M}}_g$ such that $\overline{\mathcal{P}}_g^d$ has a moduli description. We shall refer to such a space as a compactified universal degree-d Jacobian.

From this perspective there is a natural approach to the problem, namely imitate the construction of $\overline{\mathfrak{M}}_g$ itself. Recall that the moduli scheme, $\overline{M}_g$, of the stack $\overline{\mathfrak{M}}_g$ was constructed by Gieseker [1982] as the GIT-quotient of the Hilbert scheme of n-canonically embedded curves ($n \gg 0$). The moduli stack $\overline{\mathfrak{M}}_g$ is the quotient stack associated to this quotient.

Now, as the Hilbert scheme of n-canonically embedded curves of genus g has such a beautiful GIT-quotient, why shouldn't the Hilbert scheme of all projective curves of degree $d \gg 0$ and genus g have a beautiful GIT-quotient? And why shouldn't this quotient be a candidate for a compactification of the universal degree-d Jacobian? Indeed, this is what happens, and the GIT quotient of this Hilbert scheme is our compactified universal degree-d Jacobian, $\overline{P}_g^d$. The corresponding quotient stack is denoted by $\overline{\mathcal{P}}_g^d$.

Now, as d varies, the spaces $\overline{\mathcal{P}}_g^d$ are not isomorphic to one another, and their fibers over certain singular curves are not even birational to one another. Again, we see the phenomenon (appearing already in Oda and Seshadri [1979]) that non isomorphic compactifications of the Jacobian of a fixed singular curve exist. In the present case the various models depend on the degree d.

As for the basic properties of the spaces $\overline{\mathcal{P}}_g^d$ as d varies, there is a special set of degrees, namely those such that (6) holds, such that $\overline{P}_g^d$ is a geometric GIT-quotient and has good moduli properties, so that its points correspond to geometric objects up to a certain equivalence relation. Moreover, the natural (projective) morphism $\psi_d : \overline{\mathcal{P}}_g^d \longrightarrow \overline{\mathfrak{M}}_g$ is a strongly representable map of Deligne-Mumford stacks. As we said in subSection 2.3 in this case all fibers of ψ_d are Néron compactified Jacobians.

Now, (6) fails if $d = g - 1$ whereas it holds if $d = g$. We shall concentrate on these two cases, interesting for different reasons, and give a combinatorial analysis of the compactified Jacobian.

4.2 Compactified Jacobians in degree $g-1$.

We begin by reviewing an idea of Beauville. Let us fix $g \geq 2$. Among degree-d Jacobians, the case $d = g - 1$ has been object of special interest for its strong connections with the Theta divisor, the Schottky problem, the Prym varieties; in particular, it has been studied in Beauville [1977].

Let us approach the problem of compactifying the degree $(g-1)$-Jacobian of a curve X with $G = (V, E, h)$ as dual graph. We expect a good compactification to have finitely many irreducible components and each component to parametrize (at least away from the boundary) line bundles on X of a fixed multidegree $\underline{d}$ such that $|\underline{d}| = g - 1$. Now the question is to determine these “special” multidegrees. Consider the identity

$$g - 1 = \sum_{v \in V} \big(h(v) - 1\big) + |E|.$$

We can interpret the first term (i.e. the summation) as carrying the topological invariants of X, and the second term, $|E|$, as carrying the combinatorial ones. Now, while the first term exhibits the single contribution of each vertex/component, the second does not. So we may ask how to distribute the second term among the various vertices in a combinatorially meaningful way. A natural solution is to consider an orientation, O, on G, and denote by $\underline{t}_v^O$ the number of edges having v as target. Then $\sum_{v\in V} \underline{t}_v^O = |E|$. Therefore, if we define a multidegree $\underline{d}^O$ as follows

$$\underline{d}_v^O := h(v) - 1 + \underline{t}_v^O,$$

for every $v \in V$, we have $|\underline{d}^O| = g - 1$. As there are only finitely many orientations on a graph, by the above rule we have picked a finite set of special multidegrees of degree $g - 1$. More precisely, it may happen that two orientations, O and O', give the same multidedegree; in such a case we say that O and O' are *equivalent*. We denote by $\overline{O}(G)$ the set of such equivalence classes of orientations on G. Now, a closer look reveals that $\overline{O}(G)$ is still too big for it to parametrize the irreducible components of a compactified

Jacobian. Indeed, from the discussion in SubSection 2.2 we expect the number of such components to be at most equal to $|\Phi_G|$, whereas we have $|\overline{O}(G)| > |\Phi_G|$ in general (for example for a 2-cycle, as in the picture below).

So, to compactify the degree-$(g-1)$ Jacobian we must distinguish a special type of orientations. These are called *totally cyclic* orientations, defined as orientations such that any two vertices in the same connected component of G lie in a directed cycle. It tuns out that if two orientations are equivalent, one is totally cyclic if the other one is. The set of equivalence classes of totally cyclic orientations on G is denoted by $\overline{O}^0(G)$.

In the picture below we have the four orientations on a 2-cycle. The first two are totally cyclic and equivalent. The last two are not totally cyclic.

We shall adopt the convention that the empty orientation on the graph consisting of only one vertex and no edges is totally cyclic. We notice the following facts.

Remark 4.2.1. (a) $\overline{O}^0(G)$ is empty if and only if G contains some bridge.

(b) Assume G connected. Then $|\overline{O}^0(G)| \leq |\Phi_G|$ with equality if and only if $|V| = 1$.

The set of all orientations on the spanning subgraphs of a graph G admits a partial order as follows. Let O_{S_1} and O_{S_2} be two orientations on $G - S_1$ and $G - S_2$ respectively, where $S_i \subset E(G)$ for $i = 1, 2$. We set $O_{S_1} \leq O_{S_2}$ if $G - S_1 \subset G - S_2$ and if the restriction of O_{S_2} to $G - S_1$ equals O_{S_1}.

This definition is compatible with the equivalence relation defined above, and hence the set of all equivalence classes of totally cyclic orientations on G is a poset, which we shall denote as follows

$$\overline{\mathcal{OP}}^0(G) := \bigsqcup_{S \subset E(G)} \overline{O}^0(G - S).$$

Finally, we are ready to exhibit a graded stratification of $\overline{P}_X^{g-1}$ governed by totally cyclic orientations, by rephrasing some results in Caporaso and Viviani [2010].

Proposition 4.2.2. *Let X be a stable curve of genus g and G its dual graph. Then the following is a graded stratification*

$$\overline{P}_X^{g-1} = \bigsqcup_{\overline{O_S}\in\overline{\mathcal{OP}}^0(G)} P_X^{O_S}, \tag{11}$$

and we have natural isomorphisms for every $\overline{O_S} \in \overline{\mathcal{OP}}^0(G)$

$$P_X^{O_S} \cong \operatorname{Pic}^{\underline{d}^{O_S}}(X_S^\nu). \tag{12}$$

The isomorphisms (12) exhibit the recursive behaviour described in Remark 2.3.3. Indeed, $\operatorname{Pic}^{\underline{d}^{O_S}}(X_S^\nu) \cong J_{X_S^\nu}$ and $\underline{d}^{O_S}$ is the multidegree associated to a totally cyclic orientation on $G - S$. Hence the boundary of the compactified degree-$(g-1)$ Jacobian of X is stratified by Jacobians of degree $(g(X')-1)$ of partial normalizations, X', of X.

Remark 4.2.3. If X is reducible and not of compact type then $\overline{P}_X^{g-1}$ is not of Néron type, by Remark 4.2.1(b).

A tropical counterpart of the stratification (11) is not known to us.

The compactified Jacobians in degree $g-1$ have been proved especially useful in various situations and in connection with the Theta divisor, whose definition extends to these compactified Jacobians. Among the applications, we recall that the pair given by this degree-$(g-1)$ Jacobian and its Theta divisor, $(\overline{P}_X^{g-1}, \overline{\Theta}_X)$, is endowed with a natural group action of J_X and, as such, forms a so-called *principally polarized stable semi-abelic pair*. These pairs appear as boundary points in the compactification, $\overline{A}_g^{\text{mod}}$, of the moduli space of principally polarized abelian varieties constructed in Alexeev [2002]. Moreover, by Alexeev [2004], they form the image of the compactified Torelli map and we have

Proposition 4.2.4. *The extended Torelli morphism $\overline{\tau}: \overline{M}_g \to \overline{A}_g^{mod}$ mapping a curve X to $(\overline{P}_X^{g-1}, \overline{\Theta}_X)$ is the moduli map associated to the family $\psi_{g-1}: \overline{P}_g^{g-1} \to \overline{M}_g$.*

The combinatorial structure of $\overline{P}_X^{g-1}$ described in Proposition 4.2.2 is heavily used in Caporaso and Viviani [2010] to study the fibers of $\overline{\tau}$.

4.3 Jacobians in degree g: Néron compactified Jacobians. We now adapt the considerations at the beginning of the previous sections to the case $d = g$. We have $g = \sum_{v\in V}(h(v)-1)+|E|+1$ and, as before, we want to express the term $|E|+1$ in a combinatorially meaningful way. Modifying what we did earlier, we now consider orientations having one bioriented edge. More precisely, a *1-orientation* on a graph G is the datum of a *bioriented* edge, e, and of an orientation on $G - e$. For any 1-orientation we have, of course, $|\underline{d}^O| = g(G)$. Just as in the previous subsection we restricted to totally cyclic orientations, now we need to restrict to certain special 1-orientations, namely "rooted" orientations. A 1-orientation with bioriented edge e is said to be *rooted* (or *e-rooted*) if for every vertex v there exists a directed path from e to v.

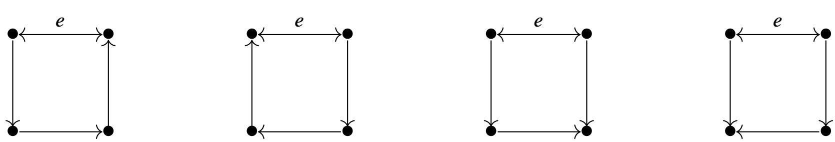
As before, two 1-orientations O and O' such that $\underline{d}^O = \underline{d}^{O'}$ are defined to be equivalent, moreover one is rooted if the other one is. We denote by $\overline{O}^1(G)$ the set of equivalence classes of rooted 1-orientations on G.

We decree the empty orientation on the graph consisting of only vertex and no edges to be rooted. Similarly to Remark 4.2.1 we have:

Remark 4.3.1. (a) $\overline{O}^1(G)$ is not empty if and only if G is connected.

(b) $|\overline{O}^1(G)| = |\Phi_G|$.

In the picture below we have all e-rooted orientations on a 4-cycle with fixed bioriented edge e. They correspond to the four elements in $\overline{O}^1(G)$.



In Theorem 2.3.1 we exhibited a stratification indexed by the poset of connected spanning subgraphs, $\mathcal{C}(G)$. The strata of that stratification are not connected, we shall now exhibit a finer stratification with connected strata.

Recall that rooted 1-orientations exist only on connected graphs. The poset of equivalence classes of rooted 1-orientations on all spanning subgraphs of G is written as follows

$$\overline{\mathcal{OP}}^1(G) := \bigsqcup_{S \in \mathcal{C}(G)} \overline{O}^1(G - S), \tag{13}$$

with the partial order defined in the previous section.

The following result of Christ [2017] states that $\overline{P}^g_X$ admits a recursive graded stratification governed by rooted orientations.

Theorem 4.3.2 (Christ)**.** *Let X be a stable curve of genus g and G its dual graph. Then $\overline{P}^g_X$ admits the following graded stratification*

$$\overline{P}^g_X = \bigsqcup_{\overline{O_S}\in\overline{\mathcal{OP}}^1(G)} P_X^{O_S}, \tag{14}$$

and we have natural isomorphisms for every $\overline{O_S} \in \overline{\mathcal{OP}}^1(G)$

$$P_X^{O_S} \cong \mathrm{Pic}^{\underline{d}^{O_S}}(X_S^\nu). \tag{15}$$

Remark 4.3.3. Comparing with the stratification of Theorem 2.3.1 we have, using (13), that (14) is a refinement of (7), with connected strata.

In this case we do have a tropical counterpart. First, consistently with the dual stratifications (9) and (10), a tropical counterpart of X is a tropical curve Γ whose underlying graph is the dual graph of X.

We now assume $\Gamma = (G, \ell)$ is compact (i.e. not extended). The tropical curve Γ has a Picard group $\mathrm{Pic}(\Gamma) = \sqcup \mathrm{Pic}^d(\Gamma)$, and each connected component, $\mathrm{Pic}^d(\Gamma)$, is isomorphic to the same $b_1(G)$-dimensional real torus; see Mikhalkin and Zharkov [2008]. In An, Baker, Kuperberg, and Shokrieh [2014], the authors show that $\mathrm{Pic}^g(\Gamma)$ has an interesting polyhedral decomposition indexed by "break divisors" on G. The connection between break divisors and rooted 1-orientations is established, as a consequence of the results in An, Baker, Kuperberg, and Shokrieh [ibid.], in Christ [2017], where the following result is obtained.

Theorem 4.3.4. *Let $\Gamma = (G, \ell)$ be a compact tropical curve of genus g. Then $\mathrm{Pic}^g(\Gamma)$ admits the following graded stratification*

$$\mathrm{Pic}^g(\Gamma) = \bigsqcup_{\overline{O_S}\in\overline{\mathcal{OP}}^1(G)^*} \Sigma_\Gamma^{O_S}. \tag{16}$$

The stratification (16) is a non-trivial rephrasing of the polyhedral decomposition established in An, Baker, Kuperberg, and Shokrieh [2014]. Such a rephrasing is needed to establish the connection with the stratification (14). From An, Baker, Kuperberg, and Shokrieh [ibid.] it follows that the strata $\Sigma_\Gamma^{O_S}$ are the interiors of the faces of a polyhedral decomposition for $\mathrm{Pic}^g(\Gamma)$.

Presently, we do not know whether the duality between the stratifications (16) and (14) can be given an interpretation in terms of tropicalization and analytification, similarly to the cases described in subsections 3.2 and 3.3.

This problem is related to a result of Baker and Rabinoff [2015], which we will state in our notation. Using Theorem 3.2.1, let $\mathfrak{X}_K$ be a smooth curve, $J_{\mathfrak{X}_K}$ its Jacobian, and let $\Gamma = \mathrm{trop}([\mathfrak{X}_K])$, where $[\mathfrak{X}_K]$ is the point of $\overline{M}_g^{\mathrm{an}}$ corresponding to $\mathfrak{X}_K$. Hence Γ is a compact tropical curve of genus g (compactness follows from $\mathfrak{X}_K$ being smooth). With this set-up, Baker and Rabinoff [ibid., Thm. 1.3] yields

Theorem 4.3.5 (Baker-Rabinoff)**.** $\mathrm{Pic}^g(\Gamma) \cong \Sigma(J^{\mathrm{an}}_{\mathfrak{X}_K})$.

With this result in mind, a natural approach to the problem mentioned above would be to study the relation between $\Sigma(J^{\mathrm{an}}_{\mathfrak{X}_K})$ and $\overline{P}^g_X$.

Finally, consider the universal compactified Jacobian. Results from Christ [2017] indicate that an analogue of Theorem 4.3.2 should hold uniformly over $\overline{\mathfrak{M}}_g$, so that the universal compactified Jacobian $\overline{\mathfrak{P}}^g_g$ can be given a graded stratification compatible with that of $\overline{\mathfrak{M}}_g$. We expect the same to hold for the universal compactified Jacobian in degree $g-1$, with Proposition 4.2.2 as starting point.

ON EXPLICIT ASPECT OF PLURICANONICAL MAPS OF PROJECTIVE VARIETIES

Jungkai A. Chen (陳榮凱) and Meng Chen (陈猛)

Abstract

In this survey article, we introduce the development of birational geometry associated to pluricanonical maps. Especially, we explain various aspects of explicit studies of threefolds including the key idea of theory of baskets and other applications.

1 Introduction

In the realm of birational geometry, divisors are perhaps the most important objects. Classically they were used to keep track of the property of zeros and poles and naturally developed into a convenient tool to study functions with preassigned conditions. Thus one may study linear systems associated to various interesting divisors. Among all divisors, the canonical divisor K, together with m-th canonical divisor mK for any $m \in \mathbb{Z}$, plays the central role. The behavior of pluricanonical maps φ_m or pluricanonical systems $|mK|$ is intensively studied in the minimal model program (in short, MMP) as well as other "canonical" classification problems. In fact, many very important concepts in algebraic geometry such as Kodaira dimension, Iitaka fibration, canonical volume, extremal contractions in minimal model program and so on, are defined on the basis of specific properties of the canonical divisor K.

More explicitly let V be any nonsingular projective variety of dimension n. For any $m \in \mathbb{Z}$, denote by $\varphi_{m,V}$ the m-canonical map of V. The following three types of problems are in the core of birational geometry:

Question 1.1. For any integer $n \geq 3$, find a practical integer r_n so that, for all nonsingular projective n-folds of general type, φ_m is birational onto its image for all $m \geq r_n$.

The first author was partially supported by NCTS and Ministry of Science and Technology of Taiwan. The second author was supported by National Natural Science Foundation of China (#11571076, #11231003, #11421061) and Program of Shanghai Subject Chief Scientist (#16XD1400400).

MSC2010: primary 14J30; secondary 14E99.

Question 1.2. For any integers $n \geq 3$ and $n > \kappa \geq 0$, find integers $M_{n,\kappa}$ and $d_{n,\kappa}$ such that, for all nonsingular projective n-folds with Kodaira dimension κ, the m-th canonical map φ_m defines an Iitaka fibration for all $m \geq M_{n,\kappa}$ and divisible by $d_{n,\kappa}$.

Question 1.3. For any integer $n \geq 3$, find an integer m_n so that, for all canonical (terminal) weak $\mathbb{Q}$-Fano n-folds (i.e. $-K$ being $\mathbb{Q}$-Cartier, nef and big), φ_{-m} is birational onto its image for all $m \geq m_n$.

First we recall some results on the quest of existence for r_n, $M_{n,\kappa}$ and m_n.

- For varieties V of general type, the remarkable theorem, proved separately by Hacon and McKernan [2006], Takayama [2006] and Tsuji [2006], asserts that there is a constant $\tilde{r}_n$ depending only on the dimension n ($n > 2$) such that $\varphi_{m,V}$ is birational for all $m \geq \tilde{r}_n$.

- For varieties of intermediate Kodaira dimension, say $0 < \kappa(V) < n$, the effective Iitaka fibration conjecture predicts that there exists a constant $\tilde{c}_n$ depending only on n such that $\varphi_{m,V}$ defines an Iitaka fibration for all $m \geq \tilde{c}_n$ and divisible. The canonical bundle formula of Fujino and Mori [2000] serves as the fundamental tool in this situation. The up-to-date result, due to Birkar and Zhang [2016] says that there exists a uniform number $M(n, b_F, \beta_{\tilde{F}})$ so that φ_m gives an Iitaka fibration for all $m \geq M(n, b_F, \beta_{\tilde{F}})$ and divisible. The numbers b_F and $\beta_{\tilde{F}}$ are defined as follows. Let F be the general fiber of Iitaka fibration. The number b_F, called the *index of fiber*, is the smallest positive integer so that $|bK_F| \neq \varnothing$. One has a covering $\tilde{F} \to F$ by $|mK_F|$. Then $\beta_{\tilde{F}}$, called the *middle Betti number*, is defined as the $(n-\kappa)$-th Betti number of the $n-\kappa$ dimensional variety $\tilde{F}$. One may refer to Viehweg and Zhang [2009], G. Todorov and Xu [2009], Pacienza [2009], X. Jiang [2013], Di Cerbo [2014] and Birkar and Zhang [2016] for more details along this direction.

- For canonical (resp. terminal) weak $\mathbb{Q}$-Fano threefolds, the boundedness was proved by Kawamata [1992] under the condition that the Picard number $\rho = 1$ and by Kollár, Miyaoka, Mori, and Takagi [2000] for the general case with $\rho > 1$. Recent breakthrough of Birkar [2016] asserts that even for $n \geq 4$ there is a constant $\tilde{m}_n$ depending only on n such that $\varphi_{-m,V}$ is birational for all $m \geq \tilde{m}_n$.

It is interesting to study the explicit aspect of pluricanonical maps of projective varieties in high dimensions. Some recent advances show that r_3, m_3, and $M_{3,\kappa}$ have realistic bounds which are very close to being optimal. The purpose of this survey article is to introduce and to sketch some of the key ideas and techniques developed from those explicit studies of 3-folds. We expect that such detailed and explicit studies of 3-folds will pave a solid path toward the understanding of higher dimensional birational geometry.

Throughout, all varieties are considered over an algebraically closed field k of characteristic zero.

2 Theory of weighted baskets

The understanding of terminal and canonical singularities plays the essential role in the development of three dimensional geometry. The milestone work of the existence of flips in dimension three, due to Mori [1988], built on the classification of terminal singularities and extremal neighborhoods. Moreover, Reid showed that each terminal singularities can be deformed into cyclic quotient singularities. Hence, the collection of deformed quotient singularities carries ample information of singularities. This leads to the notion of *baskets of terminal orbifold points*. For simplicity, a terminal orbifold point of type $\frac{1}{r}(1,-1,b)$ will be denoted as (b,r) with $b \le r/2$. A basket, which is a collection of terminal orbifold points, is written as $\mathcal{B} = \{n_i \times (b_i, r_i)\}$ where n_i denotes the multiplicities.

The subsequent result of singular Riemann-Roch formula (see Reid [1987]) can be derived by computing the contribution of basket of singularities, say

$$\chi(\mathcal{O}_X(D)) = \chi(\mathcal{O}_X) + \frac{1}{12}D(D-K_X)(2D-K_X) + \frac{1}{12}(D.c_2(X)) + \sum_{P\in B(X)} \left(-i_P \cdot \frac{r_P^2-1}{12r_P} + \sum_{j=1}^{i_P-1} \frac{\overline{jb_P}(r_P-\overline{jb_P})}{2r_P} \right),$$

where $c_2(X)$ is defined in the sense of intersection theory, $B(X) = \{(b_P, r_P)\}$ is the basket data of X and i_P is the local index of D such that $\mathcal{O}_X(D) \cong \mathcal{O}_X(i_P K_X)$ near P.

By applying the singular Riemann-Roch formula to $D = K_X$, then one gets

$$(K_X.c_2(X)) = -24\chi(\mathcal{O}_X) + \sum_{P\in B_X} \left(r_P - \frac{1}{r_P} \right).$$

This leads to various results. For example, Kawamata and Morrison's result on the global index of 3-folds with $K_X \equiv 0$ was then derived (see Section 5).

By taking $D = mK_X$ and replacing $(K_X.c_2(X))$ with $\chi(\mathcal{O}_X)$ and the contribution of singularities, we get the following plurigenus formula Reid [ibid.]:

$$\chi_m = \frac{1}{12}m(m-1)(2m-1)K^3 + (1-2m)\chi + l(m), \tag{2-1}$$

where $\chi = \chi(\mathcal{O}_X)$, $K^3 = K_X^3$, $\chi_m = \chi(\mathcal{O}_X(mK_X))$ and

$$l(m) = \sum_{P\in B_X} \sum_{j=1}^{m-1} \frac{\overline{jb_P}(r_P-\overline{jb_P})}{2r_P}. \tag{2-2}$$

It is clear from the Riemann-Roch formula that the triple (B_X, χ_2, χ) determine χ_m for all $m \geq 3$. We call the triple $\mathbb{B} = \{B, \chi_2, \chi\}$ a *weighted basket*, where B is a basket of orbifold points, χ_2 is a non-negative integer and χ is an integer. For any $m \geq 3$, χ_m can be inductively and formally defined by means of (2-1). Note that the rational number K^3, which is also uniquely determined by $\mathbb{B}$, is called the volume of $\mathbb{B}$.

Given a basket

$$B = \{(b_1, r_1), (b_2, r_2), \dots, (b_k, r_k)\},$$

we call the basket

$$B' := \{(b_1 + b_2, r_1 + r_2), (b_3, r_3), \dots, (b_k, r_k)\}$$

a packing of B, written as $B \succcurlyeq B'$. If $b_1 r_2 - b_2 r_1 = 1$, then we call $B \succcurlyeq B'$ a *prime packing*.

Then we introduced the "canonical sequence of prime unpackings of a basket" in J. A. Chen and M. Chen [2010b]:

$$B^{(0)}(B) \succcurlyeq B^{(5)}(B) \succcurlyeq \dots \succcurlyeq B^{(n)}(B) \succcurlyeq \dots \succcurlyeq B,$$

so that $B^{(n)}$ consists of orbifold points (b_i, r_i) with either $r_i \leq n$ or $b_i = 1$. The basket $B^{(0)}$, called *the initial basket*, consists of orbifold points of the form $(1, r_i)$. Take an orbifold point (b, r) for example. Let $q = \lfloor \frac{r}{b} \rfloor$. Then $\frac{1}{q} \geq \frac{b}{r} \geq \frac{1}{q+1}$. Indeed, let $\beta := r - qb$, then the initial basket of (b, r) is $\{(b - \beta) \times (1, q), \beta \times (1, q+1)\}$.

The packing of baskets naturally induces the packing of weighted baskets, namely we define

$$\{B, \chi_2, \chi\} \succcurlyeq \{B', \chi_2, \chi\}$$

if $B \succcurlyeq B'$. Furthermore, any given weighted basket $\mathbb{B}$ has the corresponding "canonical sequence":

$$\mathbb{B}^{(0)} \succcurlyeq \mathbb{B}^{(5)} \succcurlyeq \dots \succcurlyeq \mathbb{B}^{(n)} \succcurlyeq \dots \succcurlyeq \mathbb{B}.$$

As revealed in J. A. Chen and M. Chen [ibid., Section 3], the intrinsic properties of the canonical sequence provide many new inequalities among the Euler characteristic and other characteristics of a given weighted basket $\mathbb{B}$, of which the most interesting one is:

$$2\chi_5 + 3\chi_6 + \chi_8 + \chi_{10} + \chi_{12} \geq \chi + 10\chi_2 + 4\chi_3 + \chi_7 + \chi_{11} + \chi_{13} + R, \tag{2-3}$$

where R is certain non-negetative combination of all initial baskets with higher indices.

Although the above notions were introduced in a very formal way, it was proved to be quite effective for various geometric problems, which we will discuss in next sections. Also, even though the notion of packings was introduced to study the numerical behavior rather than its geometric meaning at the beginning. The relation appears in divisorial contractions to points.

Example 2.1. Let $P = \frac{1}{9}(2,7,1) \in X \cong \mathbb{C}^3/\mu_9$ be a terminal quotient singularity. Let $Y \to X$ be the weighted blowup with weights $\frac{1}{9}(2,7,1)$. Then the basket of Y is $B_Y = \{(1,2),(3,7)\}$ and the basket of X is $\{(4,9)\}$ which is a packing of B_Y. This is an example of *Kawamata blowup* (cf. Kawamata [1996]).

Example 2.2. Let $P \in X \cong (xy + z^{15} + u^2 = 0) \subset \mathbb{C}^4/\mu_5$ (of type $\frac{1}{5}(3,2,1,5)$) be a $cA/5$ singularity. Let $Y \to X$ be a weighted blowup with weights $\frac{1}{5}(3,7,1,5)$. Then the basket of Y is $\{(3,7),(1,3)\}$ and the basket of X is $\{2 \times (2,5)\}$. They have the same initial baskets $\{2 \times (1,2), 2 \times (1,3)\}$.

3 Pluricanonical maps of threefolds of general type

We consider 3-folds of general type in this section. Since minimal models exist and the problems are birational in nature, we usually work on minimal projective 3-folds of general type with $\mathbb{Q}$-factorial terminal singularities, unless otherwise stated. Denote by r_X the Cartier index of X. Define the *canonical stability index*

$$r_s(X) = \min\{t \mid \varphi_{m,X} \text{ is birational for all } m \geq t\}.$$

Clearly $r_3 = \max\{r_s(X) \mid X \text{ is a minimal 3-fold of general type}\}$.

3.1 The case $r_X = 1$.

When X is smooth and minimal, it is Wilson [1980] who first proved that $r_s(X) \leq 25$. Then this was improved, chronoligically, by Benveniste [1986] ($r_s(X) \leq 9$), Matsuki [1986] ($r_s(X) \leq 7$) and the second author M. Chen [1998] ($r_s(X) \leq 6$).

In fact, the method of Benveniste, Matsuki and the second author can be easily extended to the situation, when X is Gorenstein and minimal, by using a special partial resolution due to Reid [1983] and Miyaoka [1987]. Note also that S. Lee [2000] proved the optimal base point freeness of $|4K|$.

Example 3.1. Let $X = S \times C$ where S is a minimal surface of general type of $(1,2)$-type and C is a complete curve of genus ≥ 2. Then $r_s(X) = 5$ according to Bombieri [1973]. Thus, for Gorenstein minimal 3-folds of general type, the best one can expect is that $r_s(X) \leq 5$ holds.

Question 1.1 in the case of $n = 3$ and $r_X = 1$ was finally solved in 2007 by the authors and De-Qi Zhang:

Theorem 3.2. *(J. A. Chen, M. Chen, and Zhang [2007, Theorem 1.1]) Let X be a minimal projective 3-fold of general type with $r_X = 1$. Then $\varphi_{m,X}$ is a biratioal morphism for every integer $m \geq 5$.*

3.2 Kollár's method.

The work of Kollár on push-forward of dualizing sheaves provide various important applications in the study of higher dimensional geometry. One of the them is to reduce the birationality problem to non-vanishing of plurigenera as in the following theorem:

Theorem 3.3. *(Kollár [1986, Corollary 4.8]) Let V be a nonsingular projective 3-fold of general type with $P_k(V) \geq 2$ for some integer $k > 0$. Then φ_{11k+5} is birational.*

The key contribution of Theorem 3.3 in the process of solving Question 1.1 ($n = 3$) is that it reduces to the problem to find an effective integer k so that $P_k \geq 2$, which is the standard task of Riemann-Roch formula.

Kollár's method of proving Theorem 3.3 is as follows. If one takes a sub-pencil $\Lambda \subset |kK_V|$, modulo a further birational modification if necessary, one gets a surjective morphism $f : V \longrightarrow \Gamma \cong \mathbb{P}^1$. One has the inclusion $\mathcal{O}(1) \hookrightarrow f_*\omega_V^k$ and then, for any $p \geq 5$,

$$f_*\omega_{V/\Gamma}^p \otimes \mathcal{O}(1) \hookrightarrow f_*\omega_V^{(2p+1)k+p}.$$

Since the 5-canonical map of the general fiber is birational and by the semi-positivity of $f_*\omega_{V/\Gamma}^p$, one sees that φ_{11k+5} is birational by simply taking $p = 5$.

Theorem 3.3 was considerably improved by the second author M. Chen [2004a, Theorem 0.1] that, under the same condition as that of Theorem 3.3, φ_{5k+6} is birational. Some further optimal results were proved in M. Chen [2003], M. Chen [2004a], M. Chen [2007], and J. A. Chen and M. Chen [2010a].

3.3 The case of $r_X \geq 2$.

Turning to the general situation that minimal model contains some singularities of index ≥ 2. Suppose $\chi(\mathcal{O}_X) < 0$. Reid's Riemann-Roch formula implies $P_2(X) \geq 4$. Hence the question is solvable by Kollár's theorem. Suppose that $P_k \geq 2$ for some $k \leq 12$, one can apply Kollár's method as well.

It remains to consider $\chi(\mathcal{O}_X) \geq 0$ and $P_k(X) \leq 1$ for all $2 \leq k \leq 12$. The key inequality (2-3) reads:

$$2P_5 + 3P_6 + P_8 + P_{10} + P_{12} \geq \chi(\mathcal{O}_X) + 10P_2 + 4P_3 + P_7 + P_{11} + P_{13}, \tag{3-1}$$

which directly implies that $\chi(\mathcal{O}_X) \leq 8$. This also means that P_{13} is upper bounded by 7. In practice, one may obtain more precise bounds for both $\chi(\mathcal{O}_X)$ and P_{13}. It turns out that the 12-th weighted basket $\mathbb{B}^{12}(X)$ has only finite possibilities and so does $\mathbb{B}(X)$. It is then possible to answer Question 1.1, which was the main work in the authors' papers J. A. Chen and M. Chen [2010b,a, 2015a].

To improve or to reach the possible optimal bound, one needs to study the birational geometry explicitly. Known useful techniques include some effective method to estimate the lower bound of K_X^3 and better birationality criterion of $\varphi_{m,X}$ under the assumption that $P_{m_0} \geq 2$ for some number $m_0 > 0$, which is a kind of improvement to Kollár's method. We briefly describe the technique below. Indeed, if $P_{m_0} \geq 2$, then one has an induced fibration from a sub-pencil of $|m_0 K|$, say $f : X' \longrightarrow \Gamma$, where X' is a smooth model of X and Γ is a smooth complete curve. Denote by $\pi : X' \longrightarrow X$ the birational morphism. Pick a general fiber F of f and denote by $\sigma : F \longrightarrow F_0$ the contraction onto its minimal model. Naturally one has

$$m_0 \pi^*(K_X) \equiv pF + E_{m_0},$$

for some integer $p > 0$ and effective $\mathbb{Q}$-divisor E_{m_0}. The key point is to prove the so-called "canonical restriction inequality" (see M. Chen [2003], M. Chen [2004a], M. Chen [2007], M. Chen and Zhang [2008], M. Chen and Zuo [2008], and J. A. Chen and M. Chen [2010a, 2015a] for its development history) as follows:

$$\pi^*(K_X)|_F \geq \frac{p}{m_0 + p} \sigma^*(K_{F_0}) \tag{3-2}$$

modulo $\mathbb{Q}$-linear equivalence. The inequality (3-2) directly gives an effective lower bound of K_X^3 and it is crucial as well in proving the birationality of $\varphi_{m,X}$.

Here are the main theorems of the authors as the answer to Question 1.1 ($n = 3$):

Theorem 3.4. *(J. A. Chen and M. Chen [2010b,a, 2015a]) Let X be a minimal projective 3-fold of general type. Then*

(1) $K_X^3 \geq \frac{1}{1680}$;

(2) $\varphi_{m,X}$ *is birational for all* $m \geq 61$;

(3) $P_{12} \geq 1$ *and* $P_{24} \geq 2$.

(4) $K_X^3 \geq \frac{1}{420}$ *(optimal) if* $\chi(\mathcal{O}_X) \leq 1$.

Remark 3.5. The statements are birational in nature. More precisely, φ_m are birationally equivalent on different birational models and the canonical volume $\mathrm{Vol}(V)$ is a birational invariant, equals to K_X^3 of a minimal model X. Therefore, the above statements can be also read as: Let V be a nonsingular projective 3-fold of general type. Then $\mathrm{Vol}(V) \geq \frac{1}{1680}$ and $\varphi_{m,V}$ is birational for all $m \geq 61$, etc.

Define the *pluricanonical section index* $\delta(X)$ to be the minimal integer so that $P_\delta \geq 2$. The author proved the following results:

Theorem 3.6. *(J. A. Chen and M. Chen [2010b,a, 2015a]) Let X be a minimal projective 3-fold of general type. Then*

(1) $\delta(X) \leq 18$*;*

(2) $\delta(X) = 18$ *if and only if* $\mathbb{B}(X) = \{B_{2a}, 0, 2\}$*;*

(3) $\delta(X) \neq 16,\ 17$*;*

(4) $\delta(X) = 15$ *if and only if* $\mathbb{B}(X)$ *belongs to one of the types in J. A. Chen and M. Chen [2015a,* Table F–1*];*

(5) $\delta(X) = 14$ *if and only if* $\mathbb{B}(X)$ *belongs to one of the types in J. A. Chen and M. Chen [ibid.,* Table F–2*];*

(6) $\delta(X) = 13$ *if and only if* $\mathbb{B}(X) = \{B_{41}, 0, 2\}$

where

$$B_{2a} = \{4 \times (1,2), (4,9), (2,5), (5,13), 3 \times (1,3), 2 \times (1,4)\} \text{ and}$$
$$B_{41} = \{5 \times (1,2), (4,9), 2 \times (3,8), (1,3), 2 \times (2,7)\}.$$

Example 3.7. Consider Fletcher's example, which is a general weighted hypersurface X_{46} of weighted degree 46 in weighted projective space $\mathbb{P}(4,5,6,7,23)$ (cf. Iano-Fletcher [2000]). Note that φ_{26} is not birational, $\chi(\mathcal{O}_X) = 1$ and $K_X^3 = \frac{1}{420}$. This provides an example of 3-fold for Theorem 3.4(4).

Recently the second author M. Chen [2016] showed $r_3 \leq 57$ on the basis of above classifications. Therefore, $27 \leq r_3 \leq 57$.

For 3-folds with $\delta = 1$, the second author proved the following optimal results:

Theorem 3.8. *(M. Chen [2003, 2007]) Let X be a minimal projective 3-fold of general type with $p_g(X) \geq 2$. Then*

(1) $K_X^3 \geq \frac{1}{3}$*;*

(2) $\varphi_{8,X}$ *is birational onto its image.*

3.4 On irregular 3-folds of general type. Let X be a minimal projective 3-fold of general type with $q(X) > 0$. One may consider the Albanese map of X. A pioneer work on this topic was due to J. A. Chen and Hacon [2002], who developed the Fourier-Mukai theory to study irregular varieties and proved the following theorem:

Theorem 3.9. *(J. A. Chen and Hacon [2002, 2007]) Let X be a minimal irregular 3-fold of general type. Then*

(1) $|mK_X + P|$ *gives a birational map for all* $m \geq 7$ *(resp.* $m \geq 5$*) and for all (resp. general)* $P \in \mathrm{Pic}^0(X)$.

(2) when $\chi(\omega_X) > 0$, $|mK_X + P|$ *gives a birational map for all* $m \geq 5$ *and for all* $P \in \mathrm{Pic}^0(X)$.

Theorem 3.9(ii) is clearly optimal. For Theorem 3.9(i), the authors and Jiang proved the following theorem:

Theorem 3.10. *(J. A. Chen, M. Chen, and Zhang [2007]) Let* X *be a minimal irregular 3-fold of general type. Then* $\varphi_{6,X}$ *is birational.*

Besides, the authors gave the following effective lower bound for K_X^3:

Theorem 3.11. *(J. A. Chen and M. Chen [2008b, Corollary 1.2]) Let* X *be a minimal irregular 3-fold of general type. Then* $K_X^3 \geq \frac{1}{22}$.

Question 3.12. Are the results in Theorem 3.10 and Theorem 3.11 optimal?

4 The anti-canonical geometry of $\mathbb{Q}$-Fano 3-folds

A normal projective 3-fold X is called a *weak* $\mathbb{Q}$*-Fano 3-fold* (resp. $\mathbb{Q}$*-Fano 3-fold*) if the anti-canonical divisor $-K_X$ is nef and big (resp. ample). A *canonical* (resp. *terminal)* weak $\mathbb{Q}$-Fano 3-fold is a weak $\mathbb{Q}$-Fano 3-fold with at worst canonical (resp. terminal) singularities.

Weak $\mathbb{Q}$-Fano varieties form a fundamental class in minimal model program and various aspects of birational geometry. Given a canonical weak $\mathbb{Q}$-Fano 3-fold X, the *m-th anti-canonical map* $\varphi_{-m,X}$ (or simply φ_{-m}) is the rational map defined by the linear system $|-mK_X|$. It is worthwhile to mention that the behavior of $\varphi_{-m,X}$ in not necessarily birationally invariant, which makes Question 1.3 much harder to work on.

We may always study on a terminal weak $\mathbb{Q}$-Fano 3-fold. Take the weighted basket

$$\mathbb{B}(X) = \{B_X, P_{-1}, \chi(\mathcal{O}_X)\}.$$

By the duality and the vanishing of higher cohomology, we have $\chi_m = -P_{-(m-1)}$ for all $m \geq 2$. Hence the basket theory introduced in Section 2 has a parallel version in Fano case. In fact, the basket theory works very well in classifying weak $\mathbb{Q}$-Fano 3-folds with small invariants.

4.1 Lower bound of the anti-canonical volume.

In 2008, the authors applied the basket theory to prove the following theorem:

Theorem 4.1. *(J. A. Chen and M. Chen [2008a, Theorem 1.1]) Let X be a terminal (or canonical) weak $\mathbb{Q}$-Fano 3-fold. Then*

(1) $P_{-4} > 0$ with possibly one exception of a basket of singularities;

(2) $P_{-6} > 0$ and $P_{-8} > 1$;

(3) $-K_X^3 \geq \frac{1}{330}$. Furthermore $-K_X^3 = -\frac{1}{330}$ if and only if the basket of singularities is $\{(1,2),(2,5),(1,3),(2,11)\}$.

Theorem 4.1.(3) is optimal according to the example of general hypersurface $X_{66} \subset \mathbb{P}(1,5,6,22,33)$ (cf. Iano-Fletcher [2000]).

4.2 The anti-pluricanonical birationality.

The second author started to study the constant for anti-pluricanonical birationality in M. Chen [2011] in 2011. A practical upper bound for m_3 for $\mathbb{Q}$-Fano 3-folds with Picard number one was proved by the second author and C. Jiang in 2016:

Theorem 4.2 (M. Chen and C. Jiang [2016, Theorem 1.6])**.** *Let X be a terminal $\mathbb{Q}$-Fano 3-fold of Picard number one. Then $\varphi_{-m,X}$ is birational for all $m \geq 39$.*

Theorem 4.3 (M. Chen and C. Jiang [ibid., Theorem 1.8, Remark 1.9])**.** *Let X be a canonical weak $\mathbb{Q}$-Fano 3-fold. Then $\varphi_{-m,X}$ is birational for all $m \geq 97$.*

The result in Theorem 4.2 is very close to be optimal according to Fletcher's example Iano-Fletcher [2000]. The numerical bound in Theorem 4.3, however, might be far from optimal. Recently the second author and Jiang had an improvement on this problem:

Theorem 4.4 (M. Chen and C. Jiang [2017, Theorem 1.9])**.** *Let V be a canonical weak $\mathbb{Q}$-Fano 3-fold. Then there exists a terminal weak $\mathbb{Q}$-Fano 3-fold X birational to V such that*

1. *$\dim \overline{\varphi_{-m}(X)} > 1$ for all $m \geq 37$;*
2. *$\varphi_{-m,X}$ is birational for all $m \geq 52$.*

Theorem 4.5 (M. Chen and C. Jiang [ibid., Theorem 1.10])**.** *Let V be a canonical weak $\mathbb{Q}$-Fano 3-fold. Then, for any K-Mori fiber space Y of V,*

1. *$\dim \overline{\varphi_{-m}(Y)} > 1$ for all $m \geq 37$;*
2. *$\varphi_{-m,Y}$ is birational for all $m \geq 52$.*

One notes that an intensive classification using the basket theory developed by the authors was done in proving Theorem 4.4 and Theorem 4.5.

It is a very interesting question to ask what the optimal value of m_3 is, which is crucial in studying the anti-canonical geometry of weak $\mathbb{Q}$-Fano 3-folds. One only knows $33 \le m_3 \le 97$ so far.

5 Threefolds with Kodaira dimension $0 \le \kappa < 3$

For varieties of Kodaira dimension 0, the question is then to find a uniform bound $M_{n,0}$ such that $|mK| \ne \varnothing$ for all m divisible by $M_{n,0}$ and for all n-dimensional varieties with $\kappa = 0$. It is well-known that $M_{2,0} = 12$.

For threefolds with Kodaira dimension 0, Kawamata proved that $0 \le \chi(\mathcal{O}_X) \le 4$. Comparing $\chi(\mathcal{O}_X)$ with $(K_X \cdot c_2)$, one knows the indices of singularities in its minimal model and hence it follows that a uniform bound $M_{3,0}$ exists (cf. Kawamata [1986]). By careful classification of possible singularities, Morrison shows that $|mK_X| \ne \varnothing$ if m is divisible by the Beauville's number (cf. Morrison [1986])

$$\mathrm{lcm}\{m|\phi(m) \le 20\} = 2^5 \cdot 3^3 \cdot 5^2 \cdot 7 \cdot 11 \cdot 13 \cdot 17 \cdot 19.$$

Note that 20 is chosen as $b_3(A)$ for any abelian threefold A. Indeed, by Oguiso's examples (cf. Oguiso [1993]), the minimal universal number $M_{3,0}$ is the Beauville's number.

For threefolds with $\kappa = 2$, Ringer shows that φ_m is birational to the Iitaka fibration as long as $m \ge 48$ and divisible by 12 (cf. Ringler [2007]). The explicit effective result for threefolds with $\kappa = 1$ was obtained by Hsin-Ku Chen very recently. He show that φ_m is birational to the Iitaka fibration as long as $m \ge 96$ and divisible by 12 (cf. H.-K. Chen [2017]) and hence $M_{3,1} \le 96$ and $d_{3,1} = 12$. There exists an example which shows that $M_{3,1} \ge 42$.

6 Further applications of the theory of baskets and the singular Riemann-Roch

6.1 Weighted complete intersections.

A weighted projective space is a natural generalization of projective spaces. Together with complete intersection inside them, weighted projective spaces provide ample examples. In Iano-Fletcher [2000], Fletcher gave a very detailed account of getting well-formed weighted complete intersection threefolds, including the classification of:

- canonically embedded codimension 1 and 2 weighted 3-folds with total weights < 100;

- weighted complete intersection $\mathbb{Q}$-Fano 3-folds of codimensions 1, 2 with total weights < 100.

Let $X = X_{d_1,\ldots,d_c} \subset \mathbb{P}(a_0, \ldots, a_n)$ be a weighted complete intersection. Let $\delta_j := d_j - a_{j+\dim X}$. By modifying Fletcher's proof, it's not difficult to verify that quasi-smoothness implies that $\delta_j \geq a_{j-1}$. Then the following Theorem follows.

Theorem 6.1. *(J.-J. Chen, J. A. Chen, and M. Chen [2011, Theorem 1.3]) There is no quasi-smooth (not an intersection of a linear cone with another subvariety) weighted complete intersection $X_{d_1,\ldots,d_c} \subset \mathbb{P}(a_0, \ldots, a_n)$ of codimension c greater than* $\dim X + 1 + \alpha$*, where $\alpha = \sum_j d_j - \sum_i a_i$.*

In order to classify 3-fold weighted complete intersections with at worst terminal singularities, let $\mu_i := \#\{a_j | a_j = i\}$, and $\nu_i := \#\{d_j | d_j = i\}$. By Theorem 6.1, we have $\sum \mu_i \leq \alpha + A, \sum \nu_i \leq \alpha + B$ for some small integers A, B. One can classify tuples $(\mu_1, \ldots, \mu_6; \nu_2, \ldots, \nu_6)$ (resp. $(\mu_1, \ldots, \mu_5; \nu_2, \ldots, \nu_5)$) when $\alpha = 1$ (resp. $\alpha = -1$) under given conditions. It is then possible to classify initial baskets of weighted baskets with given μ_i, ν_i's. For a given weighted basket, one can compute its plurigenera by Reid's Riemann-Roch formula. By Reid's "table method", which mainly works on Poincaré series, one can determine all possible weighted complete intersections with given formal baskets.

There might be infinitely many initial baskets with given μ_i, ν_i's since the index of each individual basket might be arbitrarily large. In the Fano case with $\alpha = -1$, one can use the property $(-K_X \cdot c_2) \geq 0$ to obtain the maximal index of basket. In the case of general type, one can use $K_X^3 > 0$ to exclude most of the baskets with large indices. The details can be found in J.-J. Chen, J. A. Chen, and M. Chen [ibid.].

To summarize, the following statement holds:

Theorem 6.2. *(see J.-J. Chen, J. A. Chen, and M. Chen [ibid., Part II]) The lists of threefold weighted complete intersections in Fletcher Iano-Fletcher [2000, pp. 15.1, 15.4, 16.6, 16.7, 18.16] are complete.*

For higher dimensional weighted complete intersections, one may refer to the interesting paper of Brown and Kasprzyk [2016].

6.2 On quasi-polarized threefolds.

One can also apply the technique of baskets and singular Riemann-Roch to study some quasi-polarized threefolds (X, L). For example, C. Jiang [2016] proved the following interesting results:

- Let X be a minimal 3-fold with $K_X \equiv 0$ and L a nef and big Weil divisor. Then $|mL|$ and $|K_X + mL|$ give birational maps for all $m \geq 17$.

- Let X be a minimal Gorenstein 3-fold with $K_X \equiv 0$ and L a nef and big Weil divisor. Then $|K_X + mL|$ gives a birational map for all $m \geq 5$.

7 A brief review to explicit birational geometry of higher dimensional varieties

In dimension 4 or higher, it seems very difficult or hopeless to have desired description of terminal singularities. Therefore it is hard to study the singular Riemann-Roch formula on minimal $\mathbb{Q}$-factorial terminal n-folds. In other words, many techniques described above for 3-folds do not work in higher dimensions.

Even though little is known for dimension 4 or higher. There are some interesting results that we would like to recall here. Interested readers may find possible paths to move on.

7.1 Projective varieties with very large canonical volumes.

Apart from considering the number r_n, it is also interesting to consider another optimal constant r_n^+ so that, for all nonsingular projective n-folds X of general type with $p_g(X) > 0$, $\varphi_{m,X}$ is birational for all $m \geq r_n^+$. By definition $r_n^+ \leq r_n$ for any $n > 0$. One has $r_1^+ = r_1 = 3$ and $r_2^+ = r_2 = 5$ according to Bombieri. We start with the review of Bombieri's result:

Theorem 7.1. *(see Bombieri [1973]) Let S be a minimal surface of general type. Then*

(1) when $p_g(S) \geq 4$, $r_s(S) \leq r_1^+ = 3$;

(2) when $K_S^2 \geq 3$, $r_s(S) \leq r_1 = 3$.

The 3-dimensional analogy was realized by the second author and Todorov respectively:

Theorem 7.2. *Let X be a minimal projective 3-fold of general type. Then*

(1) when $p_g(X) \geq 4$, $r_s(X) \leq r_2^+ = 5$ (see M. Chen [2003, Theorem 1.2 (2)]);

(2) when $K_X^3 > 12^3$, $r_s(X) \leq r_2 = 5$ (see G. T. Todorov [2007] and M. Chen [2012]).

Recently the second author and Jiang proved the following analogy in dimensions 4 and 5:

Theorem 7.3. *(M. Chen and Z. Jiang [2017a, Theorem 1.4]) There exists a constant $K(4) > 0$ such that for any minimal 4-fold X with $K_X^3 > K(4)$, $r_s(X) \leq r_3$.*

Theorem 7.4. *(M. Chen and Z. Jiang [2017a, Theorem 1.5]) There exist two constants $L(4) > 0$ and $L(5) > 0$. For any minimal n-fold X of general type with $p_g(X) \geq L(n)$ ($n = 4, 5$), $r_s(X) \leq r_{n-1}^+$.*

It is natural to ask whether such analogy holds in any dimension.

7.2 Pluricanonical maps on varieties of higher Albanese dimensions.

We recall the following interesting theorem on varieties of maximal Albanese dimensions:

Theorem 7.5. *(see J. A. Chen and Hacon [2002] and Z. Jiang and Lahoz [2013]) Let X be a smooth projective variety of maximal Albanese dimension and of general type. Then $\varphi_{m,X}$ is birational for $m \geq 3$.*

The result in the above theorem is clearly optimal. In fact there is the following generalization:

Theorem 7.6. *(see Z. Jiang and Sun [2015]) Let X be a smooth projective variety of general type and of Albanese fiber dimension one. Then $\varphi_{m,X}$ is a birational map for $m \geq 4$.*

Question 7.7. Under what condition $\varphi_{3,X}$ is birational for varieties of Albanese fiber dimension one?

Can one find optimal statement for varieties of Albanese fiber dimensions 2 and 3?

7.3 Geography of varieties of general type.

It is interesting to know how those birational invariants, such as the canonical volume, p_g, $\chi(\mathcal{O})$ and so on, reflect geometric properties of a given variety. Inequalities among birational invariants play important roles in the classification theory and many other geometrical problems.

In high dimensions, the famous inequality of Yau [1977, 1978] discloses the optimal relations between c_1 and c_2 on canonically polarized varieties, namely:

$$\frac{2(n+1)}{n}|c_1^{n-2} \cdot c_2| - |c_1^n| \geq 0$$

holds for any n-dimensional canonically polarized variety. Miyaoka [1987] proved that $3c_2 - c_1^2$ is pseudo-effective for canonically quasi-polarized (i.e. K being nef and big) varieties. One notices that Greb, Kebekus, Peternell, and Taji [2015] had an interesting generalization of the inequality of Yau and Miyaoka.

For Gorenstein minimal 3-folds of general type, the following inequality was proved by the authors J. A. Chen and M. Chen [2015b] (see M. Chen [2004b] and Catanese, M. Chen, and Zhang [2006] for historical context):

$$K^3 \geq \frac{4}{3}p_g - \frac{10}{3},$$

which is sharp thanks to examples of Kobayashi [1992]. Applying a key lemma in J. A. Chen and M. Chen [2015b], Hu [2013] proved the following optimal inequality:

$$K^3 \geq \frac{4}{3}\chi(\omega) - 2.$$

In a recent work of J. A. Chen and Lai [2017], two series of examples with small "slope" in arbitrary higher dimensions were constructed.

MIRROR SYMMETRY AND CLUSTER ALGEBRAS

PAUL HACKING AND SEAN KEEL

Abstract

We explain our proof, joint with Mark Gross and Maxim Kontsevich, of conjectures of Fomin–Zelevinsky and Fock–Goncharov on canonical bases of cluster algebras. We interpret a cluster algebra as the ring of global functions on a non-compact Calabi–Yau variety obtained from a toric variety by a blow up construction. We describe a canonical basis of a cluster algebra determined by tropical counts of holomorphic discs on the mirror variety, using the algebraic approach to the Strominger–Yau–Zaslow conjecture due to Gross and Siebert.

1 Introduction

We say a complex variety U is *log Calabi–Yau* if it admits a smooth projective compactification X with normal crossing boundary[1] D such that $K_X + D = 0$, that is, there is a nowhere zero holomorphic top form Ω on U with simple poles along D. The mirror symmetry phenomenon for compact Calabi–Yau manifolds extends to the case of log Calabi–Yau varieties, see Auroux [2009] and Section 4. We say U has *maximal boundary* if D has a 0-stratum (a point cut out by $n = \dim_{\mathbb{C}} X$ branches of D) and *positive* if D is the support of an ample divisor[2] (so in particular U is affine) . The *tropical set* $U^{\mathrm{trop}}(\mathbb{R})$ of U is the cone over the dual complex of D; we write $U^{\mathrm{trop}}(\mathbb{Z})$ for its integral points.

Conjecture 1-1. *Mirror symmetry defines an involution on the set of positive log Calabi–Yau varieties with maximal boundary. For a mirror pair U and V, there is a basis ϑ_q, $q \in U^{\mathrm{trop}}(\mathbb{Z})$ of $H^0(V, \mathcal{O}_V)$ parametrized by the integral points of the tropical set of U, which is canonically determined up to multiplication by scalars $\lambda_q \in \mathbb{C}^\times$, $q \in U^{\mathrm{trop}}(\mathbb{Z})$.*

This paper is based on joint work with Mark Gross and Maxim Kontsevich. The algebraic approach to the Strominger–Yau–Zaslow conjecture is due to Gross and Siebert. The authors were partially supported by NSF grants DMS-1601065 (P.H.) and DMS-1561632 (S.K.).
MSC2010: primary 14J33; secondary 13F60.

[1] More generally, (X, D) has $\mathbb{Q}$-factorial divisorial log terminal singularities (Kollár and Mori [1998], Definition 2.37).

[2] More generally, D is the support of a big and nef divisor.

For example, if $U \simeq (\mathbb{C}^\times)^n$ is an algebraic torus, then the mirror V is the dual algebraic torus, and the canonical basis is given by the characters of V (up to scalars), which may be characterized as the units of $H^0(V, \mathcal{O}_V)$. The set of characters of V corresponds under the duality to the set of 1-parameter subgroups of U, which is identified with $U^{\text{trop}}(\mathbb{Z})$. The heuristic justification for Conjecture 1-1 coming from mirror symmetry is explained in Section 4.

Cluster algebras were introduced by Fomin and Zelevinsky as a tool to understand the constructions of canonical bases in representation theory by Lusztig Fomin and Zelevinsky [2002]. In Section 2 we review a description of cluster varieties in terms of toric and birational geometry Gross, Hacking, and Keel [2015a]. Roughly speaking, a cluster variety is a log Calabi–Yau variety U which carries a non-degenerate holomorphic 2-form and is obtained from a toric variety $\bar{X}$ by blowing up codimension 2 centers in the toric boundary and removing its strict transform. The existence of the 2-form greatly constrains the possible centers and accounts for the combinatorial description of cluster varieties. The mutations of cluster theory are given by elementary transformations of $\mathbb{P}^1$-bundles linking different toric models.

For a cluster variety U, Fock and Goncharov defined a dual cluster variety V by an explicit combinatorial recipe, and stated the analogue of Conjecture 1-1 in this setting Fock and Goncharov [2006]. In Section 5 we use an algebraic version of the Strominger–Yau–Zaslow mirror construction Strominger, Yau, and Zaslow [1996] to explain that if U is positive then V should be its mirror. (If U is not positive, then we expect that the mirror of U is an open analytic subset of V and the Fock–Goncharov conjecture is false, cf. Gross, Hacking, and Keel [2015a].) Under a hypothesis on U related to positivity, our construction proves Conjecture 1-1 in this case. In particular, the hypothesis is satisfied in the case of the mirror of the base affine space G/N for $G = \mathrm{SL}_m$ studied by Fomin and Zelevinsky, so we obtain canonical bases of representations of G by the Borel–Weil–Bott theorem.

2 Log Calabi–Yau varieties

Definition 2-1. A *log Calabi–Yau pair* (X, D) is a smooth complex projective variety X together with a reduced normal crossing divisor $D \subset X$ such that $K_X + D = 0$. Thus there is a nowhere zero holomorphic top form Ω on $U = X \setminus D$ (a *holomorphic volume form*) such that Ω has a simple pole along each component of D, uniquely determined up to multiplication by a nonzero scalar.

We say a variety U is *log Calabi–Yau* if there exists a log Calabi–Yau pair (X, D) such that $U = X \setminus D$.

Remark 2-2. Note that if U is a smooth variety and (X, D) is any normal crossing compactification of U, the subspace $H^0(\Omega^p_X(\log D)) \subset H^0(\Omega^p_U)$ for each $p \geq 0$ is independent of (X, D) Deligne [1971]. In particular, if U is a log Calabi–Yau variety then there is a holomorphic volume form Ω on U such that Ω has at worst a simple pole along each boundary divisor of any normal crossing compactification (X, D), uniquely determined up to a scalar.

Definition 2-3. We say a log Calabi–Yau pair (X, D) has *maximal boundary* if the boundary D has a 0-stratum, that is, a point $p \in D \subset Y$ cut out by $n = \dim_{\mathbb{C}} X$ analytic branches of the divisor D, so that we have a local analytic isomorphism

$$(p \in D \subset X) \simeq (0 \in (z_1 \cdots z_n = 0) \subset \mathbb{C}^n).$$

We say a log Calabi–Yau variety U has maximal boundary if some (equivalently, any de Fernex, Kollár, and Xu [2012], Proposition 11) log Calabi–Yau compactification (X, D) of U has maximal boundary.

Definition 2-4. We say a log Calabi–Yau variety U is *positive* if there exists a log Calabi–Yau compactification $(X, D = \sum D_i)$ and positive integers a_i such that $A = \sum a_i D_i$ is ample. In particular, $U = X \setminus D$ is affine.

Example 2-5. The algebraic torus $(\mathbb{C}^\times)^n$ is a log Calabi-Yau variety, with holomorphic volume form $\Omega = \frac{dz_1}{z_1} \wedge \cdots \wedge \frac{dz_n}{z_n}$. Any toric compactification (X, D) satisfies $K_X + D = 0$.

Example 2-6 (Non-toric blow up)**.** Let (X, D) be a log Calabi–Yau pair and $Z \subset X$ a smooth subvariety of codimension 2 which is contained in a unique component of D and meets the other components transversely. Let $\pi : \tilde{X} \to X$ be the blow up of Z and $\tilde{D} \subset \tilde{X}$ the strict transform of D. Then the pair $(\tilde{X}, \tilde{D})$ is log Calabi–Yau.

Definition 2-7. A *toric model* of a log Calabi–Yau variety U is a log Calabi–Yau compactification (X, D) of U together with a birational morphism $f : (X, D) \to (\bar{X}, \bar{D})$ such that $(\bar{X}, \bar{D})$ is a toric variety together with its toric boundary and f is a composition of non-toric blow ups as in Example 2-6.

Remark 2-8. In the description of a log Calabi–Yau variety U in terms of a toric model $(X, D) \to (\bar{X}, \bar{D})$, one can replace the projective toric variety $\bar{X}$ with the toric open subset $\bar{X}' \subset \bar{X}$ given by the union of the big torus $T \subset \bar{X}$ and the open T-orbit in each boundary divisor containing the center of one of the blow ups. Thus the fan Σ' of $\bar{X}'$ is the subset of the fan of $\bar{X}$ consisting of $\{0\}$ and the rays corresponding to these boundary divisors. Cf. Gross, Hacking, and Keel [2015a], §3.2.

Example 2-9. Let $X = \mathbb{P}^2$ and $D = Q + L$ the union of a smooth conic Q and a line L meeting transversely. We describe a toric model of the log Calabi–Yau surface $U = X \setminus D$. First, choose a point $p \in Q \cap L$ and blow up at p. Second, blow up at the intersection point of the exceptional divisor and the strict transform of Q. Let $\tilde{X} \to X$ be the composition of the two blow ups and $\tilde{D} = \pi^{-1}D$. The strict transform in $\tilde{X}$ of the tangent line to Q at p is a (-1)-curve E meeting $\tilde{D}$ transversely at a point of the exceptional divisor of the second blow up. Contracting E yields a toric pair $(\bar{X}, \bar{D})$ with $\bar{X} \simeq \mathbb{F}_2 := \mathbb{P}(\mathcal{O}_{\mathbb{P}^1} \oplus \mathcal{O}_{\mathbb{P}^1}(-2))$.

Proposition 2-10. *(Gross, Hacking, and Keel [2015b], Proposition 1.3) Let U be a log Calabi-Yau surface with maximal boundary. Then U has a toric model.*

The proof is an exercise in the birational geometry of surfaces.

Example 2-11. We describe an example of a log Calabi–Yau 3-fold with maximal boundary which is irrational. In particular, it does not have a toric model.

Smooth quartic 3-folds are irrational Iskovskih and Manin [1971]. Let $X \subset \mathbb{P}^4$ be a smooth quartic 3-fold with hyperplane section

$$D = (X_1^4 + X_2^4 + X_3^4 + X_1X_2X_3X_4 = 0) \subset \mathbb{P}^3.$$

The surface D has a unique singular point $p = (0 : 0 : 0 : 1)$. The minimal resolution of D is obtained by blowing up p and has exceptional locus a triangle of (-3)-curves (in particular, $p \in D$ is a *cusp singularity*).

We describe a sequence of blow ups $\pi : \tilde{X} \to X$ such that the inverse image of D is a normal crossing divisor. First blow up the point p. The inverse image D^1 of D consists of two components, the exceptional divisor $E \simeq \mathbb{P}^2$ and the strict transform D' of D (which is its minimal resolution). The intersection $E \cap D'$ is the exceptional locus of $D' \to D$, a triangle of smooth rational curves. Blow up the nodes of the triangle. For each of the exceptional divisors $E_i \simeq \mathbb{P}^2$, the strict transforms of E and D meet E_i in a common line $l_i \subset E_i$. Finally blow up each line l_i to obtain $\tilde{X}$.

Define the divisor $\tilde{D} \subset \tilde{Y}$ to be the union of the strict transforms of D, E, and the exceptional divisors over the lines l_i. Then $K_{\tilde{X}} + \tilde{D} = 0$. The variety $\tilde{U} = \tilde{X} \setminus \tilde{D}$ is an irrational log Calabi–Yau 3-fold with maximal boundary.

Remark 2-12. On the other hand, if (X, D) is a log Calabi-Yau pair with maximal boundary then X is rationally connected Kollár and Xu [2016], (18).

3 Cluster varieties

3.1 Birational geometric description of cluster varieties.

Definition 3-1. We say a log Calabi–Yau variety U is a *cluster variety* if

1. There is a non-degenerate holomorphic 2-form σ on U such that for some (equivalently, any Deligne [1971]) normal crossing compactification (X, D) we have $\sigma \in H^0(\Omega^2_X(\log D))$.

2. U has a toric model.

Remark 3-2. It is customary in the theory of cluster algebras to allow the 2-form to be degenerate. However, the non-degenerate case is the essential one (cf. Section 5.4).

Example 3-3. Every log Calabi–Yau surface with maximal boundary is a cluster variety by Proposition 2-10.

Suppose U is a cluster variety with 2-form σ and toric model $f : (X, D) \to (\bar{X}, \bar{D})$. Then $\sigma = f^*\bar{\sigma}$ for some $\bar{\sigma} \in H^0(\Omega^2_{\bar{X}}(\log \bar{D}))$ by Hartogs' theorem. The sheaf $\Omega_{\bar{X}}(\log D)$ is freely generated by $\frac{dz_1}{z_1}, \ldots, \frac{dz_n}{z_n}$, where $z_1, \ldots, z_n$ is a basis of characters for the algebraic torus $T = \bar{X} \setminus D \simeq (\mathbb{C}^\times)^n_{z_1,\ldots,z_n}$. See Fulton [1993], Proposition, p. 87. Thus $\bar{\sigma} = \frac{1}{2}\sum a_{ij}\frac{dz_i}{z_i} \wedge \frac{dz_j}{z_j}$ for some non-degenerate skew matrix (a_{ij}). The following lemma is left as an exercise.

Lemma 3-4. *Let (X, D) be a normal crossing pair, $Z \subset X$ a smooth codimension 2 subvariety contained in a unique component F of D and meeting the remaining components transversely, $\pi : \tilde{X} \to X$ the blow up with center Z, and $\tilde{D}$ the strict transform of D. Let $\sigma \in H^0(\Omega^2_X(\log D))$ be a log 2-form on X. Let $D_F = (D - F)|_F$ and let $\mathrm{Res}_F : \Omega^2_X(\log D) \to \Omega_F(\log D_F)$ be the Poincaré residue map. Then σ lifts to a log 2-form on $(\tilde{X}, \tilde{D})$ if and only if $(\mathrm{Res}_F\, \sigma)|_Z = 0$.*

Now let $Z \subset F \subset \bar{D}$ be the center of one of the blow ups for the toric model f. We may choose coordinates on T so that $F \setminus \bar{D}_F = (z_1 = 0) \subset \mathbb{A}^1_{z_1} \times (\mathbb{C}^\times)^{n-1}_{z_2,\ldots,z_n}$, then $\mathrm{Res}_F(\bar{\sigma}) = \sum_{j>1} a_{1j}\frac{dz_j}{z_j}$. Using the lemma, we deduce that

1. $\mathrm{Res}_F(\bar{\sigma})$ is proportional to an integral log 1-form, that is
$$\mathrm{Res}_F(\bar{\sigma}) = \nu \cdot \sum_{j>1} b_j \frac{dz_j}{z_j}$$
for some $\nu \in \mathbb{C}^\times$ and pairwise coprime $b_j \in \mathbb{Z}$. Equivalently, writing $\chi : T \to \mathbb{C}^\times$ for the character $\prod z_j^{b_j}$, $\mathrm{Res}_F(\bar{\sigma}) = \nu \frac{d\chi}{\chi}$.

2. $Z = F \cap \overline{(\chi = \lambda)}$ for some $\lambda \in \mathbb{C}^\times$.

Remark 3-5. Note that, after a change of coordinates, we may assume $\chi = z_2$. Thus, if f is a single blow up, then $U = X \setminus D$ decomposes as a product $U' \times (\mathbb{C}^\times)^{n-2}_{z_3,\ldots,z_n}$. In general U does not globally decompose as a product.

Conversely, any sequence of non-toric blow ups of $(\bar{X}, \bar{D}, \bar{\sigma})$ with the above properties yields a cluster variety.

3.2 Atlas of tori and elementary transformations.

The usual description of a cluster variety U is as follows: The variety U is the union of a countable collection of open subsets T_α (indexed by *seeds* α) which are copies of a fixed algebraic torus $T \simeq (\mathbb{C}^\times)^n$. The glueing maps between the open subsets are compositions of *mutations*, given (for some choice of coordinates $z_1, \ldots, z_n$ on T) by the formula

$$\mu \colon T \dashrightarrow T', \quad (z_1, z_2, \ldots, z_n) \mapsto (z_1(1 + cz_2)^{-1}, z_2, z_3, \ldots, z_n)$$

for some $c \in \mathbb{C}^\times$.

There is the following geometric interpretation. First, note that a toric model $f \colon (X, D) \to (\bar{X}, \bar{D})$ determines an open inclusion of the torus $T = \bar{X} \setminus \bar{D}$ in $U = X \setminus D$ via f^{-1}. This is the origin of the torus charts of a cluster variety: seeds correspond to toric models. Second, mutations correspond to birational transformations between toric models given by elementary transformations of $\mathbb{P}^1$-bundles. In the above notation, let $(\bar{X}, \bar{D})$ be the toric partial compactification of T given by $\mathbb{P}^1_{z_1} \times (\mathbb{C}^\times)^{n-1}_{z_2,\ldots,z_n}$. Let $Z = (z_1 = 0) \cap (1 + cz_2 = 0)$, let $\pi \colon X \to \bar{X}$ be the blow up of Z, and D the strict transform of $\bar{D}$. Write $H = (1 + cz_2 = 0) \subset \bar{X}$ and let $H' \subset X$ be its strict transform. Then H' can be blown down, yielding a morphism $\pi' \colon (X, D) \to (\bar{X}', \bar{D}')$ to a second toric pair such that $\bar{X}'$ is also isomorphic to $\mathbb{P}^1_{z_1} \times (\mathbb{C}^\times)^{n-1}_{z_2,\ldots,z_n}$ and π' is the blow up of $Z' = (z_1 = \infty) \cap (1 + cz_2 = 0)$. The birational map $(\bar{X}, \bar{D}) \dashrightarrow (\bar{X}', \bar{D}')$ is an *elementary transformation* of $\mathbb{P}^1$-bundles over $(\mathbb{C}^\times)^{n-1}$. Writing $U = X \setminus D$, $T = \bar{X} \setminus \bar{D}$, and $T' = \bar{X}' \setminus \bar{D}'$, we have $T \cup T' = U \setminus W$ where $W \simeq Z \simeq Z'$ is the intersection of the exceptional divisors of π and π'. The mutation $\mu \colon T \dashrightarrow T'$ is the restriction of the birational map $\bar{X} \dashrightarrow \bar{X}'$.

Remark 3-6. In general the union of tori in the original definition of a cluster variety is an open subset of a cluster variety in the sense of Definition 3-1 with complement of codimension at least 2 provided that the parameters $\lambda \in \mathbb{C}^\times$ are very general Gross, Hacking, and Keel [2015a], Theorem 3.9. For simplicity we will always assume that this is the case.

3.3 Combinatorial data for toric model of a cluster variety.

We can give an intrinsic description of the data for a toric model of a cluster variety as follows. (We use the notation of Fulton [1993] for toric varieties.) Let $T = \bar{X} \setminus \bar{D}$ be the big torus acting on $\bar{X}$. Let $N = H_1(T, \mathbb{Z}) = \operatorname{Hom}(\mathbb{C}^\times, T)$ be the lattice of 1-parameter subgroups of T and $M = N^* = \operatorname{Hom}(T, \mathbb{C}^\times)$ the dual lattice of characters of T. Then $T = N \otimes_{\mathbb{Z}} \mathbb{C}^\times$. We sometimes use the multiplicative notation z^m for characters.

Let U be a cluster variety and $f : (X, D) \to (\bar{X}, \bar{D})$ be a toric model for U. With notation as in Section 3.1, let $Z = F \cap \overline{(\chi = \lambda)}$ be the center of one of the blow ups. The toric boundary divisor $F \subset \bar{D}$ corresponds to a primitive vector $v \in N$ (the generator of the corresponding ray of the fan of $\bar{X}$). The character χ corresponds to a primitive element $m \in v^\perp \subset M$ (primitive because Z is assumed irreducible). The 2-form $\bar{\sigma}$ lies in $H^0(\Omega^2_{\bar{X}}(\log \bar{D})) = \wedge^2 M_{\mathbb{C}}$. The condition $\operatorname{Res}_F(\bar{\sigma}) = \nu \cdot \frac{d\chi}{\chi}$ is equivalent to $\bar{\sigma}(v, \cdot) = \nu \cdot m$. The associated mutation is given by

$$\text{(3-7)} \qquad \mu = \mu_{(m,v)} : T \dashrightarrow T, \quad \mu^*(z^{m'}) = z^{m'}(1 + cz^m)^{-\langle m', v\rangle}$$

where $c = -1/\lambda$.

3.4 The tropicalization of a log Calabi–Yau variety.

Definition 3-8. Let U be a log Calabi–Yau variety. We define the *tropicalization* $U^{\text{trop}}(\mathbb{R})$ of U as follows. Let (X, D) be a log Calabi–Yau compactification of U. We may assume (blowing up boundary strata if necessary) that D is a simple normal crossing divisor, that is, each component D_i of D is smooth and each intersection $D_{i_1} \cap \cdots \cap D_{i_k}$ is either irreducible or empty. The *dual complex* of D is the simplicial complex with vertex set indexed by components of D, such that a set of vertices spans a simplex if and only if the intersection of the corresponding divisors is non-empty. Let $U^{\text{trop}}(\mathbb{R})$ be the cone over the dual complex of D, and $U^{\text{trop}}(\mathbb{Z})$ its integral points. One can show using Abramovich, Karu, Matsuki, and Włodarczyk [2002] that $U^{\text{trop}}(\mathbb{R})$ is independent of the choice of (X, D) up to $\mathbb{Z}$PL-homeomorphism Kontsevich and Soibelman [2006, Sec. 6.6], de Fernex, Kollár, and Xu [2012], Proposition 11.

The set $U^{\text{trop}}(\mathbb{Z})$ has the following intrinsic description: Let Ω be a holomorphic volume form on U as in Remark 2-2. Then $U^{\text{trop}}(\mathbb{Z}) \setminus \{0\}$ is identified with the set of pairs (ν, k) consisting of a divisorial valuation $\nu : \mathbb{C}(U)^\times \to \mathbb{Z}$ such that $\nu(\Omega) < 0$ and a positive integer k. Thus roughly speaking $U^{\text{trop}}(\mathbb{Z}) \setminus \{0\}$ is the set of all pairs (F, k) where F is a boundary divisor in some log Calabi-Yau compactification (X, D) of U and $k \in \mathbb{N}$.

Example 3-9. If $U = T = N \otimes \mathbb{C}^\times$ is an algebraic torus then we have an identification $U^{\text{trop}}(\mathbb{Z}) = N$: Given $0 \neq v \in N$ write $v = kv'$ where $k \in \mathbb{N}$ and $v' \in N$ is primitive. Then v' corresponds to a toric boundary divisor associated to the ray $\rho = \mathbb{R}_{\geq 0} \cdot v'$ in $N_{\mathbb{R}}$, with associated valuation $\nu : \mathbb{C}(T)^\times \to \mathbb{Z}$ determined by $\nu(z^m) = \langle m, v'\rangle$. These are the only divisors along which Ω has a pole, by Kollár and Mori [1998], Lemmas 2.29 and 2.45.

If (X, D) is a toric compactification of T then the cone over the dual complex of D is identified with the fan Σ of X in $U^{\mathrm{trop}}(\mathbb{R}) = N_{\mathbb{R}}$.

If f is a nonzero rational function on a log Calabi–Yau variety U, then we have a $\mathbb{Z}$PL map $f^{\mathrm{trop}}\colon U^{\mathrm{trop}}(\mathbb{R}) \to \mathbb{R}$ defined on primitive integral points $v = (\nu, 1)$ by $f^{\mathrm{trop}}(v) = \nu(f)$. If $f\colon U \dashrightarrow V$ is a birational map between log Calabi–Yau varieties, then there is a canonical $\mathbb{Z}$PL identification $f^{\mathrm{trop}}\colon U^{\mathrm{trop}}(\mathbb{R}) \to V^{\mathrm{trop}}(\mathbb{R})$ defined by $f^{\mathrm{trop}}(\nu) = \nu \circ f^*$.

Example 3-10. For the mutation (3-7), we have

$$\mu^{\mathrm{trop}}\colon N_{\mathbb{R}} \to N_{\mathbb{R}}, \quad \mu^{\mathrm{trop}}(w) = \begin{cases} w & \text{if } \langle m, w\rangle \geq 0 \\ w - \langle m, w\rangle v & \text{if } \langle m, w\rangle < 0. \end{cases}$$

4 Mirror symmetry

Mirror symmetry is a phenomenon arising in theoretical physics which predicts that Calabi–Yau varieties (together with a choice of Kähler form) come in mirror pairs U and V such that the symplectic geometry of U is equivalent to the complex geometry of V, and vice versa.

4.1 The Strominger–Yau–Zaslow conjecture. Recall that a submanifold L of a symplectic manifold (U, ω) is *Lagrangian* if $\dim_{\mathbb{R}} L = \frac{1}{2}\dim_{\mathbb{R}} U$ and $\omega|_L = 0$. Let U be a log Calabi–Yau manifold with holomorphic volume form Ω and Kähler form ω. We say a Lagrangian submanifold L of (U, ω) is *special Lagrangian* if $\operatorname{Im}\Omega|_L = 0$. The Strominger–Yau–Zaslow conjecture asserts that mirror Calabi-Yau varieties admit dual special Lagrangian torus fibrations Strominger, Yau, and Zaslow [1996]. More precisely, there exist continuous maps $f\colon U \to B$ and $g\colon V \to B$ with common base B and a dense open set $B^o \subset B$ such that

1. The restrictions $f^o\colon U^o \to B^o$ and $g^o\colon V^o \to B^o$ are C^∞ real n-torus fibrations such that the fibers are special Lagrangian, and
2. The associated local systems $R^1 f^o_* \mathbb{Z}$ and $R^1 g^o_* \mathbb{Z}$ on B^o are dual.

Example 4-1. Let $U = (\mathbb{C}^\times)^n_{z_1,\dots,z_n}$,

$$\Omega = \left(\frac{1}{2\pi i}\right)^n \frac{dz_1}{z_1} \wedge \cdots \wedge \frac{dz_n}{z_n} \qquad \text{and} \qquad \omega = \frac{1}{2\pi}\frac{i}{2}\sum_{j=1}^{n} \frac{dz_j}{z_j} \wedge \frac{d\bar{z}_j}{\bar{z}_j}$$

Then the map $f: U \to \mathbb{R}^n$, $f(z_1, \dots, z_n) = (\log|z_1|, \dots, \log|z_n|)$ is a special Lagrangian torus fibration. (Topologically f is the quotient by the compact torus $(S^1)^n \subset (\mathbb{C}^\times)^n$.)

Example 4-2. Let $U = T = N \otimes \mathbb{C}^\times \simeq (\mathbb{C}^\times)^n$ and let (X, D) be a smooth projective toric compactification. Let A be an ample line bundle on X. Let $K \subset T$ be the compact torus. Then, using the description of X as a GIT quotient of affine space, the Kempf–Ness theorem (Mumford, Fogarty, and Kirwan [1994], Theorem 8.3), and symplectic reduction, one can construct a K-invariant Kähler form ω on X in class $c_1(A) \in H^2(X, \mathbb{R})$. If μ is the associated moment map, then μ maps X onto the lattice polytope $P \subset M_{\mathbb{R}}$ associated to (X, A), and is topologically the quotient by K. The restriction of μ to T is a special Lagrangian torus fibration for the Kähler form $\omega|_U$ and holomorphic volume form Ω as in Example 4-1.

Construction 4-3. If $f: (U, \omega) \to B$ is a Lagrangian torus fibration, then the locus $B^o \subset B$ of smooth fibers inherits an *integral affine structure* (an atlas of charts with transition functions of the form $\mathbf{x} \mapsto A\mathbf{x} + \mathbf{b}$ for some $A \in \mathrm{GL}(n, \mathbb{Z})$ and $\mathbf{b} \in \mathbb{R}^n$). This may be constructed as follows. Fix $b_0 \in B^o$ and let $W \subset B^o$ be a small contractible neighborhood of b_0. For $\gamma \in H_1(f^{-1}(b_0), \mathbb{Z})$ define $y_\gamma: W \to \mathbb{R}$ by $y_\gamma(b) = \int_\Gamma \omega$ where $\Gamma \subset X$ is a cylinder fibering over a path from b_0 to b in W swept out by a loop in the class γ. Applying this construction to a basis of $H_1(f^{-1}(b_0), \mathbb{Z}) \simeq \mathbb{Z}^n$ gives a system of integral affine coordinates $y_1, \dots, y_n$ on $W \subset B^o$. In Examples 4-1 and 4-2 this integral affine structure is the restriction of the standard integral affine structure on $\mathbb{R}^n$.

Example 4-4. Let U, (X, D), etc. be as in Example 4-2 and consider a non-toric blow up $(\tilde{X}, \tilde{D})$ of (X, D) as in Example 2-6. Then we can modify the moment map $\mu: X \to P$ to obtain a map $\tilde{\mu}: \tilde{X} \to \tilde{P}$ such that the restriction $f: \tilde{U} \to B$ to the interior B of $\tilde{P}$ is a Lagrangian torus fibration with singular fibers Abouzaid, Auroux, and Katzarkov [2016].

Assume first that $n = \dim_{\mathbb{C}} X = 2$. Thus we have a smooth point p of D, $\pi: \tilde{X} \to X$ is the blow up of p, and $\tilde{D} \subset \tilde{X}$ is the strict transform of D. Let $S^1 \subset K$ be the stabilizer of the point $p \in X$, so that S^1 acts on $\tilde{X}$. Let $e \subset P$ be the edge of P containing $\mu(p)$, and choose integral affine coordinates y_1, y_2 on $M_{\mathbb{R}} \simeq \mathbb{R}^2$ such that $p = (0, 0)$, $e \subset (y_1 = 0)$, and $P \subset (y_1 \geq 0)$. Let $\epsilon > 0$ be sufficiently small so that the triangle T with vertices $(0, -\epsilon/2), (0, +\epsilon/2), (\epsilon, 0)$ is contained in P and its intersection with the boundary of P is contained in the interior of e. Let $\tilde{P}$ be the topological space obtained by collapsing $T \subset P$ via the map $y_1: T \to [0, \epsilon]$. Then $\tilde{P}$ is the base of an S^1-invariant map $\tilde{\mu}: (\tilde{X}, \tilde{\omega}) \to \tilde{P}$ such that the restriction to the interior B of $\tilde{P}$ is a Lagrangian torus fibration with a unique singular fiber (a pinched torus) over the image $q \in B$ of the point $(\epsilon, 0) \in P$. The fibration has monodromy around q given by the Dehn twist in the vanishing cycle (the class of the S^1-orbits). The exceptional (-1)-curve $E \subset \tilde{X}$ fibers over the interval $I \subset \tilde{P}$ given by the image of $T \subset P$. The class of the symplectic form in $H^2(\tilde{X}, \mathbb{R})$ is $[\tilde{\omega}] = \pi^*[\omega] - \epsilon c_1(E) = c_1(\pi^* A - \epsilon E)$. The symplectic form $\tilde{\omega}$ and the fibration $\tilde{\mu}$ agree with ω and μ over the complement of a tubular neighborhood of $I \subset \tilde{P}$.

A similar construction applies in dimension $n > 2$ Abouzaid, Auroux, and Katzarkov [2016], §4. (Here we work over the open set $X' \subset X$ given by the complement of the codimension two strata, cf. Remark 2-8.) Applying this construction repeatedly, we can construct a Lagrangian torus fibration on any log Calabi-Yau variety with a toric model. (Note that the fibration is *not* special Lagrangian (but cf. Abouzaid, Auroux, and Katzarkov [ibid.], Remark 4.6).)

4.2 Homological mirror symmetry. The homological mirror symmetry conjecture of Kontsevich [1995] asserts the following mathematical formulation of mirror symmetry: For mirror compact Calabi–Yau varieties U and V, the derived Fukaya category $\mathfrak{F}(U)$ of U is equivalent to the derived category of coherent sheaves $D(V)$ on V. Roughly speaking, the objects of the Fukaya category of U are Lagrangian submanifolds L together with a unitary local system, and the morphisms are given by Lagrangian Floer cohomology. See Auroux [2014] for an introduction.

If U is a log Calabi–Yau variety then, at least if U is positive (Definition 2-4), the HMS conjecture is expected to hold with the following adjustments. First, we must allow non-compact Lagrangian submanifolds with controlled behaviour at infinity. Second, the definition of the morphisms in the Fukaya category is modified at infinity using a Hamiltonian vector field associated to a function $H : U \to \mathbb{R}$ such that $H \to \infty$ sufficiently fast at infinity. The resulting category $\mathfrak{F}(U)$ is called the wrapped Fukaya category Auroux [ibid.], §4.

The HMS and SYZ conjectures are related as follows. Suppose U and V are mirror log Calabi–Yau varieties with dual Lagrangian torus fibrations $f : U \to B$ and $g : V \to B$. Let $L = f^{-1}(b)$ be a smooth fiber of f. The rank 1 unitary local systems ∇ on L are classified by their holonomy $\mathrm{hol}(\nabla) \in \mathrm{Hom}(\pi_1(L), U(1)) = L^*$ (the dual torus). It is expected that the pairs $[(L, \nabla)] \in \mathfrak{F}(U)$ correspond under the equivalence $\mathfrak{F}(U) \simeq D(V)$ to the skyscraper sheaves $\mathcal{O}_p \in D(V)$ for $p \in g^{-1}(b) \simeq L^*$. (More generally, the equivalence should be given by a real version of the relative Fourier–Mukai transform for the dual torus fibrations, cf. Kontsevich and Soibelman [2001], §9, Polishchuk [2003], §6.)
